Abstract. Low-level jets (LLJs), characterized by wind speed maxima in the lower part of the atmospheric boundary layer, play a crucial role in shaping wind resource availability, particularly as modern wind turbines reach heights exceeding 200 m. Understanding the climatology of LLJs is essential for optimizing wind energy assessments in offshore environments. We leverage wind measurements from lidars and a mast at five sites in the North and Baltic seas to evaluate the ability of the Weather Research and Forecasting (WRF) model and the widely used reanalysis ERA5 to characterize LLJs and use the optimal WRF setup to generate a detailed 5-year climatology. We test the sensitivity of LLJ representation to key WRF model configurations, including grid spacing, vertical resolution, surface layer (SL), and planetary boundary layer (PBL) parameterizations.

Results reveal that LLJ representation strongly depends on the PBL scheme, with LLJ frequency varying by more than a factor of 3 across configurations. For example, the Mellor–Yamada–Janjic (MYJ) scheme favored LLJ formation, while Yonsei University (YSU), BouLac (BL), and Mellor–Yamada–Nakanishi–Niino (MYNN) 2.5 (with `bl_mynn_mixlength=0`) were less prone. The best-performing setup employed scale-aware subgrid mixing (`km_opt=5`; 3DTKE), accurately capturing LLJ occurrence rates, intensity, and vertical profiles. In contrast, ERA5 significantly underestimated LLJ frequency and failed to resolve key features, highlighting its limitations for detailed LLJ analysis.

The 5-year LLJ climatology provides new insights into the spatial and seasonal distribution of LLJs, offering valuable guidance for offshore wind resource assessment and plan-

ning in the region. In the North and Baltic seas, LLJs occur along the western sea basins around 10%–15% of the time, with average jet heights between 140–220 m, which are well within the height of operation of modern wind turbines. The most LLJ-prone region is east of southern Sweden, especially during spring and summer, where LLJs contribute to up to 30% of the wind capacity. In spring and summer, strong coastal gradients are observed in jet timing, height, and direction, particularly along eastern shorelines. Strong variations in the mean duration are also seen, with the longest-lasting jets occurring in the Southern Bight.

1 Introduction

Low-level jets (LLJs) are wind speed maxima in the lower part of the atmospheric boundary layer (ABL). When they occur on a large scale, they play a vital role in heat, moisture, and momentum transport, as well as deep convection, and are thus important for the simulation of regional and global climate (Stensrud, 1996; Rife et al., 2010). They are also sometimes responsible for the transport of pollutants outside urban areas (Darby et al., 2006; Haikin and Castelli, 2022). The formation of LLJs is associated with frictional decoupling (Blackadar, 1957), low-level baroclinicity due to horizontal temperature gradients, large-scale baroclinic zones in sloping terrain (Holton, 1967), and orographic blockage. The first two mechanisms, frictional decoupling and low-level baroclinicity, typically occur at lower heights (Luiz and Fiedler, 2024) and are relevant for coastal jet formation. Due to the different driving mechanisms, LLJs happen at many spatial

and temporal scales. The term “low-level jet” has been used for many of them. Herein, we focus on the jets that form in the lowest part of the atmosphere relevant to wind energy applications (the lowest 500 m) and use the term low-level jet in that context.

It is crucial to accurately consider LLJs in wind resource assessment, especially as wind turbines continue to grow taller and encounter a wider range of them. LLJ events lead to increased wind speeds and higher power output (Smedman et al., 1996; Gadde and Stevens, 2021). However, the vertical wind shear and veer associated with LLJs can impact turbine performance and reliability (Gutierrez et al., 2017, 2019; Porté-Agel et al., 2020; Gadde and Stevens, 2021; Jong et al., 2024). Due to the increased shear, LLJs may also modify wake dissipation in large offshore wind farms, depending on the height of the LLJ relative to the wind turbine rotor (Gadde and Stevens, 2021).

Many have investigated LLJ characteristics in the North Sea (Kalverla et al., 2017, 2020; Wagner et al., 2019) and the Baltic Sea (Smedman et al., 1996; Gottschall et al., 2018; Svensson et al., 2019; Hallgren et al., 2022; Rubio et al., 2022), where LLJs are particularly prevalent in spring and early summer when air–sea temperature differences can easily reach 15 to 20 °C (Smedman et al., 1996; Hallgren et al., 2020; Rubio et al., 2022). The occurrence of LLJs significantly enhances the available wind resources in these areas. In the Baltic Sea, Smedman et al. (1996) identified frictional decoupling as a key formation mechanism with warm air advecting over cold water, creating a stable marine atmospheric boundary layer (ABL) and an inertial oscillation in space resulting in a super-geostrophic jet. This is akin to the Blackadar mechanism (Blackadar, 1957), except the evolution happens in space, not just in time. Low-level baroclinicity also plays a role. Smedman et al. (1997) show how the initially stable ABL transitions to a near-neutral and well-mixed (capped) layer as the traveling time over the cold water increases, giving rise to a jet near the capping inversion after this transition. Because LLJs are transient atmospheric phenomena with a strong diurnal cycle that can be confined to small regions (Stensrud, 1996), they are hard to detect in conventional observing systems, such as surface synoptic observations (SYNOP) stations, weather balloons, and satellite remote sensing, which often lack information in the boundary layer. Thus, LLJ assessments have often been done using output from model simulations. In the past decade, the occurrence of LLJs has been verified in various models: ERA5 (Kalverla et al., 2019; Hallgren et al., 2024; Luiz and Fiedler, 2024), the Weather Research and Forecasting (WRF) model (Rijo et al., 2018; Wagner et al., 2019; Rubio et al., 2022; Aird et al., 2021; Sheridan et al., 2024), and case studies (Nunalee and Basu, 2014; Redfern et al., 2023). However, no study to date has produced a high-resolution climatology of LLJs based on an objective and evaluated choice of model parameters, including physical parameterizations.

This study aims to create the first validated climatology of LLJ characteristics for the Baltic and North seas to support offshore wind energy development. To generate the climatology, we will use the WRF model by first carrying out a comprehensive sensitivity study and model evaluation using lidar measurements from offshore floating lidar systems (FLSs) and one tall mast to choose the optimal model configuration. To generate the LLJ climatology, we run a long-term hindcast simulation using the best-performing model configuration. Due to the sensitivity of LLJ rates to classification methods, temporal–spatial resolution, and vertical levels (Kalverla et al., 2019), the climatology will be presented with an emphasis on relative spatial patterns over absolute rates.

The LLJ climatology is anticipated to provide valuable supplementary information alongside wind atlases such as the Global Wind Atlas (Davis et al., 2023), the New European Wind Atlas (Dörenkämper et al., 2020), and the Dutch Offshore Wind Atlas (Wijnant et al., 2019), thereby supporting offshore wind resource assessment and planning in the region. While spatial climatologies of LLJs have previously been presented for the North Sea (Kalverla et al., 2020) and the Baltic Sea (Svensson et al., 2019), this work contributes by encompassing both seas, refining the model configuration and evaluation, and presenting critical aspects of LLJ characteristics.

The study is organized as follows: Sect. 2 covers the methodology, including measurements, models, datasets, LLJ criteria, reference turbine, and evaluation metrics. Section 3 details the LLJ characteristics from measured data. Section 4 evaluates the models’ ability to capture observed LLJ characteristics. Section 5 presents the climatology results from the long-term WRF model simulation. Finally, in Sects. 6 and 7, a discussion and conclusions are provided.

2 Methods

2.1 Observations

This study considers measurements from five sites: two offshore FLSs in the North Sea (NS1 and NS2), two FLSs in the Baltic Sea (BS1 and BS2), and the northern mast at Østerild (Peña, 2019) in Northern Jutland. The locations of the five sites are shown in Fig. 1, and relevant details about the sites are provided in Table 1. The four FLSs are instrumented with ZephIR ZX300 vertical profiling lidars sampling at 11 vertical levels every 17.4 s, aggregated to 10 min averages. For comparison with the WRF model and ERA5, the samples were further resampled to 1 h averages. The FLS measurement periods cover 15 November 2021 to 15 December 2022. The northern lightning mast at Østerild is equipped with cup anemometers mounted on northward-facing $0 \pm 1^\circ$ booms at six heights (excluding one at 7 m; see Table 1). Following Peña (2019), measurements from 133 to 192° wind direction are excluded to avoid wind shadow effects from the test tur-

Figure 1. Map of the wider study area covering the North and Baltic seas. The map highlights important bodies of water, islands, and other landmarks referenced in the study. The five observation sites are marked with black crosses, and dashed boxes outline the WRF model domains. The outermost WRF domain (D2-P; full black line) is used for the LLJ climatology, and the four innermost domains (D2-E–D5-E; dashed black lines) are used during model evaluation; see Sect. 2.2.3. The D2-E and D2-P domains share a common parent domain (D1; not shown). The coral-colored areas mark current wind farms, farms under construction, or future wind farm development zones from the openly available EMODnet Human Activities database (version dated 8 May 2024).

bines at the site. All five sites were assessed over the same period: 15 December 2021 to 14 December 2022 (8760 h total).

The FLS data underwent quality control and assessment, including filtering via status flags from the sensor, flagging, and removal of unrealistic values and duplicates. Observations with missing data at any height were further filtered for vertical consistency. The 10 min averages were aggregated to 1 h averages (when at least 50 % of samples are available) for consistency with ERA5 and WRF model output. After filtering, between 80 % (7003 at Østerild N) and 93 % (8132 at NS2) of the 8760 h samples remain; see Table 1.

To understand how representative the study period is of the long-term offshore climatology, we compared the year 2022 to the 20-year period 2005–2025 in ERA5 for points near the North Sea and Baltic Sea sites for a number of variables of interest, including the 100 m wind speed and wind direction, the 2 m temperature, and the sea surface temperature. We will not show this analysis here but simply offer our brief summary: we find that the year as a whole is not particularly extreme in any direction, but relevant deviations are present in specific seasons, for instance, in the spring and summer seasons, which are the second and sixth calmest (less windy) of the 20 years, respectively, and with a more warm-biased air–sea temperature contrast in summer (fifth highest), which may be favorable to LLJ genesis.

2.2 Models

2.2.1 The ERA5 reanalysis

The ERA5 reanalysis (Hersbach et al., 2020) is a global, gridded reanalysis product that represents the best estimates of weather conditions that span 1940 to the present day. It consists of hourly variables on 137 model levels in $0.25^\circ \times 0.25^\circ$ grid cells forming a regular global grid. In this study, it serves as a well-established baseline, commonly used in wind energy applications. It has also been extensively used in studies related to LLJs (Kalverla et al., 2019; Rubio et al., 2022; Sheridan et al., 2024; Hallgren et al., 2023; Luiz and Fiedler, 2024). Herein, we use the bottom 16 levels (index 122–137), which gives us levels that span above 500 m at our particular sites.

2.2.2 The NEWA wind atlas

The New European Wind Atlas (NEWA) dataset (Dörenkämper et al., 2020) is also used as a baseline comparison with the model simulations. Wind speed and other meteorological parameters are available at 50, 75, 100, 150, 200, 300, and 500 m above ground with a horizontal grid spacing of 3 km. In the NEWA project, the best setup for the model was identified by a large set of simulations and compared in terms of the accuracy of the simulated wind speed distribution (Hahmann et al., 2020), but not concerning its depiction of LLJs. The NEWA WRF model simulations used version 3.8.1 and

Table 1. Measurement instruments, locations, vertical levels, and data availability after filtering and resampling for the five measurement sites.

Site	Instrument	Latitude	Longitude	Levels	Data avail.
NS1	ZephIR ZX300 lidar	56.6279° N	6.3019° E	30, 40, 60, 90, 100,	85 %
NS2		56.3444° N	6.4574° E	120, 150, 180, 200,	%
BS1		54.9944° N	14.3547° E	240, and 270 m	85 %
BS2		54.7170° N	14.5882° E		92 %
Østerild N	Boom-mounted cup anemometers on lightning mast	57.0870° N	8.8807° E	40, 70, 106, 140, 210, and 244 m	80 %

were extended to cover the required time period in this study. Given the limited number of vertical levels available from NEWA, we only include it in parts of the model evaluation focused on spatial variations in LLJ occurrence.

2.2.3 The WRF model simulations

We used the Advanced Research WRF (WRF-ARW) model (Skamarock et al., 2019) v4.2.1 to derive a spatially consistent high-resolution climatology of LLJs in the North and Baltic seas. The modeling work is divided into three phases: the first phase, initial sensitivity experiments; the second phase, incremental sensitivity experiments of the chosen setup to changes made towards the production run; and finally, phase three, the production run. The full list of experiments is presented in Table 2.

For phase one, we created an ensemble of WRF model simulations to identify the model configuration that best simulates the wind climate and the occurrence and characteristic of LLJs for a set of cases (days), as explained later in Sect. 4.1. The simulations for each ensemble member consist of many short runs, covering 36 h each, where the first 12 h are ignored (spin-up). The configuration of the WRF model domains for these runs is the “E” domains (dashed lines in Fig. 1). These domains used an outer domain (D1) with 9 km grid spacing and a smaller domain (D2-E) of 3 km grid spacing. Within D2-E, there are three smaller localized domains (D3-E–D5-E) with a 1 km grid spacing centered within each measurement site.

We use five PBL parameterizations: 3DTKE (Zhang et al., 2018), BouLac (Bougeault and Lacarrere, 1989), Mellor–Yamada–Janjic (MYJ) (Janjić, 1994), Mellor–Yamada–Nakanishi–Niino (MYNN) level 2.5 (Nakanishi and Niino, 2009), and Yonsei University (YSU) (Hong et al., 2006). We use three surface layer (SL) schemes: MM5 similarity (Jimenez et al., 2012), eta similarity (Janjić and Zavisla, 1994), and the default SL used with the MYNN PBL scheme (Nakanishi and Niino, 2009). The five SL and PBL combinations are shown in Table 3. To limit computational demand, we chose a sparse ensemble matrix and only varied other parameters for one of the PBL schemes, MYNN. For this scheme, we changed the number of vertical levels (55,

85, or 125) and included spectral nudging for one member in the outer model domain (D1). Because the NEWA simulations use an earlier version of the MYNN scheme with a default `bl_mynn_mixlength` = 0, this configuration was also included in the phase-one ensemble. For all other MYNN-based experiments, the new default `bl_mynn_mixlength` = 2 was used. See Olson et al. (2019) for a description of the changes between them.

After identifying the best-performing WRF ensemble member in phase one, we used it as the baseline for phase-two experiments (see Table 2). This phase aimed to assess sensitivities to key reconfigurations necessary for longer, more efficient simulations over a wider area. To reduce spin-up time in the climatology runs, we tested the sensitivities to extended lead times, running 72 h simulations with 12 h spin-up and 168 h simulations with 24 h spin-up. Additionally, for longer runs, we incorporated spectral nudging in D1. Throughout phase two, we continued using the E domains. We ran the longer runs for a whole year to cover the evaluation period, with each run overlapping only by the spin-up period with the subsequent run.

Lastly, in phase three, we conducted a multiyear simulation (26 June 2019–26 June 2024), labeled P_CLIM. Using the same model configuration as the final phase-two run, however, we reduced the spin-up to 12 h and expanded the geographic coverage to the North Sea and southern Baltic Sea (Fig. 1). This “P” domain configuration retained the 9 km outer domain from the E configuration but extended the 3 km nested domain (D2-P) westward, eastward, and slightly northward to include the North Sea and southern Baltic. The 1 km inner domains were omitted for the climatology production.

The WRF model configuration options, which remained the same across all the WRF simulations, are presented in Table 4. It is worth mentioning that two modifications were made to the land use determination. First, several large lakes were transformed to sea since their temperatures are included in the OSTIA dataset (Table 4). Second, much of the coastal area of the Wadden Sea from Holland to Denmark is converted from “swamp” to “tidal zone” as explained in Hahmann et al. (2020).

Table 2. The ensemble of WRF model experiments. Unless stated otherwise, 36 h runs were used, which includes a 12 h spin-up. See Table 3 for the PBL and SL combinations.

Experiment	Phase	Domains	PBL–SL	Levels	Additional changes
E_MYNN	1	E	MYNN	85	bl_mynn_mixlength = 0 (Olson et al., 2019)
E_MYNN_ML0	1	E	MYNN	85	
E_MYNN_L125	1	E	MYNN	125

2.3 Reference turbine

To illustrate the impact and relevance of a specific offshore wind turbine, we use the International Energy Agency (IEA) 15 MW turbine (Gaertner et al., 2020) as a reference. This turbine model has a proposed hub height of 150 m and a rotor diameter of 242 m, spanning heights of 29 to 271 m, nearly matching the FLS scan levels (30 to 270 m). The turbine has a cut-in and cut-out wind speed of 3 and 25 m s^{−1}, while rated power is reached at 10.59 m s^{−1}.

2.4 Low-level jet detection

Classifying whether a vertical wind speed profile is a LLJ event or not involves two steps: (1) identifying reference levels on the vertical profile for jet metrics and (2) filtering out undesirable profiles based on specific criteria calculated from the reference levels. The profiles may be truncated at a certain height to focus on a specific atmospheric layer.

First, we identify a local maximum in wind speed (i.e., the “jet maximum”). Following Baas et al. (2009), we consider only the lowest 500 m of the atmosphere. When mul-

tiple minima are present above or below the jet maximum, a 1 m s^{−1} wind speed recovery is required for a local minimum to be accepted, as illustrated in Fig. 2. Profiles without a local maximum are classified as non-LLJ events. Potential LLJ profiles are filtered using the absolute ($U_{\max} - U_{\min}$) and relative $(U_{\max} - U_{\min})/U_{\max}$ wind speed fall-offs. To obtain sufficient samples, we use thresholds of 1.5 m s^{−1} and 15 % fall-off instead of 2 m s^{−1} and 20 %. While the dilution of the thresholds means allowing more ambiguous LLJ cases and reducing the emphasis on the strongest cases, we gain more robustness in our results. For the observations, the threshold change means more than doubling the number of available samples at the five sites. For example, instead of 19 samples at NS2, we have 51, and instead of 65 samples at BS2, we have 173. Thresholds differing from 1.5 m s^{−1} and 15 % are applied in specific situations, as will be detailed in the text in those cases.

There is no strong consensus on the most appropriate LLJ detection criteria in the literature, and they will, to some extent, be specific to the context. Hallgren et al. (2023) suggest a shear-based definition for wind energy applications, as it

Table 4. WRF model configuration used in all the simulations.

Parameter	Option
WRF model version	4.2.1
Grid spacing (Δx , Δy)	E domains: five one-way nested domains – 9 km (D1), 3 km (D2-E), 1 km (D3-E, D4-E, D5-E)
	P domains: two one-way nested domains – 9 km (D1), 3 km (D2-P)
	The same outer domain (D1) is used for all runs. E domains were also used for the S runs.
Time step	Adaptive, using a Courant–Friedrichs–Lewy (CFL) criterion target of 1.1 (horizontally and total); a max step increase percentage of 5 (D1; the adaptation domain) and 51 (D2–5); a starting time step of 90 s (D1), 30 s (D2), and 10 s (D3–5); and a minimum and maximum time step of 20 and 90 s (D1), 7 and 30 s (D2), and 3 and 10 s (D2–5)
Terrain data	Global Multi-resolution Terrain Elevation Data 30'' (Danielson and Gesch, 2011)
Land use data	CORINE 100 m (Copernicus Land Monitoring Service, 2019); ESA CCI (Poulter et al., 2015) where CORINE not available
Dynamical forcing	ERA5 reanalysis ($0.25^\circ \times 0.25^\circ$) on pressure levels (Hersbach et al., 2020)
Sea conditions	OSTIA sea surface temperature (SST) and sea ice ($0.05^\circ \times 0.05^\circ$) (Donlon et al., 2012)
Land surface model	NOAH land surface model (LSM) (Tewari et al., 2004)
Microphysics	WSM5 (Hong et al., 2004)
Radiation	RRTMG, 12 min call frequency (Iacono et al., 2008)
Cumulus	Kain–Fritsch scheme in D1 (Kain, 2004)
Diffusion (horizontal)	diff_opt=2 evaluates mixing terms in physical space (stress form) by applying a turbulence parameterization based on the Smagorinsky first-order closure.
Advection	Positive-definite advection of moisture and scalars

captures sharp wind profile transitions and is less sensitive to the vertical window. The detection of a LLJ is influenced by the chosen definition, spatiotemporal variability, and dataset resolution (see, e.g., Kalverla et al., 2019). Using 10 min averages from measurements results in more LLJs than longer averaging periods and mesoscale data. High sample density is crucial to accurately resolve the LLJ structure, as they can be short-lived and shallow. Therefore, extra care is needed when comparing studies, especially with regard to the vertical levels, data sampling, averaging, and detection criteria.

To ensure consistency between observations and models, we take several steps in this study. Observations are averaged into hourly means to better match the temporal variability of the mesoscale model and ERA5 reanalysis. Additionally, model outputs are interpolated to the measurement sampling heights for direct comparison. However, complete consistency is inherently unattainable due to differences in spatial scales: point observations (or small volume averages, such as with the FLSs) are contrasted with models and reanalysis data that operate at much coarser spatial resolutions.

This limitation, however, is a deliberate part of the study's aim, as we evaluate the model's ability to reproduce LLJs despite its resolution constraints.

2.5 Vertical levels

The FLS-based measurements are provided at fixed height levels listed in Table 1, alongside the Østerild mast measurement heights. The ERA5 and WRF models use time-varying vertical levels, shown in Fig. 3, with average heights (horizontal line) and ± 1 standard deviation (vertical line). The span of the IEA 15 MW wind turbine is depicted in gray. The number of levels within the rotor plane is 11 for FLSs, 6 for the Østerild mast, 8–9 for ERA5, 7–8 for WRF-L55, 11–12 for WRF-L85, and 14 for WRF-L125 (Table 2).

For direct comparison between measurements and model simulations (Sect. 4), model data are interpolated to measurement heights using log-linear interpolation of wind speed, while wind directions are obtained by linear interpolation of the wind components U and V . For the final WRF-modeled

Figure 2. Schematic of a wind speed profile and the various parameters used to detect the occurrence of a LLJ.

long-term LLJ climatology, we use the native WRF model levels with variable heights for LLJ identification, restricted to the lowest 500 m of the atmosphere.

2.6 Evaluation metrics and LLJ characterization

To assess model performance, we use metrics relevant to LLJ characterization, wind resource assessment, and wind power modeling. Due to time lags in simulated atmospheric features, the modeling accuracy for individual LLJ events is often limited. Therefore, we focus on modeling the distribution of LLJ characteristics over the 70 d evaluation period rather than individual events. Additionally, to ensure the models perform well in all weather conditions, we include traditional wind power metrics, reflecting state-of-the-art numerical weather prediction (NWP) hindcasts.

Rotor-equivalent wind speed (REWS) (Wagner et al., 2014) and its conversion to power via the reference power curve are used to assess wind speed and power production. The REWS accounts for the rotor-area-averaged wind speed and veer, providing a realistic impact on turbine conditions and reducing sensitivity to evaluation level choice.

As a statistical distance measure, we use the Earth mover's distance (EMD; Rubner et al., 1998), originally proposed by Kantorovich (1960). The EMD measures the statistical distances between observed and modeled distributions. The EMD quantifies the “work” needed to align distributions, corresponding to the area between marginal cumulative dis-

Figure 3. Height of the wind speed samples from the floating lidar measurements (FLSs), the sonic anemometers on the Østerild mast, the levels available from NEWA, and the model levels ± 1 standard deviation for ERA5 and the three WRF model configurations using 55, 85, and 125 vertical levels. The IEA 15 MW rotor-swept heights are shown in gray.

tribution functions (CDFs) for 1D distributions, capturing both overlap discrepancies and mean distance between these discrepancies.

2.6.1 Model evaluation metrics

- *Hindcast power accuracy.* To evaluate the hindcast accuracy for power, we use the REWS root mean square error (RMSE) and the coefficient of determination for the Pearson correlation coefficient (R^2).
- *Annual energy production accuracy.* To evaluate the mean annual energy production accuracy, we use the mean percentage error (MPE), the mean absolute percentage error (MAPE), and the statistical distance between empirical distributions for both REWS and hub-height wind direction. The accuracy of the wind power climatology is measured using the EMD for REWS and hub-height wind direction at 150 m, denoted D_{150} .
- *Shear and veer accuracy.* To evaluate the accuracy of the wind shear ($\Delta U/\Delta z$) and veer ($\Delta D/\Delta z$) across the rotor plane, we use the EMD between modeled and observed distributions for all levels in the area (30 to 270 m), averaged equally with height. These vertically averaged metrics are denoted MEMDS (shear) and

MEMDV (veer) and favor models that replicate the correct distribution at each height, unlike simple average measures.

- *LLJ Characterization.* To evaluate the LLJ characterization, we focus on the mean rate of occurrence and distribution accuracy using MAPE, MPE, and EMD of D_{150} during LLJ events. The EMD is also used for hourly and monthly LLJ rates, core heights, and wind speeds to assess the diurnal and annual cycle and the core height and speed characteristics of the LLJs. MEMDS and MEMDV presented above were also used to evaluate the shear and veer distributions during LLJ events.
- *Spatial variability of LLJ comparison.* To compare the normalized spatial variability of LLJ rates between models, we use Z scores, or “standard scores”. The Z score is a statistical measure that describes a value’s relationship to the mean of a set of values, expressed in terms of standard deviations from the mean. It is calculated using the formula $Z = \frac{(X-\mu)}{\sigma}$, where X is the value being measured, μ is the mean of the dataset, and σ is the standard deviation. Here, the samples are the individual LLJ occurrence rates in each model grid cell. This measure is useful for standardizing different datasets, allowing for comparison across different scales. A high positive Z score indicates the value is significantly above the mean, while a high negative Z score indicates it is significantly below the mean. Z scores are widely used in various fields to identify outliers and to normalize data for further statistical analysis.
- *Best-performing model ranking.* To indicate the best-performing ensemble member, we use the equally weighted rank of scores. The score simply ranks the models according to the scores from 1 to n , with the best-performing model getting rank 1, the second-best rank 2, and so on. The ranks are then averaged across all scores with an equal weight. Lower values thus indicate a “better-performing” model. The score provides an objective ranking of model performance but should not be seen as the definitive indication of which model is “best”; a further detailed analysis of each metric and other factors is needed for that.

2.6.2 Data processing and tools

We conduct the data analysis using Python. The `wasserstein_distance` function from the SciPy package (Virtanen et al., 2020) is used to calculate EMD for linear data, while the `wasserstein_circle` function from the POT (Python Optimal Transport) package (Flamary et al., 2021) is used for circular data (e.g., wind direction, hour of the day, month of the year). All maps are made using matplotlib (Hunter, 2007) and Cartopy (Met Office, 2010–2015) with base maps from

<https://www.naturalearthdata.com/downloads/> (last access: 26 May 2025). We also present the duration of LLJ events. To calculate this duration, LLJ occurrence times are grouped into events by counting consecutive LLJs in each time series. A one-time-stamp gap is allowed, with longer gaps indicating separate events.

3 Low-level jet observations in the evaluation period

Figure 4 shows the time–height evolution of the wind speed for the entire evaluation period, with detected LLJ cores marked as red dots and WRF model ensemble simulation days as black dots. The figure highlights the missing data periods, particularly in May for NS1 and parts of March and December 2022 for BS1, and southeasterlies are filtered out from the Østerild N measurements. LLJs occur more often at the Baltic Sea sites with 138 ($\approx 1.86\%$) cases at BS1 and 173 ($\approx 2.14\%$) at BS2, respectively. In the North Sea area, the occurrence is below 1% at all three sites. Missing data at NS1 and BS1, particularly in LLJ-favorable seasons (spring), likely introduce a relative bias in annual LLJ statistics (the larger number of cases at BS2 relative to BS1 is illustrative of this). However, this has a minimal impact on model evaluation since biases can be inferred from nearby FLSs, and the missing periods are removed from the modeled time series before evaluation.

Figure 5 presents seasonal and diurnal LLJ detection rates (a, b) and distributions of LLJ duration and core heights (c, d). LLJ occurrence is highly seasonal, peaking in spring and summer, with BS1 and BS2 showing 2% to 4% detection rates compared to less than 1% in other seasons. LLJs are nearly absent in winter (January–February). This seasonality aligns with findings from the North Sea (Kalverla et al., 2019, 2020) and the Baltic Sea (Svensson et al., 2019; Hallgren et al., 2022).

Diurnal cycles vary by site. At BS1 and BS2, LLJ frequency is 40% to 50% higher in the late afternoon and evening, in contrast to Svensson et al. (2019), who found peaks closer to midnight – likely due to spatial differences (points near Bornholm vs. all of the Baltic Sea). NS1 and NS2 show limited diurnal variation, except for a morning peak at NS1, occurring later than observed in the Dutch and Belgian North Sea (Kalverla et al., 2019). Østerild N favors nighttime LLJs, with minimal midday occurrences. The regional differences in the diurnal cycles likely stem from climatic variations, such as differences in land–sea temperature contrasts aligned with prevailing wind directions, influencing coastal LLJ formation more at the Baltic Sea sites.

Most LLJs are short-lived; over 50% last just 1 h (or less), with multi-hour events being rare. BS1 and BS2 exhibit slightly longer-lasting LLJs than other sites. LLJ core heights typically range 45 to 165 m, with mean values around ≈ 106 m (BS1, BS2), ≈ 104 m (NS1), ≈ 121 m (NS2), and 117 m (Østerild N). These heights often fall below the ref-

Figure 4. Time–height evolution of the wind speed from the measurements at the five sites (NS1, NS2, BS1, BS2, and Østerild N) for the period 15 November 2021 to 15 December 2022. Red dots indicate the core of a detected LLJ. Black dots in the top and bottom margins indicate that the day is part of the WRF model ensemble evaluation. Missing data are left blank.

Figure 5. Distribution of the occurrence of LLJs for hourly data as a function of season (a), time of the day in UTC (b), LLJ duration (c), and core height from the measurements at the five sites. In panel (d), the span of the IEA 15 MW rotor is shown in gray, with the hub height indicated by a dashed black line.

erence turbine hub height (dashed line), placing the rotor's upper part in a strong negative shear region.

Figure 6 presents wind roses at 150 m for all conditions and LLJ events across the five sites. At the North Sea sites, prevailing winds are westerly and northwesterly, but LLJs predominantly occur with easterly winds from Denmark and

Germany. Similarly, Østerild N experiences more LLJs with easterly winds, deviating from its typical westerlies. In the Baltic Sea, while westerlies remain dominant overall, LLJs are more frequent from the east and southeast, likely influenced by a strong air–sea gradient and a coastal baroclinic zone.

4 Model evaluation

For our model evaluation, we use a 70 d evaluation period and divide the analysis into general conditions using all the data from the 70 d evaluation period and LLJ-related performance metrics, where we compare modeled vs. observed distribution from all samples with a detected LLJ. This means that the samples are the same for the general metrics and represent different times for the LLJ-related metrics. The hourly model time series were extracted from the grid cell closest to the measurement locations of the same type (nearest offshore point for BS1–2 and NS1–2; nearest land point for Østerild N).

4.1 Selecting the simulation days for ensemble evaluation

The 70 d used to evaluate the model performance are selected from the period 15 December 2021 to 14 December 2022. Of the 70 d, 47 d are selected due to the detection of a strong LLJ (2 m s^{-1} and 20 % fall-offs) for at least one of the five sites during that day. To balance the sample of days to include more general weather conditions, 23 additional days are randomly selected, stratified by month, ensuring at least 5 d per

Figure 6. Comparison of the wind direction roses for all available samples (gray) and LLJ occurrence periods (orange) at 150 m (FLS) and 150 m (Østerild) at the (a) North Sea and Østerild sites and (b) Baltic Sea sites. Note that to avoid overlap, the wind roses are offset from their geographic location, which is denoted by red dots. The same radial scale is used for the wind roses at each site but may differ between sites.

month (see Table D1 in the Appendix). The chosen days are marked by black dots along the margin of Fig. 4. Although still skewed somewhat towards situations favorable to LLJ development, this more balanced sample of days should improve annual average performance estimates and help assess the simulations' ability to correctly model non-events, i.e., the absence of LLJs when none are observed.

4.2 General model evaluation

Figure 7 displays the mean model performance scores. Compared to ERA5, the WRF model simulations exhibit reduced forecast accuracy, as indicated by higher RMSE (REWS) and lower R^2 (REWS) values. This is alleviated somewhat by grid nudging (ensemble member E_MYNN_NUD). On the other hand, several WRF model runs demonstrate enhanced performance relative to ERA5 for scores relating to average quantities and distributions. The largest improvements are seen for the vertically averaged statistical distances of shear and veer distributions (MEMDS and MEMDV), indicating that the vertical structure of the ABL is better captured in the WRF model runs. Notable exceptions to this are ensembles E_BL and E_MYNN_ML0. An improvement in EMD of wind direction is also seen for E_YSU, E_MYJ, and E_3DTKE.

Only one WRF ensemble member, E_MYJ, outperforms ERA5 according to the equally weighted mean rank of scores (Fig. 7i). Conversely, two WRF ensemble members, E_BL and E_MYNN_ML0, perform significantly worse, underestimating REWS by approximately 4% on average. These members also display poorer distributions of REWS and, as discussed above, MEMDS and MEMDV, resulting in the lowest mean rank scores. Changing the WRF model setting of the scale-aware mixing length (bl_mynn_mixlength) in

the MYNN PBL scheme from option 0 to 2 leads to substantial improvements, with the six versions using E_MYNN performing on par with most other configurations.

Nearly all scores improve, e.g., EMD(WD₁₅₀) and MEMDV for the 1 km domains, relative to 3 km domains. The MEMDS and EMD(REWS) also generally improve for most members with a 1 km grid spacing, though some members show slight deterioration. When evaluated using equally weighted mean rank scoring, the 1 km domains outperform the 3 km domains for eight out of nine WRF ensemble members.

The effect of varying the number of vertical model levels on the evaluation statistics is not very pronounced, though differences do arise. Among the ensemble members, E_MYNN_L125 with 125 vertical levels and a 1 km grid achieves the best overall performance of the MYNN-based members. Despite this, individual scores for the evaluated metrics remain similar across different vertical-level configurations.

The MEMDS and MEMDV metrics hide a lot of details. The primary source of MEMDS error for all the models is an underestimation of the wind speed shear at lower levels (below 100 m) at all sites; in particular, ERA5, E_BL, E_MYNN_ML0, and E_MYNN_L55 have a strong underestimation, while E_MYJ is most accurate. Higher up (above the turbine hub height), the shear is generally weaker and captured better by the ensemble members, even though most continue to underestimate the shear there; E_YSU, E_BL, and especially ERA5 overestimate it. For wind veer, all models show an underestimation at lower levels, except for E_MYJ, which overestimates it. Considering only the standard statistics in Fig. 7, the E_MYJ ensemble would be considered the best-performing WRF model ensemble member. The mean rank of the scores is lower than any other member.

Figure 7. Performance scores averaged over the five sites for the 70 evaluation days: (a) MAPE of REWS, (b) MPE of REWS, (c) EMD of REWS, (d) RMSE of REWS, (e) Pearson correlation coefficient of REWS, (f) EMD hub-height wind direction, (g) MEMDS, (h) MEMDV, and (i) the mean rank across all scores. The models are ERA5 (dark blue), the WRF model run chosen for the LLJ climatology (P_CLIM; light blue), and the different WRF model ensemble members from Table 2. The error bar represents the ± 1 standard deviation spread among the five sites. For each WRF model ensemble, the light color is for the 1 km domain (D3-E–D5-E) and the darker color is for the 3 km (D2-E) domain as shown in panel (g).

4.3 LLJ-related model performance

In Fig. 8, the results for the 10 different LLJ-related performance scores, focusing on average errors and statistical distances between distributions, are presented. The number of LLJ samples detected in the observations and each model simulation is shown in Appendix E. The scores in Fig. 8 highlight significant differences between the WRF model runs in their ability to correctly simulate LLJs and model their characteristics. For the Østerild N site, several of the models detected fewer than seven LLJs (including ERA5). Thus, for all the average scores in Fig. 8, except for MAPE and MPE of LLJ rates, only the four other sites were used in the calculation for all the models.

Some of the most notable results for LLJ-related model performance are the following.

- The E_MYJ ensemble member significantly overestimates the mean LLJ rate (especially in win-

ter; not shown), while ERA5, E_YSU, E_BL, and MYNN2_ML0 substantially underestimate it.

- ERA5 not only underestimates LLJ rates but also overestimates the LLJ core height, resulting in an average bias of $\approx 45\%$ (not shown) and the poor EMD score shown in Fig. 8c. ERA5 also fails to capture the annual and diurnal cycles of LLJs accurately. ERA5 also performs significantly worse for distributions of jet wind speeds, the shear and veer distributions, MEMDS, and MEMDV.
- The E_YSU ensemble member best captures the distribution of LLJ core heights (Fig. 8c). The EMD errors shown in the figure for jet core heights come from a general overestimation of the height of the LLJ peak by $\approx 10\%$ for most WRF model members: E_YSU at $\approx 5\%$ and E_BL at $\approx 20\%$.

Figure 8. Performance scores aggregated over the five sites for the observed vs. modeled rates and distributions of LLJ-related quantities during LLJ events detected during the 70 d evaluation period: MAPE of LLJ rate (a), MPE of LLJ rate (b), EMD of LLJ core height (c), LLJ core wind speeds (d), EMD of hub-height wind roses (e), EMD of monthly LLJ rates (f), EMD of hourly LLJ rates (g), MEMD_{SLLJ} (h), and MEMD_{VLLJ} (i), and the mean rank across all scores (j). The bar represents the ± 1 standard deviation spread among the five sites. For each WRF model ensemble, the light color is for the 1 km domain (E3–E–D5–E) and the darker color is the 3 km (D2–E) domain as shown in panel (g). Because too few LLJs were detected for some of the models at Østerild N, the scores in (c)–(j) are based only on NS1, NS2, BS1, and BS2 for all models.

- The WRF ensemble generally overestimates the LLJ wind speeds at the LLJ core by $\approx 5\%$ on average and less so at BS1 and BS2 (0% to 5%). The E_MYNN_ML0 ensemble member is an outlier from the rest. It underestimates the wind speed ($\approx -3\%$ on average). The best-performing ensembles, in terms of

EMD(LLJ Max wind speed), are the E_MYNN members (the versions with both 85 and 125 levels.)

- The E_3DTKE captures the diurnal and annual cycles of LLJ occurrence rates well. Its annual cycle of LLJ occurrence is consistently accurate at all five sites. The other WRF ensemble members also capture the diurnal cycles well but are less accurate at other sites, mostly

NS2. E_MYNN_ML0, again, stands out negatively with the lowest scores for the diurnal cycle. With the exception of E_MYJ, which consistently overestimates the LLJ rate in all seasons, all WRF ensemble members underestimate the fall and winter rates and overestimate the summertime rates (not shown). Most models capture the diurnal cycle well at the BS1 and BS2 sites (E_3DTKE has the lowest errors there) but score lower at BS2 in particular.

- The distributions of shear and veer during LLJ events averaged across rotor heights (as measured by MEMDS by MEMDV) are captured about equally well by several WRF members (E_MYJ, E_3DTKE, E_MYNN, and E_MYNN_NUD, and E_YSU for shear only). E_3DTKE is slightly better for shear and E_MYJ for veer. E_BL and E_MYNN_ML0 stand out with the worst scores. This comes from large underestimations of the shear across several levels compared to the other ensemble members.

The performances of the 3 km WRF domains are generally not significantly worse than the 1 km domain for LLJ-related metrics, with the rank average scores only improving for four out of nine ensemble members.

Among the ensemble members, E_3DTKE emerges as the best performer, accurately capturing the mean LLJ rate, seasonal and diurnal trends, and vertical shear and veer structure. Although E_MYJ also captures the seasonality and diurnal structure well, it tends to exaggerate the occurrence of LLJs and has a less accurate wind rose compared to E_3DTKE. Consistent with their performance in the general metrics, E_BL and E_MYNN_ML0 produce the worst LLJ-related scores overall. In contrast, E_MYNN, the baseline setup using MYNN, generally scores high on most of the metrics. Interestingly, there are no significant differences between the three ensembles with different numbers of vertical levels in the E_MYNN configuration for many of the metrics. A slight deterioration vs. the baseline MYNN is seen for both L55 and L125 when looking across all metrics, indicating that the number of vertical levels investigated here has a minimal impact on LLJ-related performance metrics.

4.4 Spatial LLJ variation model evaluation

Figure 9 illustrates the mean LLJ occurrence rate across the various ensemble members in Table 2 during the evaluation period. For these maps, all model levels up to 500 m are used. All maps exhibit consistent spatial patterns, with higher occurrence in the Baltic Sea around Bornholm and northern Germany near Hamburg. However, absolute LLJ jet frequency varies significantly among the models.

The E_MYJ ensemble member stands out, showing the highest rates, with values exceeding 28 % across substantial regions of the Baltic Sea near Bornholm and along the Swedish east coast. Conversely, the lowest rates are produced

by ERA5, NEWA, and E_MYNN_ML0. The other ensemble members present rates that are relatively similar to each other. In the case of the E_MYNN member, an increase in the number of vertical levels in the simulation notably enhances the LLJ rates, particularly when the levels are raised from 55 to 85 (Fig. 9e, h, and k), but much less from 85 to 125.

While the absolute LLJ occurrence rate is important, it is quite sensitive to the detection window and thresholds chosen for detection. To evaluate the relative spatial variations of LLJ rates, we compute the spatial Z scores as shown in Fig. 10. The maps reveal striking similarities of spatial variation but also member-specific variations. While all the models show LLJ “hot spots” in the Baltic Sea around Bornholm and along the Swedish east coast as well as around Hamburg in northern Germany, some models make the Baltic Sea rate more pronounced (in these relative Z-score terms), including E_BL and E_MYJ. The same members also have stronger LLJ rates in the nearshore areas in the North Sea, e.g., Kattegat, Wadden Sea, and the Southern Bight. The influence of the island of Bornholm varies as well, with some models showing a stronger island-to-sea gradient in LLJ occurrence rates, including E_YSU, E_3DTKE, and the MYNN-based members, in contrast to E_MYJ and E_BL. In the North Sea, the models agree that a tongue of low rates extends from the west coast of Jutland into the central North Sea, but with member-specific variations: in E_YSU, E_3DTKE, and the MYNN-based scenes, it is more pronounced than E_MYJ and E_BL. Onshore, northern Germany is more pronounced in E_MYNN_ML0. The NEWA and ERA5 grids are different from the WRF ensemble domains and they have different vertical levels; this influences the results somewhat, but strong similarities in the spatial variation are still visible. In E_BL and ERA5, the North Sea close to the Strait of Dover is more pronounced than in the maps from the other models. Although the absolute levels are different, the spatial distribution of LLJ rates of ERA5 is consistent with those presented in, e.g., Rubio et al. (2022) (strong LLJ prevalent in the sea south of Götland).

4.5 Evaluation of the climatological run

As shown in Sect. 2.2.3, the WRF simulation for the LLJ climatology (P_CLIM) uses the same physics parameterization as E_3DTKE, but for computational efficiency, it uses longer simulation times (7 d vs. 1 d simulation used in phase one), the larger D2-P domain (Fig. 1), and grid nudging above level 50 (2000 m above ground level). These changes were necessary to include most of the North and Baltic Sea regions and to increase computational efficiency (reduced number of spin-up hours per simulated day).

Our evaluation of E_3DTKE, the phase-two experiments (see Table 2), and P_CLIM highlights the impact of transitioning from E_3DTKE to P_CLIM. While results are only shown for E_3DTKE and P_CLIM (in the previous parts), key findings are summarized as follows: spectral nudging in

Figure 9. Maps of modeled LLJ occurrence rates during the 70 evaluation days: (a–i, k) WRF ensemble members in Table 2, (j) NEWA, and (l) ERA5. The black crosses show the measurement site locations.

D1 (E_3DTKE_NUD) improved correlation (R^2 of REWS) and reduced RMSE(REWS), with a minimal effect on LLJ metrics. Extending run durations (E_3DTKE_NUD_72H and E_3DTKE_NUD_168H) slightly lowered correlation, EMD(REWS), and EMD(WD₁₅₀) but maintained LLJ characterization. Expanding the domain in P_CLIM further reduced correlation and RMSE(REWS). Although P_CLIM showed lower general model evaluation scores (Fig. 7) compared to E_3DTKE, LLJ-related performance remained strong, with consistent spatial LLJ occurrence rates (Figs. 9, 10).

5 LLJ Climatology

The P_CLIM WRF model simulation spans 5 years, from 26 June 2019 to 26 June 2024. To create the climatological lay-

ers presented here, we use all output from the WRF model domain D2-P (after removing the spin-up period) at 30 min intervals in the same manner as was done in the NEWA simulations (Dörenkämper et al., 2020). Here we present various aspects of the LLJ characteristics. The strong seasonality of the LLJs means that most quantities are presented as seasonal aggregates.

5.1 Occurrence rates

Figure 11 shows the spatial distribution of annual mean LLJ occurrence rates for the 5-year climatology. It highlights significant LLJ prevalence south of Öland in the Baltic Sea, onshore in central Europe, and along eastern-facing coastlines, particularly in Sweden and the UK. Skagerrak shows higher LLJ prevalence than Kattegat and the Danish North

Figure 10. Maps of normalized LLJ rates (Z scores) during the evaluation period for (a–i, k) WRF ensemble members in Table 2, (j) NEWA, and (l) ERA5. The extents of maps for NEWA and ERA5 are slightly different compared to the WRF ensemble. The black crosses show the measurement site locations.

Sea. Smaller islands, urban areas, lakes, and rivers generally have lower LLJ rates than the surrounding areas, evident in the large Swedish lakes Vänern and Vättern; the islands of Bornholm and Götland; the Warta, Noteć, and Vistula rivers in Poland; and urban centers around Berlin, Hamburg, and Warsaw, which all clearly stand out. Mountainous regions exhibit higher local spatial variation in LLJ rates. The parts of the North Sea furthest from shore, including Dogger Bank, show lower LLJ rates than most coastal areas.

The contrast in occurrence rates for the longer P_CLIM simulation against the rates of the 70 d periods for E_3DTKE (Fig. 9) points to some remaining skewness towards LLJ weather conditions in the 70 d sample. The higher rates of LLJ occurrence in the Baltic Sea are quite similar in the long and short simulations; however, the concentration in LLJ rates around Hamburg (especially north of the city) seems

less pronounced in the long WRF model simulation than in some of the ensemble ones. Instead, we see a more broad on-shore area with higher rates in the northern parts of central Europe.

Figure 12 shows that offshore LLJ occurrence rates exhibit strong seasonality, while rates over land remain more constant throughout the year. In spring, the Baltic Sea has a high prevalence (over 20%), especially southeast of Öland, extending from Denmark to the Bay of Finland. In summer, LLJ prevalence remains high in these areas, particularly south of Öland, with a slight reduction elsewhere. The seas east of the UK show high LLJ rates in spring and summer, notably in the Southern Bight and around Norfolk Banks and Silver Pit. Skagerrak also sees higher spring and summer LLJ concentrations than other parts of the North Sea and Kattegat. In fall and winter, offshore LLJ rates drop significantly

Figure 11. LLJ occurrence rates in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024.

(6 % or less). Onshore, LLJ rates stay close to the annual average (10 to 20 %), which is slightly higher in summer and fall over northern central Europe.

5.2 Annual and diurnal patterns

Figure 13 shows the most prevalent month of the year for LLJ occurrence. The figure reflects how seasonal offshore LLJs are, with rates peaking in May and June. Onshore, LLJ occurrences are not strongly seasonal. However, even though the onshore LLJ rate is fairly consistent throughout the seasons, one must expect that a seasonally varying mix of driving mechanisms is responsible for LLJ formation.

Figure 14 shows maps of the most prevalent hour of the day for LLJ occurrence in each season. Onshore, LLJ occurrence is highly tied to the time of the day, with peaks happening at night. In summer, the peak is around midnight, while the peak happens later in the early morning hours in other seasons. Offshore, in the spring and summer seasons, the most prevalent hours are not as significantly defined as onshore. However, some clear patterns still emerge. Along coastlines, the peaks in LLJ rates happen in the afternoon and early evening hours, with some clear temporal evolution with distance to shore, so further offshore corresponds with later LLJ peak hours (see, e.g., in the Baltic Sea and along the UK east coast). This is consistent with the peaks in the diurnal cycle shown in Svensson et al. (2019). Another pattern in the seasonal maps is that the peak occurrence in the middle of the North Sea occurs in the morning hours and not in the afternoon and evening as could be expected.

5.3 Mean core heights

Figure 15 shows maps of the mean LLJ core height for the four seasons. The heights are highest offshore in the fall and winter and furthest from the coast. The lowest mean heights happen in the spring and summer, especially along the coasts, where occurrence rates are also higher. In general, an inverse

relation exists between the LLJ rates and the LLJ heights. The seasonality in heights is much less pronounced onshore but is lowest in the summer across most of north-central Europe, the Baltic states, and Scandinavia. The underlying distributions of LLJ heights are slightly positively skewed, meaning the bulk of events take place below the mean but with a longer tail of higher LLJs. This underscores the fact that many of the LLJs happen at or below the typical hub height of large offshore turbines, especially along the coasts in the summertime.

5.4 Mean duration

The mean duration of LLJs is presented in Fig. 16 and shows that LLJs are often short-lived, typically lasting no more than a couple of hours. However, the offshore spring and summertime LLJs occurring in the Baltic Sea and along the east coast of the UK tend to last longer on average. The longest-lasting LLJs are seen in Southern Bight and the English Channel, where a few very long-lasting jets increase the mean duration. The distribution of LLJ duration is generally “short-heavy” in most places but with long tails of long-duration events of lower probabilities. In central Europe, a band of longer-duration LLJs appears in the fall and winter. Interestingly, an area of longer mean duration is present in winter offshore east of the Scottish mainland, possibly indicating some form of interaction between LLJ events and the inland terrain.

5.5 Jet magnitude and direction

In Fig. 17, we present the seasonal maps of the average relative wind speed fall-offs from detected LLJ cores to its minimum above (colors), with the circular average wind directions of the detected LLJ cores indicated by black arrows. Because the value of the surface roughness length strongly influences the fall-off and shear below the maximum, we use the fall-off above the maximum as a proxy for “LLJ

Figure 12. LLJ occurrence rates in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024 separated by season.

Figure 13. The most prevalent month of the year for LLJ occurrence in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024. Black lines and dots indicate that the month is respectively 50 % and 100 % more prevalent than the equal rate (1/12).

strength”. During fall and winter, the strong jets, in relative terms, appear close to geographic features, such as the Norwegian mountains (in Skagerrak), hills in southern Germany, and the Grampian Mountains in Scotland. The jet direction tends to follow the predominant wind direction in the fall and winter (mostly southwesterly flow). During spring and summer, the offshore coastal regions have the strongest relative fall-offs from the jet core to the minimum above, indicating the most intense LLJs. The directions of LLJ cores in these near-coastal offshore regions point parallel to the coast with the landmass to the left and the ocean to the right, which would be consistent with coastal LLJs formed in a low-level baroclinic zone driven by a land–sea temperature contrast, as shown, e.g., by Svensson et al. (2019). The prevalent directions match the wind roses observed during LLJ events at the four FLS sites well (Fig. 6); on average winds come

from the southeast south of Bornholm for LLJ situations and tend to come from east and southeast at the North Sea sites during spring and summer. The weakest fall-offs offshore are furthest from shore, for example in the middle of the North Sea.

5.6 Wind energy resources

The power capacity factor for the IEA-15MW is significantly higher in the windy fall and winter seasons (Fig. 18), while less energy is available in spring and summer. This makes LLJ events a large share of the total capacity in the latter two seasons, as is evident in Fig. 19, which shows the share of the total capacity happening during LLJ events in each season. This figure can be compared with Fig. 12, which shows the occurrence rate of LLJs, to see whether LLJs serve to lift the

Figure 14. The most prevalent hour of the day for LLJ occurrence in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024, separated by season. Black lines and dots indicate that the hour is respectively 50 % and 100 % more prevalent than the equal rate (1/24). Hours are in Coordinated Universal Time (UTC).

Figure 15. Mean height of LLJs in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024 separated by season.

capacity factor or not. From this, we see that LLJs are most important in increasing the capacity factor during the summer and spring (when the overall capacities are lowest). They are also an important source of energy during summer in central Europe. In mainland Denmark, LLJ does not play a big role in the total capacity, suggesting that LLJ events tend to happen during weather patterns associated with lower-than-usual wind speeds in this area.

6 Discussion

Our model evaluation shows large differences in the prevalence and characteristics of LLJs produced by the different WRF model ensemble members and reanalysis. The ERA5 captures too few LLJs (average underestimation of about 80 % at the sites), making meaningful statistical comparisons difficult. However, the results show that ERA5 does not capture the annual and diurnal cycles well, places the LLJs too high up, and does not resolve the shear and veer structure when compared to the observations. However, when a larger detection window up to 500 m is used, the large-scale rela-

Figure 16. Mean duration of LLJs in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024, separated by season.

Figure 17. Mean wind speed fall-off above the LLJ peak in the climatology (P_CLIM) from 26 June 2019 to 26 June 2024, separated by season. Black arrows indicate the (circular) mean direction of the jet cores.

tive spatial distribution of mean LLJ occurrence rates shows largely similar characteristics as the WRF ensemble members, suggesting that the relative spatial distribution of LLJs is well captured in ERA5. These findings agree with Kalverla et al. (2019), who assessed ERA5's ability to capture LLJs in the North Sea, showing that ERA5 tends to smear out the LLJs and place them too high up but captures a lot of the relative spatial–temporal variation. In their study, similarly to ours, higher LLJ rate of occurrences offshore in ERA5 were observed, particularly near the Southern Bight, on the UK east coast, and around Skagerrak.

Significant differences in LLJ simulation exist among WRF ensemble members. Across the five sites, the MYJ PBL scheme (E_MYJ) overestimates LLJ rates by 30 % on average, while the MYNN 2.5 scheme with “bl_mynn_mixlength=0” (E_MYNN_ML0) underestimates them by over 70%. Using “bl_mynn_mixlength=2” (E_MYNN) reduces the mean LLJ rate bias to approximately 15 %. These biases are more pronounced offshore, whereas onshore LLJ rates are more similar between models. The overestimation in MYJ may result from excessive atmospheric stability in the marine boundary layer, consis-

Figure 18. IEA 15MW capacity factor in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024, separated by season.

tent with prior findings of stable boundary layer overestimation onshore (Tastula et al., 2015).

E_MYNN_ML0 was included in the WRF ensemble due to its similarity to the setup used in NEWA (Hahmann et al., 2020; Dörenkämper et al., 2020). In contrast, E_MYNN represents the updated default scheme, designed to improve turbulent mixing length formulation for stable boundary layers (Olson et al., 2019), an improvement also supported by our findings. This suggests that the model setup used for the production of NEWA was not favorable to LLJ characterization.

The YSU PBL scheme (E_YSU) underestimated the LLJ rates but captured the distribution of LLJ heights well. Ex-

cessive lower-atmosphere momentum mixing in YSU has been linked to LLJ underestimation (Shin and Hong, 2011), as seen in the CASES-99 experiment (Poulos et al., 2002), where MYJ captured the LLJ better. However, other studies suggest that YSU underestimates LLJ height but captures the wind speed well (Kleczeck et al., 2014), a discrepancy likely due to differences in the surface layer scheme (Jimenez et al., 2012) used.

Refinements in model resolution show limited impact. Increasing horizontal resolution from 3 to 1 km or vertical levels from 85 to 125 within the MYNN scheme does not significantly improve LLJ accuracy. These results suggest that

parameterization choices, particularly within PBL schemes, play a more critical role in LLJ representation than grid resolution adjustments.

It is interesting to note that when choosing a WRF model configuration, standard evaluation metrics will select a different model configuration from what will be chosen when optimizing for LLJ occurrence and characteristics. The reasons for this are multiple and might be related not only to the PBL scheme's momentum in the vertical (Draxl et al., 2014) but also to the simulation of the interaction between the atmosphere and the surface where the conditions for LLJ formation develop. The investigation of such effects is, unfortunately, outside the scope of this paper.

The LLJ climatology highlights regions favorable to LLJ occurrence, especially in the Baltic Sea and along the UK east coast, the Strait of Dover, and the Dutch and German seas in spring and summer. As previously discussed, the spring and summertime LLJs in the Baltic Sea have been explained by the strong thermal contrasts between warm air over land and the colder sea surfaces persisting in those seasons (Smedman et al., 1996). This causes frictional decoupling at the coastline and results in an internal oscillation in space and the occurrence of a super-geostrophic jet (Blackadar, 1957; Smedman et al., 1995). Smedman et al. (1996) suggest that, with increasing travel time over the sea, the LLJs can sometimes transition from the Blackadar kind to inversion-capped LLJs in a neutral well-mixed boundary layer. The formation at the coastline and gradual transition with travel time over the sea may explain the elevated rates close to the coastlines and the tendency for LLJs to increase in height and “depth” with distance to the coast. The most prevalent hours in LLJ climatology (Fig. 14c) are also consistent with this, as the occurrence peaks happen in late afternoon hours but are gradually delayed with distance to shore. The strong thermal contrast in the spring and summer suggests some low-level baroclinicity, and sea breezes also play a role. So-called *corkscrew* sea breezes have a strong coastline-parallel component with land to the left in the Northern Hemisphere (Miller et al., 2003), implying higher pressure over the sea and lower over land. Corkscrew sea breezes are associated with coastal jets (Steele et al., 2015), making these situations more likely to occur in our LLJ detection algorithm. The averaged LLJ wind directions in the LLJ climatology show strong coastline-parallel components in wind directions in spring and summer, which could indicate the influence of corkscrew sea breezes. The Strait of Dover jet (Capon, 2003; Hunt et al., 2004; Steele et al., 2015) shows up clearly in the climatology, with peak occurrence in the summer. The most likely driving mechanism for the jet is land–sea roughness and temperature contrasts, the first causing convergence over land when the wind coming from the sea decelerates over higher surface roughness, resulting in an internal boundary layer and accelerated recirculation winds and subsidence over the sea, and the latter producing corkscrew sea breezes (Capon, 2003; Hunt et al., 2004;

Steele et al., 2015). Orographic channeling is not expected to play a major role (Capon, 2003), but there are some indications around the southern tip of Norway. In the LLJ climatology that we present here, the longest-lasting jets are found near the Strait of Dover in the summer, which is consistent with stronger ties to synoptic-scale weather conditions and wind directions than other coastal jets, e.g., in the Baltic Sea, which may be tied more strongly to the diurnal cycle.

One key challenge in LLJ studies is obtaining comparable LLJ rates across studies due to variations in spatiotemporal resolution and LLJ detection methods. Measurement resolution is constrained by instrument accuracy, averaging volume (in the case of remote sensing), and sampling rates, while reanalysis and mesoscale models are limited by their resolvable scales and post-processing methods, e.g., interpolation and resampling. The spatiotemporal resolution acts as an implicit filter for LLJs, while the detection method serves as an explicit filter. Both directly influence the characteristics of detected LLJs. Additionally, the vertical window used for detection significantly affects which LLJ samples are retained (Kalverla et al., 2019). In this study, the simulated LLJ climatology, using the best evaluated WRF model configuration, shows LLJ rates of $\approx 12\%$ at the Baltic measurement sites and $\approx 6\%$ for the North Sea and Østerild N sites using all model levels up 500 m. These rates are much greater than the observed rates (0.5 % to 2.1 %) due to the different windows used. See Appendix B for more on this. Consequently, we have mainly focused on relative rates and spatial patterns, rather than absolute rates, when presenting the climatology and comparing it to other studies.

7 Summary and conclusion

Offshore LLJs are complex flow features that represent an important wind resource, especially in specific parts of the North and Baltic seas. Understanding not just how they boost power generation but also their impact on wind farm reliability and wake losses via modulation of turbulence and wake dissipation remains an important area of study for future wind farm planning and development.

Herein, we have presented a validated high-resolution mesoscale LLJ climatology of the North Sea and southern Baltic Sea based on a 5-year simulation using an optimized configuration of the WRF model. The climatology is openly available (Olsen et al., 2024). To choose the best WRF configuration for LLJ modeling in the region, we evaluated nine different configurations, varying the PBL scheme, the vertical levels, horizontal grid spacing, and grid nudging. The evaluation is done by comparing the models against observations from FLSs and a mast at five sites, three in and near the North Sea and two in the Baltic Sea. The evaluation period is 70 individual days distributed throughout 1 year from December 2021 to December 2022. We use a modified version of the Baas et al. (2009) method for LLJ detection. In

the measurements, we detect about 3 times more LLJs at the Baltic Sea sites than in the North Sea area. Spring and summer are the most prevalent seasons, and nighttime, early morning, and afternoon hours were the most prevalent hours for the Østerild, NS1–2, and BS1–2 sites, respectively. LLJs lasted a few hours at most, with most only showing up in one 1 h sample. The mean height of detected LLJs varied from 104 to 121 m, but with many jets below 100 m. Wind during LLJ events comes mostly from easterly and southerly directions at NS1–2 and BS1–2 and from west and east at Østerild N.

Our model evaluation shows that using the ERA5 reanalysis for LLJ characterization is insufficient, hence the need for downscaling with the WRF model to generate the climatology. While several WRF ensemble members capture LLJ characteristics well at the sites, the member using the 3DTKE PBL scheme is ultimately chosen for the climatology because it captures most aspects of LLJ characteristics and occurrence rates well.

Our LLJ climatology highlights well-known areas favorable to LLJ occurrence, particularly the Baltic Sea, along the UK east coast, in the Strait of Dover, and Skagerrak. The novelty is the validated climatology covering a wide area used for wind energy development and the number and wide range of characteristics made available that help indicate the spatial variations in LLJ rates, seasonality, heights, durations, direction, levels, and heights, and magnitude of maximum shear.

Appendix A: Stability during observed LLJs

In our study, we present characteristics of LLJs in the observations. Here we further provide some evidence for the atmospheric conditions during LLJ events in our samples. Figure A1 shows distributions of hub-height wind speeds, air–sea temperature differences (at the offshore sites), and atmospheric stability classifications for all conditions and LLJ events. ERA5 data (nearest in time and space) provided temperature differences and stability classes, while wind speeds were measured directly. The stability classes are adapted from Gryning et al. (2007) and shown in Table A1.

The figure shows that LLJs typically occur at intermediate wind speeds, avoiding both the weakest and strongest winds. Offshore LLJs are linked to positive air–sea temperature differences (warm air over cold water) and stable atmospheric stratification. At Østerild N, LLJs also prefer stable conditions, though they can occur under neutral and unstable conditions as well. The strong tendency for LLJs to occur during stable conditions is evidence that frictional decoupling is the likely mechanism of formation, resulting in inertial oscillations in time or in space with a period of super-geostrophic winds.

Table A1. Stability classification based on Obukhov length adapted from Gryning et al. (2007).

Class	Obukhov length (L)
Very stable (vs)	$L \leq 50$
Stable (s)	$50 < L \leq 200$
Near-neutral stable (nns)	$200 < L \leq 500$
Neutral (n)	$L > 500, L < -500$
Near-neutral unstable (nnu)	$-500 \leq L < -200$
Unstable (u)	$-200 \leq L < -100$
Very unstable (vu)	$-100 \leq L$

Figure A1. Frequency distributions of wind speeds at 150 m (a–e), air–sea temperature difference (f–j), and atmospheric stability (k–o) at the five sites. The two distributions are for all samples (gray) and using the LLJ samples (orange). The air–sea temperature difference and the stability category come from the coincident (nearest in time and space to the measurements) ERA5 reanalysis data.

Appendix B: The sensitivity to the maximum height for LLJ detection

Expanding the vertical window for LLJ detection results in more jets being detected. To understand the sensitivity to the maximum height of detection, $z_{\max}$ in Fig. 2 of the main text, we repeatedly detected LLJs in the wind speed profiles of the observations and evaluated models for the 70 d evaluation period, varying $z_{\max}$ from near the surface, resulting in no LLJs being detected up to 500 m, which was the height we aimed to use for the climatology, but the observations only go up to 270 and 244 m so they are capped there. We used the native levels of each model but discarded any levels below 25 m to better align the lower height bound with the measurements.

Figure C1 displays the number of jets detected as $z_{\max}$ increased. It shows the strong sensitivity to the vertical window for the rate of LLJ detection. Taking just E_MYJ at BS2 for example, the rate is about 4 % at 200 m but more than 10 % at 300 m and grows to more than 20 % somewhere between 400 and 500 m. E_MYJ does have the steepest increase, but the measurements and other models also show a rapid increase with $z_{\max}$. The figure also reveals significant discrepancies among the models. ERA5 and the E_MYNN_ML0 model detect considerably fewer LLJs compared to the others, whereas E_MYJ detects substantially more, with a sharp increase in LLJ numbers as $z_{\max}$ rises, surpassing the increase indicated by the measurements. Overall, the E_3DTKE and E_MYNN models most closely align with the LLJ rates observed in the measurements. A minor

increase in the number of LLJs is observed across most models when the grid spacing is reduced from 3 to 1 km. However, the impact of changes in PBL schemes and the number of vertical levels is more pronounced than the effect of horizontal resolution in this context.

Appendix C: Evaluating LLJ detection thresholds

As described in Sect. 2.4, the selection of LLJ detection thresholds varies across studies, and there is no strong consensus. To understand the sensitivities to the thresholds in our study, we performed a sensitivity analysis with three levels of thresholds termed “weak”, “moderate”, and “strong” detection thresholds (Table C1). The moderate thresholds are our chosen thresholds in the main part of this paper. We evaluated the thresholds for the model ensemble for the same 70 d period as in Sect. 4, focusing on spatial Z-score-difference distributions between two threshold levels for the LLJ occurrence rates. We chose to focus on these differences because they indicate how stable the spatial variation of LLJ occurrence rates is to changing thresholds, providing a good indication of the generality of the spatial variations of our final WRF LLJ climatology. We analyzed the Z-score-difference histograms (Fig. C2) and standard deviation ($\sigma_{Z_{LLJ}}$) maps (Fig. C3) to define how sensitive a given model ensemble is to the threshold selection and what geographical areas are most sensitive. If the histogram kurtosis is higher (narrow distribution), the spatial variation of LLJ rates is robust to changes in the LLJ detection threshold. On the other hand, if

the histogram displays greater width (lower kurtosis), there will be larger differences in spatial variation with different thresholds used.

We refer to the baseline thresholds from Baas et al. (2009) as strong and analyze the relative differences in spatial variation to more moderate threshold levels that expand the subset of LLJ events to obtain more statistically robust results.

Table C1. LLJ detection thresholds: weak, moderate, and strong. Each threshold is defined based on the minimum fall-off both above and below the LLJ core in both absolute and relative terms.

Threshold	Fall-off	
	Absolute	Relative
Weak	1.0 ms ^{−1}	10 %
Moderate	1.5 ms ^{−1}	15 %
Strong	2.0 ms ^{−1}	20 %

that the differences manifest in largely ensemble-member-specific locations but tend to be around complex terrain (Norwegian mountains), where higher rates are produced (Baltic Sea and near Hamburg), and where the largest gradients of LLJ occurrence are in Fig. 10. The biggest differences are seen in the BL and ERA5 panels.

In conclusion, the spatial variation in the rate of LLJ occurrence is sensitive to the thresholds, and model-specific sensitivities should be expected.

Figure C1. Rates of LLJ detection with increasing maximum height used in detection using the native height levels of each observational or modeled dataset. For the modeled datasets, to bring the available vertical levels more in line with the observations, only levels above a height of 25 m were used here.

Figure C2 shows the Z-score-difference histograms for every model ensemble plus the NEWA and ERA5 datasets. Notably, the “moderate–strong” and “weak–moderate” histograms are very similar, indicating that similar differences arise for these two similar jumps in threshold magnitudes (0.5 ms^{−1} and 5 %). The “weak–strong” histograms are wider, showing that the spatial distribution of variations continues to change with threshold magnitude. The ensemble-member-specific results show that some members (e.g., all the MYNN-based members) have narrower distributions, indicating robustness to thresholds, while other members have wider distributions (E_MYJ, E_3DTKE, E_BL, and ERA5), indicating larger reconfiguration in the spatial variation with changing thresholds. The maps of $\sigma_{Z_{LLJ}}$ in Fig. C3 show

Figure C2. Z-score-difference histograms for three LLJ detection thresholds. The gray histograms show the weak–moderate differences, the orange histograms show the weak–strong differences, and the blue shows the moderate–strong differences. Panels (a) to (j) contain the WRF ensembles, and panels (k) and (l) contain the NEWA and ERA5 datasets, respectively.

Figure C3. Z-score standard deviation for three LLJ detection thresholds. (a–i, k) WRF ensemble members in Table 2, (j) NEWA, and (l) ERA5. The domains are slightly different for NEWA and ERA5 compared to the WRF domain used by the ensemble members. The black markers show the measurement sites.

Appendix D: Simulation days

The 70 d used for model evaluation were chosen based on two criteria: first, 47 d were selected because LLJs (at least 2 m s^{-1} and 20 % wind speed fall-offs between the maximum and the minima) occurred in the measurements at one or more of the sites during that day. Second, to balance the annual distribution, 23 additional days were selected randomly but stratified by month to obtain at least 5 d per month. Table D1 shows the number of days chosen based on each criterion.

Table D1. Number of simulation days per month in the selected sample for ensemble evaluation.

Month	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Total
LLJ	0	0	9	5	7	6	4	7	0	2	1	6	47
Extra	5	5	0	0	0	0	0	1	0	5	3	4	23
Total	5	5	9	5	7	6	5	7	5	5	5	6	70

Appendix E: The number of LLJs detected by each model

Figure E1 shows the total number of LLJs detected at each site for each model and in the observations during the 70 d evaluation period. The detected LLJs form the basis for distributions used in Fig. 8 and the associated evaluation in Sect. 4.3.

Figure E1. Number of detected LLJs at each site during the evaluation period in the observations and different models. For the WRF ensemble members in the sensitivity study (colors orange through teal as shown in the legend on the right), the light- and dark-colored bars show the counts for the 1 and the 3 km domains, respectively.

Appendix F: Additional insights from LLJ climatology

F1 Wind shear and veer above and below the jet core

Here we present additional layers from the LLJ climatology to show the spatial variations in the mean shear and veer above and below the LLJs. Figures F1 and F2 show maps of seasonal mean values of the maximum (absolute) wind speed shear ($\Delta U/\Delta z$) found between the LLJ core and the wind speed minimum below and the minimum (largest negative value) found between the core and the wind speed minimum above. Colors are scaled to show the variation for offshore regions. Onshore, the shear below the jet cores is dominated by the higher roughness relative to the sea. The maps show that winter and spring are especially associated with stronger shear over the Baltic Sea, while it tends to be slightly weaker in summer and fall. In the North Sea, the strongest shear below the jets occurs in winter and near geographic features and coastlines year-round. Above the jets, the strongest negative shear happens in spring and summer, particularly close to the UK east coast, the Netherlands, and south of Norway.

Figures F3 and F4 show the mean veer between the LLJ core and the wind speed minima below and above, respectively. The veer maps show similar trends as the shear shown above, with a higher mean veer below the jet core in spring and summer. For the veer above the jet core, the seasons and locations with stronger wind speed shear are associated with weaker mean veer, reducing the negative veer (backing) that is present most of the time. Thus, offshore LLJs are associated with a reduced veer above the jet core.

Figure F1. Mean of $\max\left(\frac{\Delta U}{\Delta z}\right)$ in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024, separated by season. Onshore, the shear is dominated by surface roughness effects, so these are grayed out to keep the focus on offshore locations.

Figure F2. Mean of $\min\left(\frac{\Delta U}{\Delta z}\right)$ in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024, separated by season.

Figure F3. Maps showing the mean in time of the mean veer between the wind speed minimum below the jet and the jet core in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024, separated by season. Onshore, the veer is dominated by surface roughness effects, so these are grayed out to keep the focus on offshore locations.

Figure F4. Maps showing the mean in time of the mean veer between the jet core and the wind speed minimum above in the WRF model climatology (P_CLIM) from 26 June 2019 to 26 June 2024, separated by season.

Figure F5. Locations of the three chosen sites to show distributions of selected LLJ characteristics.

Figure F6. Distributions at the three chosen sites of (a) $\min\left(\frac{\Delta U}{\Delta z}\right)$ above the jet core, (b) veer between the jet core and the wind speed minimum above, (c) jet height, (d) jet duration, (e) $\max\left(\frac{\Delta U}{\Delta z}\right)$ below the jet core, (f) veer between the jet core and the wind speed minimum below, and (g) jet speed.

F2 Distributions of LLJ characteristics in climatology at three offshore sites

The LLJ climatology presented shows large spatial and seasonal variations in LLJ occurrence rates, jet heights, jet duration, shear, and veer. To provide further insights, we present the distributions of several key LLJ characteristics for three offshore sites. The three sites, shown in Fig. F5, were selected due to their representativeness for some of the more extreme locations in one respect or another, related to LLJs. Öland south was selected for the high LLJ occurrence rate and to represent the Baltic Sea. The Southern Bight was chosen for its high LLJ occurrence rate and long-lasting jets. Finally, The North Sea site was selected to serve as a low-occurrence reference site in an active development region.

Figure F6 shows distributions of shear and veer above and below the jet core, as well as the jet height, duration, and wind speed. The figure shows that although all three sites have similar distributions across all the metrics, some notable differences can be seen. In particular, LLJs in the North Sea are placed higher up (a few tens of meters across the distribution), have slightly weaker shear and veer below the jet core, and have jets tending to last less time compared to the two other locations. The two sites Öland south and the Southern Bight have more similar distributions (compared with the North Sea), but jets last longer at the Southern Bight, showing more cases with very long-lasting jets.

Code availability. The WRF model is freely available via <https://doi.org/10.5065/1dfh-6p97> (Skamarock et al., 2019). The WRF v4.2.1 code, as well as the analysis code and data used to produce the results, are available on Zenodo: <https://doi.org/10.5281/zenodo.14354487> (Olsen et al., 2025).

Data availability. The LLJ climatological dataset is freely available <https://doi.org/10.5281/zenodo.13154214> (Olsen et al., 2024). The floating lidar system measurements were made available by EnergiNet. The ERA5 reanalysis data are available from the Copernicus Climate Change Service (C3S): complete ERA5 global atmospheric reanalysis at <https://doi.org/10.24381/cds.143582cf> (Hersbach et al., 2017). The NEWA mesoscale data can be downloaded from <https://map.neweuropeanwindatlas.eu/> (Dörenkämper et al., 2020). Freely available base maps from <https://www.naturalearthdata.com/downloads/> (Kelso and Patterson, 2010) were used for maps.

Author contributions. ANH and BTO planned and scoped out the study, with useful suggestions from MD and MZ. ANH set up the WRF model configuration and conducted the simulations. BTO pre-processed measurements and model data for analysis. BTO and NGA carried out the model evaluation. BTO created the LLJ climatological layers from the long-term WRF model simulations. All authors participated in the writing, editing, and internal reviews of the manuscript.
