Abstract. With increasing number and proximity of wind farms, it becomes crucial to consider wind farm effects (WFEs) in the numerical weather prediction (NWP) models used to forecast power production. Furthermore, these WFEs are also expected to affect other weather-related parameters at least locally. Thus, we implement the explicit wake parameterization (EWP) in the NWP model HARMONIE–AROME (hereafter HARMONIE) along-side the existing wind farm parameterization (WFP) by Fitch et al. (2012) (FITCH). We evaluate and compare the two WFPs against research flight measurements as well as against similar simulations performed with the Weather Research and Forecasting (WRF) model using case studies. The case studies include a case for WFEs above a wind farm as well as two cases for WFEs at hub height in the wake of farms. The results show that EWP and FITCH have been correctly implemented in HARMONIE. For the simulated cases, EWP underestimates the WFEs on wind speed and strongly underestimates the effect on turbulent kinetic energy (TKE). FITCH agrees better with the observations, and WFEs on TKE are particularly well captured by HARMONIE–FITCH. After this successful evaluation, simulations with all wind turbines in Europe will be performed with HARMONIE and presented in the second part of this paper series.

1 Introduction

Wind turbines extract kinetic energy from the atmospheric flow to produce electricity. Thereby, they reduce the wind speed upstream, referred to as blockage effect, and downstream, referred to as wake effect, and sometimes increase the wind speed on the sides, referred to as speed-up effect (e.g. Fischereit et al., 2022a). In addition, they increase turbulence both directly through tip vortices, as well as indirectly through shear production. Hence, wind and turbulence profiles are modified around wind farms and consequently also local temperature and humidity profiles (e.g. Siedersleben et al., 2018; Baidya Roy and Traiteur, 2010).

Since wind turbines increase in number and size both on- and offshore (IRENA, 2019), their impact on numerical weather prediction (NWP) can no longer be generally ignored. According to a recent review by Fischereit et al. (2022a), the Weather Research and Forecasting (WRF) model is the most wide-spread applied model equipped with a wind farm parameterization (WFP). Extensive validation of WRF with the built-in WFP by Fitch et al. (2012), hereafter “FITCH”, has been performed as summarized in Fischereit et al. (2022a). Besides WRF + FITCH, the explicit wake parameterization (Volker et al., 2015), hereafter EWP, is the second most frequently applied WFP in WRF according to the review in Fischereit et al. (2022a). In addition, FITCH has been implemented in other NWP models, among others in HARMONIE–AROME (Bengtsson et al., 2017, https://hirlam.github.io/HarmonieSystemDocumentation, last access: 4 October 2023), hereafter HARMONIE, by van Stratum et al. (2022).

While WRF+WFP has been extensively applied and verified as summarized in Fischereit et al. (2022a), WFPs in HARMONIE are still relatively unexplored. Since HARMONIE is used by at least 11 national weather services in Europe, it is relevant to also integrate wind farm ef-
fects (WFEs) in HARMONIE. van Stratum et al. (2022) started this process with the implementation of FITCH. They evaluated a 1-year-long simulation against measurements of power production, from lidar and mast, as well as in a case study against aircraft measurements. They showed that using FITCH provided a more realistic representation of the atmosphere near wind farms than a simulation without WFP. In this study, we extend the work by van Stratum et al. (2022) by implementing the EWP into HARMONIE. Having two WFPs available is advantageous, because it allows one to create an ensemble of possible wind farm effects (WFEs), highlighting the uncertainty of the forecast.

Previous studies have explored the differences between wind farm effects predicted by FITCH and EWP in WRF. Pryor et al. (2020) noted in their 9-month-long study of the US Midwest that capacity factors were lower for simulations with FITCH than with EWP. They also found that wind speed deficits and turbulent kinetic energy (TKE) enhancements extended over a larger area for FITCH than for EWP. Similar conclusions were drawn by Shepherd et al. (2020), who performed a yearlong simulation for Iowa. They also noted that the differences lead to differences in impacts on near-surface climate variables. Fischereit et al. (2022b) compared high-resolution Reynolds-averaged Navier–Stokes (RANS) simulations with WRF+WFP simulations and noted that EWP underestimated the wake wind speed deficits between farms, while FITCH performed reasonably well. Larsen and Fischereit (2021) found that above a wind farm both EWP and FITCH can capture the wind speed deficit fairly well compared to measurements. However, EWP significantly underestimated TKE above the farm. This study builds upon and extends the previous studies on comparing EWP and FITCH by comparing with actual measurements within the wake.

The work is divided into two parts. Part 1 is presented in this article and describes the implementation of EWP in HARMONIE, as well as the comparison with the WRF results and flight measurements for three case studies. The specific objectives of Part 1 are given below. Part 2, presented in Fischereit et al. (2024), deals with the set-up of a wind turbine database for Europe, the long-term evaluation of the HARMONIE simulations, and the sensitivity of the forecast to the applied WFP.

Part 1 in the present article has three objectives: (1) ensure that EWP and FITCH are correctly implemented in HARMONIE, (2) evaluate how wind farm effects are manifested and transported in HARMONIE and verify that by comparing to WRF, and (3) check how well the wind farm effects in both HARMONIE and WRF agree with flight measurements in the wake and above wind farms. To archive those objectives the article is structured as follows: key features of EWP and the implementation of EWP into HARMONIE are described in Sect. 2.1. The model set-ups for HARMONIE and WRF for the simulations are described in Sect. 2; the results and comparisons are shown in Sect. 3, discussed in Sect. 4, and concluded in Sect. 5.

2 Modelling frameworks and case studies

In the following the applied WFPs, models and model set-ups are described. Section 2.1 describes the characteristics of the EWP and highlights the differences to the more widely used FITCH (Fitch et al., 2012). Sections 2.2 and 2.3 introduce the two applied NWP models, HARMONIE and WRF, respectively. The investigated case studies are described in Sect. 2.4 and 2.5.

2.1 Implementation of EWP in HARMONIE

The theory and derivation of EWP are described in detail in Volker et al. (2015). For convenience we repeat the main concepts here.

To parameterize the effect of wind farms on the atmosphere, EWP imposes an elevated momentum sink or drag force on a control volume $\Delta V$ of the flow $U$, which acts on the rotor area $A_r$ and is proportional to the thrust coefficient $C_T$:

$$\bar{f}_r = \frac{1}{2} C_T U^2 A_r / \Delta V.$$  \hfill (1)

This is similar to the FITCH parameterization. However, in contrast to FITCH, EWP accounts for a subgrid scale vertical wake expansion. The idea behind this is that due to the size of the mesoscale grid cell of typically 1–5 km$^2$, the wind turbine wake has expanded vertically when reaching the grid cell boundary. To account for this effect, EWP builds upon classical wind turbine wake theory, by assuming an exponential expansion based on an effective length scale $\sigma_e$ to define the drag force at grid cell $x, y, z$:

$$f_{x,y,z} = N_t \sqrt{\frac{\pi}{8}} \frac{C_T r_h^3 |\bar{u}_{r,w}|^2}{\Delta x \Delta y \sigma_e} \exp \left( \frac{1}{2} \left( \frac{z - h}{\sigma_e} \right)^2 \right).$$  \hfill (2)

Here, $N_t$ is the number of turbines per grid cell, $r_h$ is the rotor radius = $0.5D$ with $D$ being the rotor diameter, $\bar{u}_{r,w}$ denotes the horizontal wind speed $\bar{u}_r = (\bar{u}_1^2 + \bar{u}_2^2)^{0.5}$ with 1 and 2 denoting the wind components in the two horizontal directions at hub height $h$ averaged over one grid cell and a finite time increment, as indicated by the overbar. $z$ is the height of the model level $z$, and the thrust coefficient is used as a function of the wind speed at hub height $C_T = C_T(\bar{u}_r,h)$. The effective length scale, $\sigma_e$, is related to the model grid size ($L = 0.5 \Delta x$), the turbulent diffusion coefficient from mesoscale turbulence scheme ($K$), and an initial length scale that represents the unresolved wake expansion in the near wake $\sigma_h = f_r r_h$ with $f_r$ being a tuneable wake expansion scaling factor:

$$\sigma_e = \frac{\bar{u}_{r,h}}{3KL} \left( \frac{2K \bar{u}_{r,h} L + \sigma_h^2}{\bar{u}_{r,h}^2} \right)^{3/2} - \sigma_h^3.$$  \hfill (3)
Using the wind direction, WD, the drag force \( f_{xyz} \) is split into the two wind components:

\[
\begin{align*}
\mathcal{T}_{1,xyz} &= f_{xyz} \cos(WD_{xyz}) \\
\mathcal{T}_{2,xyz} &= f_{xyz} \sin(WD_{xyz}).
\end{align*}
\] (4)

Another difference between FITCH and EWP is the treatment of turbulent kinetic energy (TKE) within these schemes. For EWP Volker et al. (2015) assume that the heterogeneous part of the mean flow (e.g., organized motions) is part of the mean flow kinetic energy and not part of random TKE. Based on that, the remaining addition of TKE due to the rotation of wind turbines is negligible in a mesoscale model. In FITCH such a distinction is not made, and thus an explicit TKE source term is added to the mesoscale model equations (Fitch et al., 2012). In both the EWP and the FITCH scheme, wind turbines are an implicit source of TKE through shear-generated turbulence arising from the turbine wake. More details on the derivation for EWP are given in Volker et al. (2015), and more discussions on the difference between FITCH and EWP can be found in, for example, Fischereit et al. (2022a).

The implementation of EWP in HARMONIE follows the implementation of FITCH as described in van Stratum et al. (2022). The only difference is that for EWP the TKE tendencies are not modified, and a different drag force is used. The turbulent diffusion coefficient, \( K \), is used to calculate the wake expansion. \( K \) is derived from the stability corrected turbulence length scale \( \ell \) (Lenderink and Holtslag, 2004) and TKE from the planetary boundary layer (PBL) scheme in HARMONIE:

\[
K = \ell \cdot \sqrt{TKE}.
\] (5)

For the implementation of Eq. (4), WD is not the true wind direction, since \( u \) and \( v \) are grid-following in HARMONIE and are thus not necessarily aligned with the cardinal directions north–south and east–west.

This implementation is similar to the implementation of EWP in WRF except that turbulent diffusion coefficient, \( K \), is different, since it is provided by a different PBL scheme. Having EWP implemented in HARMONIE allows for comparisons of different WFPs in HARMONIE as well as comparisons of WFEs in HARMONIE and WRF.

2.2 HARMONIE

We implement EWP in HARMONIE–AROME cycle 43.2.2. HARMONIE is a nonhydrostatic, convection permitting limited-area NWP model that is developed within the HIRLAM-C consortium (Bengtsson et al., 2017, https://hirlam.github.io/HarmonieSystemDocumentation, last access: 4 October 2023). The dynamics are based on the fully compressible Euler equations (Simmons and Burridge, 1981), which are solved numerically using a semi-Lagrangian advection scheme with semi-implicit time stepping (Bénard et al., 2010). The physical parameterizations include a multiband radiation scheme, prognostic equations for liquid and solid hydrometeors, a prognostic equation for turbulent kinetic energy, and a mass-flux-based shallow convection scheme called EDMFM. Surface physics is modelled using the SURFEX scheme (Masson et al., 2013). For further details on HARMONIE see Bengtsson et al. (2017).

Here we use the model grid design of the operational NWP set-up at the Danish Meteorological Institute (DMI): we simulate the Northern Europe DMI domain A (NEA), which covers all of Scandinavia, the United Kingdom, Iceland, and parts of Germany and is centred around 60° N and 7° E (Fig. 1b). It has a horizontal resolution of 2.5 km and 65 vertical layers, running from the surface up to 10 hPa. The lowest 10 full levels are most relevant for this study, located approximately at 12, 38, 63, 89, 117, 146, 177, 211, 247, and 287 m height above the ground. These levels along with those defined in WRF and rotor areas for the different turbine types are shown in Fig. 2.

We run HARMONIE in forecasting mode using hourly boundary fields from the Integrated Forecasting System (IFS) global model at ECMWF as lateral boundary condi-
These cases also include a variety of conditions of wind. The WIPAFF project (Bärfuss et al., 2019) are available. Open-access flight measurements conducted within the German WIPAFF project (Bärfuss et al., 2019) are included. The data assimilation includes surface synoptic observation (SYNOP) pressures, radiosonde winds, temperatures and humidities, buoy pressures, aircraft winds, and temperatures (AMDA). In addition several types of surface and near-surface data are assimilated. For sea surface temperatures OSTIA (Donlon et al., 2012) is used. The evaluated forecast was performed at the closest synoptic hour, which corresponds to 12:00 for the three test cases. We use the parameterizations and settings mostly corresponding to the operational forecasts at DMI. The only exception is the use of WFPs and the number and type of assimilated observations. A summary of all settings is given in Table 1.

2.4 Case studies

We investigate three case studies (Table 2) to evaluate the performance of the simulations above a wind farm. This case follows up on existing analysis in Larsén and Fischereit (2021), since in that study good agreement was found for the mean wind structures between the simulations and three types of measurements.

All WRF simulations are initialized at midnight and run for 24 h, except for the simulation on 15 October 2017. For the simulation on 15 October 2017, it was investigated whether initialization at 00:00 or 06:00 would show better results. The simulation initialized on 00:00 underestimated the wind speed, and therefore we used 06:00 as the initial time. Sensitivity tests show that for stable cases the later initialization helps to better capture transient meteorological conditions by properly introducing the initial conditions to the simulation. A similar behaviour was reported in Larsén and Fischereit (2021) for 14 October 2017 and could be solved by initializing the simulations at 06:00. Since the analysis presented in this study starts after 12:00, a spin-up time of 6 h is still maintained. The other simulations use a spin-up time of around 12 h.

2.3 WRF

We apply WRF 4.2.2 (Skamarock et al., 2019) in a nested domain set-up with the corresponding spatial resolutions 18, 6, and 2 km shown in Fig. 1a. We use 80 non-equidistant vertical model levels with more levels in the lowest 200 m of the atmosphere around the rotor (Fig. 2, Table 1). We run WRF in hindcast mode and use ERA5 data as the initial and boundary conditions. More details on the physical schemes are given in Table 1. The settings follow mostly those in Larsén and Fischereit (2021), since in that study good agreement was found for the mean wind structures between the simulations and three types of measurements.

The flight tracks during the three cases in relation to the corresponding wind farms are shown in Fig. 3. The case study on 14 October 2017 (blue lines in Fig. 3) is used to evaluate the performance of the simulations above a wind farm. This case follows up on existing analysis in Larsén and Fischereit (2021) and Siedersleben et al. (2020). The other two cases evaluate the wake of the farm around hub height (purple and orange lines in Fig. 3). Background and evaluation objective are summarized in Table 2.

For the calculating the standard deviations, we use the same data window of 2 km, as in Larsén and Fischereit (2021) and close to that used in Platis et al. (2020).

In addition to the WIPAFF measurements, we also use synthetic aperture radar (SAR) data taken from https://science.globalwindatlas.info/#/map (last access: 22 March 2023) (Badger et al., 2022) to evaluate the general meteorological situation during the case studies. The SAR images are retrieved from ENVISAT and combined with an empirical transfer function to derive the neutral 10 m wind speed from the radar backscatter of small locally generated waves. All the SAR images shown in Sect. 3 are made up of more than one SAR scene recorded at around 17:00 UTC. The area in the SAR scene does not always cover the full flight track but serves to assess the background conditions.

### 2.5 Wind turbines

The position and types of wind turbines are taken from Larsén and Fischereit (2021) for both the HARMONIE and WRF simulations. The rotor areas with respect to the vertical grid for the various turbines are shown in Fig. 2, and the positions are shown in Fig. 1, respectively. Since the flight measurements (Sect. 2.4) were conducted in 2017, we only include wind turbines present in the North Sea at that time. For the case studies, we focus on four wind farms (Table 2): for the case studies on 14 and 15 October 2017 on Gode Wind 1 + 2 and Nordsee One and for the case study on 8 August 2017 on Amrumbank West, Nordsee Ost, and Meerwind Süd/Ost (Fig. 3). Gode Wind 1 + 2 and Nordsee One are equipped respectively with 110 m tall SWT-6.0-154 wind turbines (SWT-6.0-154_110 in Fig. 2) and 90 m tall 6.2M126 wind turbines (6.2M126_90 in Fig. 2). In Amrumbank West and Meerwind Süd/Ost, 88 m tall SWT-3.6-120 wind turbines are installed. Nordsee Ost is equipped with 95 m tall 6.2M126 wind turbines. The thrust and power curves of these three wind turbine models for the complete range of operating wind speeds are shown in Fig. 4. Note that $C_T$ is always smaller than or equal to 1, since below 3 m s$^{-1}$ or 4 m s$^{-1}$, depending on the turbine model, the turbines are not operating and therefore $C_T$ is not defined. The $C_T$ curves cannot be extrapolated to lower wind speeds.

The turbines are assigned to the grid cells in WRF and HARMONIE. Figure 5 shows how many turbines are assigned to each grid cell around the wind farms of interest.

We simulate three scenarios for each case study (Table 2) for both the HARMONIE and WRF simulations. The three scenarios are (1) a scenario without WFEs included (denoted NWF), (2) a scenario with the parameterization by Fitch et al. (2012) (denoted FITCH), and (3) a scenario with the EWP parameterization (denoted EWP). For FITCH we use a turbulent kinetic energy (TKE) factor of 1 in WRF to make it comparable to the implementation in HARMONIE, which does not include a TKE factor. The correction factor for TKE was introduced following the discovery of a bug in the implementation of turbine-generated TKE in the WRF model (Archer et al., 2020). It is an empirical factor that was derived based on the best agreement between a large eddy simulation and a WRF–FITCH simulation. Using this comparison Archer et al. (2020) suggested to use a factor of 0.25. However, a subsequent study by Larsén and Fischereit (2021) found inconclusive results when comparing simulations using correction factors of 0.25 and 1 with measurements. Thus, while a correction factor of 1 deviates from the default, the “best” choice is still unclear. Hence, it is reasonable to use a correction factor of 1, i.e. no correction factor, here. For EWP we set the tuneable initial wake ex-
pansion coefficient, as introduced in Eq. (3), to $f_r = 1.7$, as recommended in Volker et al. (2015) and used in other studies (Volker et al., 2017; Pryor et al., 2020). Previous studies (e.g., Volker et al., 2015; Larsén and Fischereit, 2021) found that simulated wind speed deficits in the wake are not very sensitive to variation in $f_r$ between 1.5 and 1.7. To confirm the low sensitivity within this range, we reproduced the case 15 October 2017 with $f_r = 1.5$ and found only minor biases $< 0.1 \text{ m s}^{-1}$ close to the farm (not shown). Values for $f_r$ outside the range of 1.5 and 1.7 were tested in Ali et al. (2023). They noted larger impacts for the tested values of 1.36 and 2.04 on wake length and wind speed deficit. However, a more detailed investigation of different $f_r$ values is beyond the scope of the current study, which focuses on existing best practices.

2.6 Evaluation metrics

To assess the agreement between observations and simulations, several error measures are used to evaluate the different components of the overall error: the bias assesses the systematic error, the standard deviation of errors (STDEs) assesses the non-systematic error, and the root mean square error (RMSE) assesses the combined error. In addition, the correlation coefficient (CORR) is derived to assess the temporal agreement with the observations. CORR and STDEs evaluate similar aspects of the model performance, but STDEs is not dimensionless and therefore gives additional insights. The equations for the different error measures can be found, for example, in Schlünzen and Sokhi (2008). While two different models can perform the same in terms of one error measure, e.g. the same correlation coefficient, they might perform differently in terms of another error measure, e.g. different biases. Thus, having four different error measures has the advantage that different aspects of the performance can be evaluated. The error metrics are calculated for each transect and the median error over all transects is given in this article.

Besides the agreement with measurements, the magnitude of the wind farm effect is evaluated. To characterize the magnitude, the difference between simulations with wind farms (FITCH/EWP) and simulations without wind farms (NWF) is calculated: FITCH–NWF and EWP–NWF for both WRF and HARMONIE. The correctness of the magnitude of the WFE cannot simply be assessed against the flight observations, since there are no observations without a WFE. To circumvent this problem, artificial observations without WFE (obsNWF) are constructed based on a simple linear interpolation between two locations at either sides of the farm (or wake) on a flight transect. These artificial observations are shown exemplary as grey dashed–dotted lines in Fig. 6. Since the background conditions also vary in time and space and the width of the wake increases with increasing distance from the farm, it is difficult to define which part of the track is already under wake influence and which part is not. Thus, two different locations are chosen to measure the uncertainty of the observational wake effect. The two locations are based on the location of the minimum and maximum wind speed (WS) value to the left of the farm (or wake) with respect to the mean wind direction (Fig. 6, left red crosses).

The presented method is very simplistic but provides a way to quantify the wake effect in the observations. The method is similar to the method presented in Cañadillas et al. (2020), but instead of evaluating the maximal WFE, it provides the mean WFE. In addition, it also works for the case of measurements above the farm and for other variables other than WS. As a comparison, also the method by Cañadillas et al. (2020) is applied for the wake cases. Cañadillas et al. (2020) use an exponential function $U_R(x) = 1 - a \cdot \exp(-bx)$ for the wind speed recovery $U_R$ as function of downstream distance $x$ with coefficients $a$ and $b$ given in their study. The reference wind speed $U_{ref}$ for each transect to calculate the maximum WFE at each $x$ as WFE$(x) = U_{ref}(x) - U_R(x) \cdot U_{ref}(x)$ is not provided in Cañadillas et al. (2020). Therefore, the reference wind speed is derived as mean over the three points of obsNWF (Fig. 6, red crosses).

3 Results

3.1 Above a wind farm

3.1.1 Background conditions

In this case study, the simulations of WRF and HARMONIE with and without WFP are evaluated with WIPAFF aircraft measurements above the wind farm on 14 October 2017 (Table 2). During this case, the wind was from the south-west (Table 2, Fig. 3), the atmosphere was stably stratified, and low-level jets were present as discussed in detail in Siedersleben et al. (2020) and Larsen and Fischereit (2021). The prominent wind direction can also be seen in the wind farm wake direction visible in the 10 m winds from SAR and simulations (Fig. 7). HARMONIE winds simulated for 10 m height agree visually well with the SAR-derived winds, while WRF slightly overestimates the wind. Both models and both parameterizations, i.e. FITCH and EWP, visually capture the extent of the farm wakes well compared to SAR.

3.1.2 Transects above the farm

The measurement aircraft flew at a height of about 250 m six times above Gode Wind 1 + 2, as can be seen in the flight track in Fig. 8a, b (upper rows). The corresponding time is given in the title of the subfigures in Fig. 8. Although all transects were measured within 2 h, wind speed varies quite considerably (Fig. 8a, b, centre rows) by 1 m s$^{-1}$. Neither WRF nor HARMONIE can fully capture this temporal variability. For the models, the two closest model output time steps (Table 1) to the transect times are shown to highlight the temporal variability of the conditions during the passing of the aircraft over the transect. Thus, for a good match between model and observations, the observations should be within the shaded area of the model output. Overall the wind speed at 250 m matches well with the observations for some transects, even though WRF overestimated the 10 m wind speed if compared to SAR (Fig. 7).

Above Gode Wind 1 + 2 WS decreased and TKE increased (Fig. 8a, b, second and third rows) due to effect of the wind farm. Both WRF and HARMONIE equipped with the FITCH WFP (blue) can capture this effect. The EWP (red) can capture the wind speed reduction but underestimates the magnitude of the reduction in both models. Furthermore, EWP does not capture the increased magnitude of TKE above the farm. However, in contrast to the simulation without wind farms (NWF, yellow), EWP shows a reduced WS above the farm. Due to the relatively coarse resolution of 2 km in WRF and 2.5 km in HARMONIE, the speed-up on the side of the farm cannot be properly captured.

The wind direction, WD, is slightly off in HARMONIE (Fig. 8a, b bottom rows), especially in the earlier transects up to 15:50. A consequence is that the exact location of the wind speed deficit is not captured as well in HARMONIE as it is in WRF (Fig. 8a, b second rows).

3.1.3 Error statistics

The quantitative evaluation of the simulations against the flight measurements is difficult, since for some transects the background wind is not well simulated. This is visible on both sides of the farms, where HARMONIE and WRF overestimate WS (Fig. 8 second row). Since the thrust coefficient depends on wind speed (see SWT-6.0-154-curve in Fig. 4), the WFE differs for different background conditions. This is a common problem for evaluating WFPs as found in the review in Fischereit et al. (2022a).

In our case, the wind speed is within the range of 14–16 m s$^{-1}$, where the sensitivity of the thrust is already reduced compared to lower wind speeds but still high (Fig. 4). To circumvent this problem, we calculate several error metrics that assess the different components of the overall error as described in Sect. 2.6. All error metrics are calculated for both WS and TKE, as well as for the two models with each three different scenarios, as shown in Sect. 2.5.

The statistics (Table 3) confirm that FITCH agrees best with the observations and that EWP performs reasonably well for WS but as bad as NWF for TKE. Overall the error measures indicate comparable performance of WRF+WFP and HARMONIE+WFP, which indicates that the implementation of EWP was successful.

3.1.4 Wind farm effects

To evaluate the WFEs above the farm (60 m above the rotor tip), the NWF scenario is subtracted from the simulations with wind farms as described in Sect. 2.6. Those differences are shown in Table 4. It shows that wind speed deficits at that height above the farm are around $-0.75$ m s$^{-1}$, and TKE increase is around $0.5$ m$^2$ s$^{-2}$ according to the observations. However, there is some uncertainty in the artificially generated NWF observations. FITCH matches the magnitudes quite well, although it underestimates the mean TKE effect and slightly overestimates the WS effect. EWP slightly underestimates the WFE with respect to WS and has almost no WFE with respect to TKE.

Comparing the results for HARMONIE and WRF shows that the mean WFEs are slightly higher for HARMONIE compared to WRF for both FITCH and EWP (Table 4). There could be multiple reasons for this. Firstly, different planetary boundary layer schemes are applied in WRF and HARMONIE (Table 1). Secondly, the horizontal and vertical resolution differ between WRF and HARMONIE (Table 1), and consequently the wind turbines are differently assigned to the grid cells (Fig. 5).
3.2 In the wake of a wind farm

To evaluate the performance of the model in the wake of the wind farm at around hub height, we look at two case studies: 15 October and 8 August 2017. The case 15 October 2017 is chosen because the background meteorology was better matched from the simulations due to a less complex meteorological situation. The case 8 August 2017 is chosen because an effect on the temperature of the wind farm was observed, which is interesting to consider from a NWP point of view, which does not focus solely on power forecast.

3.2.1 Background conditions

On 15 October 2017 around the flight time, wind was coming from the southern coast of the German Bight. The aircraft was flying at about 120 m height in the wake of Nordsee One and Gode Wind 1 + 2. The atmosphere was slightly stably stratified (Cañadillas et al., 2020). Compared to SAR, both
Figure 8. Transects for the case study on 14 October 2017 for (a) earlier transects and (b) later transects. First row: flight track (grey) with transect of interest (black) and turbines (orange) and mean upwind transect wind direction (WD, as in Table 2) as an arrow with respect to flight track. Second row: wind speed (WS). Third row: turbulent kinetic energy (TKE). Fourth row: wind direction (WD) for flight measurements (black), WRF simulations (brighter colours, densely broken lines), and HARMONIE simulations (darker colours, loosely broken lines) for the no-wind-farm scenario (NWF, solid yellow and dashed–dotted yellow lines), EWP parameterization (dotted red lines), and FITCH parameterization (dashed blue lines), shown for the median flight height of each transect (around 250 m). For each simulation two lines for the nearest model output time steps with shaded area between them are shown. Observational wake effects (obsNWF) are shown as dashed–dotted grey lines (Sect. 2.6). The title of each column corresponds to the time of the respective transect.

Table 4. Median wake effect over all transects for 14 October 2017 for WRF (two left-most columns), HARMONIE (two centre columns), and observations (right-most column) for the difference of FITCH and no-wind-farm (NWF), EWP and NWF scenario and observations (obs), and artificially generated NWF observations for both wind speed (WS) and turbulent kinetic energy (TKE).

HARMONIE and WRF overestimate the 10 m wind speed but show the same gradient of increasing wind towards the north (Fig. 9).

The meteorological situation on 8 August 2017 is much more dynamic with patches of high and low wind speeds (Fig. 10), but it is also classified as slightly stable in Cañadillas et al. (2020). The models can capture this general behaviour but do not correctly simulate the location of these patches in the 10 m wind with respect to SAR (Fig. 10).

### 3.2.2 Transects in the wake

While the wind speed at 10 m was overestimated by the simulations with respect to SAR for 15 October 2017 (Fig. 9), the wind speed at the transects at 120 m height is quite well matched (Fig. 11a, b second rows). In the sequence of transects, a wind speed reduction in the wake downstream of Gode Wind 1 + 2 and with a smaller amplitude also for Nordsee One is visible in the transects from 12:35 onward compared to the transect upstream of the farms at 12:25. The magnitude of the wake deficit gradually decreases with increasing distance from the farm.

TKE is increased downstream of the farm (Fig. 11a, b, third rows), especially near the farm. The TKE increase diminishes faster with increasing distance from the farm than the WS decrease and is only visible through two peaks around 19 km behind the farm (transect at 13:15). High TKE values are visible especially at the edges of the wake as indicated by the “M” shape around the wake (e.g. Fig. 11, third row, for 13:05 onward). This increased turbulence is generated by the shear in that region due to the gradient in wind speed inside and outside of the wake. This was also described in Platis et al. (2020).

Both HARMONIE and WRF agree quite well with the observations ahead of the farm and for some flight legs. The wind direction is slightly more westerly in WRF, which causes a slight displacement of the maximum wind speed deficit at, for example, 30 km (13:25–13:35). Both EWP and FITCH in both models can capture the wake deficit. However, EWP underestimates the magnitude of the wind speed deficit and also strongly underestimates the increase in TKE in the wake. HARMONIE–FITCH best captures the magnitude of the TKE increase just downwind of the farm. WRF–FITCH produces slightly smaller magnitudes, although both use a TKE factor of 1. Neither of the models can capture the “M”-shaped behaviour of the TKE distribution further downstream the wake. This is expected from the coarse resolution of the mesoscale models.

Figure 11b only shows the transects up to about 30 km downstream (13:35), since for increasing distance, the performance of especially WRF deteriorates due to the increasing offset in the simulated wind direction. As the main objective is to evaluate the performance of the WFP in HARMONIE and WRF and not the background physics, the figure for the later transects is placed in the Appendix (Fig. A1). At these transects, the trend of increasing wake recovery and decreasing effects on TKE continues, and later closer transects (at 15:05), are again better captured.

For 8 August 2017 the respective figure showing the transects is placed in the Appendix (Fig. A2), because the general trends of the results are quite similar to those for 15 October 2017: the magnitudes of the wind speed deficit and the TKE enhancement agree better for FITCH than for EWP. Both EWP and FITCH capture the gap between the two farms.

### 3.2.3 Error statistics

We calculate error metrics as described in Sect. 2.6 to quantify the agreement for the different scenarios with observations for the transects highlighted in Figs. 11 and A2. As for the case above the farm, overall HARMONIE and WRF perform similarly (Tables 5, 6), and again the FITCH agrees best with the observations, indicated by high correlation coefficients and low biases for 15 October 2017. For 8 August 2017, the FITCH simulations show large biases for WS (Table 6) and better performance of EWP. This is due to a systematic underestimation of the wind speed compared to the observations, which is amplified in FITCH and is highlighted by the bias. However, looking at the correlation and STDE as a non-systematic error metric indicates that FITCH also outperforms EWP in this case. This again highlights the challenge of simulating background meteorology correctly. For TKE FITCH performs best in terms of all error measures.

For Tables 5 and 6 the mean over all transects is taken. Since this also includes transects with very small TKE-related WFE 20 km and more downstream (Figs. 11b, A2b), the difference between EWP and FITCH in the error measures is not that pronounced except for the correlation. This indicates that although EWP greatly underestimates TKE close to the farm, further downstream at hub height this underestimation is of minor importance due to the diminishing effects for wind-farm-generated TKE.

### 3.2.4 Wind farm effects

The magnitude of the WFEs is derived again by the difference between the simulations with and without WFP. By calculating the mean difference across each transect, the magnitude of the WFE is derived with increasing distance from the farm for simulations and observations (Fig. 12). For the observations the methods described in Sect. 2.6 are used to generate an artificial NWF observation. Note that the method by Cañadillas et al. (2020) can only be applied to WS and not to TKE.

Both cases show that TKE (Fig. 12, dotted lines above zero) recovers faster to background levels compared to WS (Fig. 12, solid lines) behind the farm at hub height: after 20–30 km downstream almost no mean TKE effect along the transect is detectable, while wind speed is still reduced compared to the NWF scenario. The wind speed deficit is
stronger on 8 August than on 15 October 2017, but recovery is also faster, as indicated by the steeper lines. This is also confirmed by the artificially derived observational WFE and by the exponential function provided by Cañadillas et al. (2020). The WFEs based on Cañadillas et al. (2020) are stronger, since they represent the maximal WFE, in contrast to the mean WFE in our study.

The WFEs in WRF and HARMONIE are comparable for the two WFPs with slightly higher values for HARMONIE–FITCH than for WRF–FITCH and slightly higher values for WRF–EWP than for HARMONIE–EWP. The similarity confirms the conclusions in Sect. 3.1.4 that the implementations of FITCH and EWP in HARMONIE have been successful.

Figure 12. Wake effect at around hub height defined as scenario with WFP (FITCH and EWP) minus scenario without wind farm (NWF) in terms of WS reduction in m s$^{-1}$ (lines with crosses) and TKE increase in m$^2$ s$^{-2}$ (lines with circles) for different transects with a certain minimal distance to the farm for WRF and HARMONIE with same colour and line style coding as in Fig. 8 for (a) 15 October 2017 and (b) 8 August 2017. Observational wake effects have been derived based on the methods described in Sect. 2.6. The unbiased standard error of the mean is used to draw the error bars around the observational wake effect.

### 3.2.5 Impact on temperature and humidity

On 8 August 2017 a slight cooling (less than 0.5 K) and humidification (less than 0.5 hPa) was observed in the wake of the farm at hub height a few kilometres downstream of the farm (Fig. 13; compare first with the second and third columns). This WFE is superimposed by a general cooling and humidifying trend as moving further offshore. On the transects 6 km and further downstream this effect is difficult to detect, since it is super-imposed by the variability in the background conditions. Both HARMONIE and WRF only match the background conditions well for some transects. Therefore, it is difficult to compare the effect quantitatively. However, at least for WRF, of the three scenarios, EWP best captures this effect, since it shows the largest temperature drop and humidity increase compared to the other scenarios. In HARMONIE the transects upwind of the farm already differ greatly for the different scenarios; thus it is difficult to conclude whether the WFPs capture this effect. Therefore, only WRF will be used for a more detailed analysis in the following.

The profiles in Fig. 14 show the reason for this WFE. The yellow NWF scenario indicates how profiles evolve with increasing distance from the shore: the inversion moves upward, the air cools and humidifies, and wind speed and TKE increase. These changes happen throughout the lower atmosphere, e.g. also close to the surface.

Due to the presence of wind farm effects in EWP and FITCH, the evolution of these profiles is modified. Compared to NWF, in EWP the inversion height is increased and...
reaches the upper part of the rotor. This results in lower temperatures and higher vapour pressure at hub height. The weak low-level jet present in NWF is removed through the introduced wind speed deficit from the turbines (Fig. 14d), and TKE levels close to the ground are reduced in EWP compared to NWF. Similarly, temperature, humidity, and wind speed are modified close to the ground, indicating that also the surface fluxes have changed. It is difficult to quantify this effect, however, due to the evolving profile with distance from the shore in the NWF case, as discussed above.

In contrast to EWP, the strong mixing in FITCH (Fig. 14c) leads to lower inversion height compared to NWF, which is even moved below hub height (Fig. 14a). This causes the cooling that is also visible in FITCH compared to NWF at hub height in the transects in Fig. 13.

4 Discussion

The main goal of this study was to derive how well the implemented WFPs agree in WRF and HARMONIE to evaluate the implementation of the WFPs in HARMONIE. Therefore, the set-ups of WRF and HARMONIE follow best practices for standard use of the two models, respectively (Table 1). Thus, we applied HARMONIE in forecast mode and WRF in hindcast mode, which is a common set-up for wind energy research. Since a control simulation without wind farms was conducted both for WRF and HARMONIE, the main goal could be reached even with the different setups. However, we acknowledge that due to the different resolution and grids, wind turbines have been assigned to different grid cells (Fig. 5) in WRF and HARMONIE. This influences the direct comparison between WRF and HARMONIE. In addition, the different grids in WRF and HARMONIE could also affect the modelling of the background meteorology, which has implications for comparison against real measurements as discussed below. It is difficult to isolate and quantify the effects of the different grids directly, since also the physics schemes as well as the initial and boundary data differ between WRF and HARMONIE (Table 1). More idealized test cases and set-ups with WRF and HARMONIE could be used in the future to compare WRF and HARMONIE directly and isolate some effects, such as differences in the grids and in the physics schemes.

The control simulation without wind farms (NWF) for WRF and HARMONIE was used to derive the magnitude of the wind farm effects both for WS and TKE as bias compared to a simulation with WFP. To compare these magnitudes with the research flight measurements, an artificial

![Figure 13. As Fig. 8 but for 8 August 2017 and around 90 m height and for (centre row) temperature and (last row) vapour pressure.](https://doi.org/10.5194/gmd-17-2855-2024)
Figure 14. Profiles at the transects in Fig. 13 for (a) temperature, (b) vapour pressure, (c) turbulent kinetic energy, and (d) wind speed at different distances from the farm (line style) at latitude 54.4°. All results are for WRF for NWF (yellow), EWP (red), and FITCH (blue).

observation without wind farms was created by simple linear interpolation between two points outside the farm wake. However, there is some uncertainty in how to define whether a location is outside the farm wake while still being close enough to not be influenced by other meteorological background effects. This exhibits uncertainty that was captured by using different artificially produced observations without wind farm effects. However, as indicated by the NWF simulation, there was considerable variability in the background wind speed within the farm area. Thus, a linear interpolation can only provide a rough estimate of the magnitude of the wake effect in the observations.

The evaluation of the WFP against real measurements is challenging, since the model's ability of simulating the background meteorological conditions influences the calculations of the WFP: the thrust coefficient depends non-linearly on the wind speed (Fig. 4), and thus different background conditions will result in different WFEs. Standard operational verification of HARMONIE includes mostly observations from automatic weather stations close to the surface. Some evaluation has also been done for masts (Kangas et al., 2016), but further evaluation of the forecasts from HARMONIE in heights relevant to wind energy is needed. This evaluation should also include masts undisturbed by wind farms to be able to evaluate the forecast skill at heights of up to 250 m.

5 Conclusions

Wind farm effects are increasingly important to consider in numerical weather prediction (NWP) models. In this study, we implemented the explicit wake parameterization (EWP; Volker et al., 2015) in the nonhydrostatic NWP model HARMONIE. The newly implemented EWP scheme and the already implemented (van Stratum et al., 2022) WFP by Fitch et al. (2012) (FITCH) were evaluated against research flight measurements taken from the project WIPAFF (Bärffuss et al., 2019) as well as against model simulations with the NWP model WRF, which has been frequently used before to evaluate wind farm effects (Fischereit et al., 2022a).

The results show that the implementations of EWP and FITCH are successful and that, of the two WFPs, FITCH agrees in general better with measurements, especially for TKE. Most noteworthy is the underestimation of TKE by EWP close to the farm, which has also been reported previously (Larsén and Fischereit, 2021). The high values of TKE decrease fast with increasing distance of the farm, leaving an “M”-shaped pattern with high TKE values close to the edge of the wake. Due to this fast decrease, the underestimation of TKE by EWP is of minor importance further downstream. Nevertheless, this study indicates that taking only the implicit TKE formation due to vertical shear into account is not sufficient. Instead, an explicit source of TKE is required to consider the TKE formation from the rotational motion of the rotor as well as from tip vortices. Furthermore, this study showed that EWP also exhibits a different wake recovery at hub height as well as a different vertical wake profile of TKE, wind speed, and other parameters. The reasons for these differences are both the vertical wake expansion considered in EWP and the missing explicit TKE source. However, observations of the vertical profile in the wake were not available for comparison, and thus further studies are necessary to investigate the correct shape of the profile in the wake. Nevertheless, according to this study, EWP shows possibilities of improvement that will be addressed in future work.

As the next step, forecasts with all wind turbines, both onshore and offshore, within the northern Europe DMI domain will be performed for longer periods. This allows the estimation of the full impact of currently installed wind turbines on weather and weather forecasting. The established wind turbine database and the results will be presented in Part 2 of this series (Fischereit et al., 2024).

Code and data availability. The ALADIN and HIRLAM consortia cooperate on the development of a shared system of model codes. The HARMONIE–AROME model configuration forms part of this shared ALADIN–HIRLAM system. According to the ALADIN–HIRLAM collaboration agreement, all members of the ALADIN and HIRLAM consortia are allowed to license the shared ALADIN–HIRLAM codes to nonanonymized requests within their home country for noncommercial research. Access to the full HARMONIE–AROME codes can be obtained by contacting one of the member institutes of the HIRLAM consortium (see https://hirlam.github.io/HarmonieSystemDocumentation, HIRLAM consortium, 2023). The code changes to enable wind farms in HARMONIE–AROME are available in the Supplement.

The WRF model is available from https://github.com/wrf-model/WRF (National Center for Atmospheric Research, 2021). Modifications to WRF for EWP are available in the Supplement. Updates to WRF will be made available in the future at https://gitlab.windenergy.dtu.dk/WRF/AROME (DTU Wind and Energy Systems, 2024).

The flight measurements are available from https://doi.org/10.1594/PANGAEA.902845 (Bärfuss et al., 2019). The SAR data are available from https://doi.org/10.11583/DTU.19704883.v1 (Badger et al., 2022). ERA5 data are available from https://doi.org/10.24381/cds.adbb2d47 (Hersbach et al., 2018), and the OSTIA data are available from http://my.cmems-du.eu/motu-web/Motu (Copernicus CMEMS, 2022). The wind farm input data as well as the namelists for WRF are permanently archived at https://doi.org/10.5281/zenodo.10700701 (Fischereit et al., 2023) along with the scripts to reproduce the tables and figures in this article.

Supplement. The supplement related to this article is available online at: https://doi.org/10.5194/gmd-17-2855-2024-supplement.

Author contributions. JF implemented the EWP parameterization with the help of NET and HV. JF designed the experiments, performed the simulations, and analysed the results. XGL post-processed the flight measurements. GG and EK acquired funding for this research. JF prepared the manuscript with contributions from XGL and HV. All co-authors discussed the analysis and reviewed and edited the manuscript.

Competing interests. The contact author has declared that none of the authors has any competing interests.
