Abstract

Short-term and decadal sea-ice prediction systems need a realistic initial state, generally obtained using ice-ocean model simulations with data assimilation. However, only sea-ice concentration and velocity data are currently assimilated. In this work, an Ensemble Kalman Filter system is used to assimilate observed ice concentration and freeboard (i.e. thickness of emerged sea ice) data into a global coupled ocean–sea-ice model. The impact and effectiveness of our data assimilation system is assessed in two steps: firstly, through the assimilation of synthetic data (i.e., model-generated data) and, secondly, through the assimilation of satellite data. While ice concentrations are available daily, freeboard data used in this study are only available during six one-month periods spread over 2005–2007. Our results show that the simulated Arctic and Antarctic sea-ice extents are improved by the assimilation of synthetic ice concentration data. Assimilation of synthetic ice freeboard data improves the simulated sea-ice thickness field. Using real ice concentration data enhances the model realism in both hemispheres. Assimilation of ice concentration data significantly improves the total hemispheric sea-ice extent all year long, especially in summer. Combining the assimilation of ice freeboard and concentration data leads to better ice thickness, but does not further improve the ice extent. Moreover, the improvements in sea-ice thickness due to the assimilation of ice freeboard remain visible well beyond the assimilation periods.

1 Introduction

Even if sea ice is an important component of the global climate system, it have been only observed since recent period. Sea ice observations are mainly limited to ice concentration, ice drift and, recently, to total sea-ice freeboard (height of the top of snow or sea ice above sea level, call hereafter ice freeboard) and thickness. Ice concentration and drift have been observed at large scale since the late 1970s, in both the Arctic and

Antarctic regions, using passive microwave sensors onboard satellites (e.g., Gloersen et al., 1992). Comparatively, ice thickness observations are much sparser, hampering a proper estimate of the ice volume. Originally, they stemmed only from upward looking sonar from submarines in the Arctic (Rothrock et al., 2008) and from ship-based visual observations in the Southern Ocean (Worby et al., 2008). The launch of the Ice, Cloud, and land Elevation Satellite (ICESat) in 2003 with laser altimeter system was therefore a valuable addition to the previous sea-ice observing capabilities. This satellite has shown potential for estimating ice freeboard which may, when combined with snow depth estimates, be used to retrieve sea-ice thickness (Kwok and Cunningham, 2008) in the Arctic. Measuring campaigns have been restricted to March–April and October–November (Kwok et al., 2007). However, sea-ice predictability is likely to reside partly in its thickness. Therefore, an accurate knowledge of the sea-ice thickness field is required to understand and predict the sea ice evolution, at least up to 3–5 yr (Blanchard-Wrigglesworth et al., 2011).

To complete the sketch outlined by the sea-ice observations, another source of information is provided by regional or global ocean–sea-ice general circulation models. These models produce consistent fields useful to document and to understand the mean state and variability of sea ice over the last few decades (e.g., Fichefet et al., 2003; Rothrock and Zhang, 2005). However, the ability of models to accurately simulate the variability as well as summer features of the ice cover remains limited (e.g., Massonnet et al., 2011).

Those model results and observations could be combined to improve sea-ice state estimates using data assimilation techniques. Those methods can be used for process studies or to obtain initial states for short-term and decadal predictions. Different data assimilation techniques have been applied to coupled ocean–sea-ice models, assimilating ice concentration (Lisaeter et al., 2003; Lindsay and Zhang, 2006) and drift (Stark et al., 2008) data in the Arctic. However, no attention has been paid to the Southern Ocean region and to ice freeboard data assimilation. Consequently, the main objective of this study is to discuss first the impact of sea-ice concentration data assimilation in

both hemispheres and, secondly, the interest of ice freeboard data assimilation. To do so, we have included an Ensemble Kalman Filter (EnKF) system in the global coupled ocean–sea-ice model NEMO-LIM2 (Madec, 2008). Since improving sea-ice drift does not have a significant impact on ice concentration (e.g., Stark et al., 2008), the ice drift is not assimilated here.

Section 2 describes the ocean–sea-ice model. Section 3 gives a brief overview of the EnKF method. Data used in this work are described in Sect. 4. In Sect. 5, we present what improvements can be expected with ice freeboard data assimilation by showing results of using synthetic (model-generated) data. In Sect. 6, the impact and benefit of real sea-ice concentration and ice freeboard data assimilation are discussed. Our conclusions are drawn in the final section.

2 Model description and validation

All the simulations analyzed in this study are performed with the global ocean modelling system NEMO¹ (Madec, 2008) including LIM2² (Fichefet and Morales Maqueda, 1997) as sea-ice component. This section briefly describes the model, the configuration and the atmospheric forcings.

2.1 Model setup

2.1.1 The ocean model

The ocean model is OPA³, a free surface, primitive equation ocean general circulation model. The grid, named ORCA2, is common to both ocean and sea-ice models. It has a nominal, nearly isotropic, horizontal resolution of 2° (110 km at 60° N and 90 km at the

¹NEMO = Nucleus for European Modelling of the Ocean

²LIM = Louvain-la-Neuve sea-Ice Model

³OPA = Ocean PARallélisé

North Pole). The vertical discretization includes 31 levels, with higher resolution near the surface (10 m) than below (500 m at 5500 m depth). Surface boundary layer mixing and interior vertical mixing are parameterized according to a turbulent kinetic energy closure model (see NEMO reference manual; Madec, 2008). The bottom boundary layer parametrization is based on Beckmann and Döscher (1997). More details can be found in the NEMO reference manual (Madec, 2008).

2.1.2 The sea-ice model

The sea-ice model is LIM2, a large-scale dynamic-thermodynamic model designed for climate studies. The thermodynamic component of LIM2 is the Semtner (1976) three-layer model. The temperature profile of the snow-ice system is computed by a one-dimensional heat diffusion equation, resolved using one snow layer and two sea-ice layers. Vertical snow and sea-ice growth and melt rates are derived from the energy budgets at the upper and lower interfaces of the snow-ice system. Open water is taken into account using ice concentration as a prognostic variable. Within the ice pack, heat budget allows computing ice growth in open water. Parameterizations of the most relevant sea-ice physical processes are included (brine pockets, lateral melting, effective heat conduction due to unresolved subgrid-scale ice thickness variations, surface albedo, penetration of radiation through the ice, snow ice formation). The velocity field is determined from a momentum balance considering sea ice as a two-dimensional viscous-plastic continuum in dynamical interaction with atmosphere and ocean (Hibler, 1979). More details on LIM2 can be found in Fichefet and Morales Maqueda (1997).

2.1.3 Forcing fields and initialization

Atmospheric forcing fields combine NCEP/NCAR daily reanalysis data of 10 m wind speed and 2 m temperature (Kalnay et al., 1996) with monthly climatologies of relative humidity (Trenberth et al., 1989), total cloudiness (Berliand and Strokina, 1980) and precipitation (Xie and Arkin, 1997). A quadratic bulk formula with a drag coefficient

of 1.4×10^{-3} is applied to compute the surface wind stress. The downwelling short-wave radiation, the net longwave radiation and the turbulent sensible and latent heat fluxes are computed following empirical parameterizations described in Goosse (1997). Evaporation/sublimation is derived from the latent heat flux. River runoff rates are prescribed from the climatological dataset of Baumgartner and Reichel (1975) combined with a mean seasonal cycle derived from the Global Runoff Data Centre data (GRDC, 2000). To avoid spurious model drift, a weak restoring of sea surface salinity towards the seasonal Polar Science Center Hydrographic Climatology (PHC; Steele et al., 2001) is applied. The time scale selected for salinity restoring is 1 yr.

The spin-up run (named REF), used to initialize all the assimilation experiments, covers the period 1960–2007. Initial conditions of temperature and salinity are based on the PHC climatology for REF simulation. Ice is assumed to be initially present where the sea surface temperature is below 0°C . Initial snow depth and ice thickness are 0.5 and 3 m in the Northern Hemisphere (NH) and 0.1 and 1 m in the Southern Hemisphere (SH).

2.2 Model performance without data assimilation

Figure 1 shows the simulated mean sea-ice thicknesses and compares the mean sea-ice extent in February and September to the corresponding observations from the Ocean and Sea Ice Satellite Application Facility (OSISAF, Eastwood et al., 2010), for both the NH and the SH over 1979–2005. Qualitatively, our results are close to simulations performed with an earlier version of the model (Timmermann et al., 2005).

2.2.1 Northern Hemisphere

The seasonal cycle of ice extent simulated by the model in the NH is rather close to the observed one (Fig. 1a, b). However, in September (Fig. 1a), the ice extent appears somewhat overestimated. Sea ice protrudes too far southwards in the Baffin Bay and in the Barents and Kara Seas. Furthermore, a comparison (not shown) with submarine

(Rothrock et al., 2008) and satellite ice thickness estimates (Kwok and Cunningham, 2008; Kwok et al., 2009) indicates that the model largely overestimates the sea-ice thickness by about ~ 2 m in the East Siberian Sea, in the Laptev Sea and in the Beaufort gyre and by about 0.5 m in the Kara Sea and near the North Pole. In the Canadian Basin, the ice thickness is overestimated by 0.5 m. As in Timmermann et al. (2005), the winter sea-ice thickness overestimation and the summer melting underestimation are related to each other. Note that the ice thickness overestimation in the Beaufort, East Siberian and Laptev Seas are also present in another recent study with another model, forcing and resolution (Uotila et al., 2012).

The modelled winter sea-ice thickness field in the Arctic (Fig. 1b) features a pronounced gradient from about ~ 2 m in the Western Siberian Sea to ~ 4 m at the North Pole and ~ 6 m along the Canadian Archipelago, in agreement with previous simulations with ORCA2-LIM2 (Timmermann et al., 2005) and with other modelling studies (Vancoppenolle et al., 2009; Hunke, 2010). Results of the model from Arctic Ocean Model Intercomparison Project (AOMIP) indicate also similar behaviour. Johnson et al. (2012) demonstrate that the models overestimate thickness of ice thinner than 2 m and underestimate the thickness of measured ice thicker than 2 m.

2.2.2 Southern Hemisphere

In the austral winter (Fig. 1c), the simulated sea-ice edge agrees relatively well with observations. Besides, the simulated summer minimum ice extent is too small around Antarctica (Fig. 1d). The sea ice does not extent far enough northwards along the eastern side of the Antarctic Peninsula and sea ice is absent in the model off East Antarctica.

The mean simulated Antarctic winter sea-ice thickness is 0.6 m. This value is close to the ASPeCt climatology (not shown), which stems from visual ship-based observations (Worby et al., 2008). In the Western Ross Sea, the ice thickness is smaller than the circumpolar average, which is consistent with observations in this sector (Jacobs and Comiso, 1989).

[Interactive Discussion](#)

In February (Fig. 1d), the opening of the Ross Sea is well reproduced by the model. A tongue of thick ice (maximum thickness about 1.5 m) is simulated from the Amundsen Sea to the Eastern Ross Sea, as in the ASPeCT climatology. Along the eastern side of the Antarctic Peninsula, the modelled ice thickness is greater than in the rest of the pack, as observed. Nonetheless, the ice thickness there appears underestimated by more than 2 m during both winter and summer, compared to both the ASPeCT climatology and satellite freeboard-based ice thickness estimates (Zwally et al., 2008). This is classically attributed to a poor representation of the cold barrier winds along the Antarctic Peninsula in the forcing fields (Timmermann et al., 2005; Vancoppenolle et al., 2009; Massonnet et al., 2011).

This brief overview has allowed to identify a number of shortcomings in the results of the control run conducted with the model, that are consistent with earlier studies. The discussion above demonstrates, however, that the model shows a sufficiently good agreement with the seasonal behaviour of sea-ice cover in both hemispheres to permit a sound study of the effect of sea-ice concentration and ice freeboard data assimilation.

3 The Ensemble Kalman Filter

The EnKF is a sequential data assimilation technique that approximates model error statistics by using an ensemble of model runs (Evensen, 1994, 2003). A fully non-linear model is used to propagate the model error statistics. Gaussian error distributions are however still assumed for the analysis as in Lisaeter et al. (2003, 2007). However, for many modelled variables, this hypothesis is not necessarily realistic, particularly in the case of sea ice.

As we apply a sequential data assimilation, each ensemble member is first propagated up to the next time data is available (once a day in our case). This is called the “forecast” step. Then, the data is used in the analysis step to correct the forecast by adding to it a term proportional to the misfit between observations and the forecast as

explained in Sect. 3.1. This ensemble of analyses is then again propagated forward in time until the next analysis step.

Our version of the EnKF is based on the code developed by the Nansen Environmental and Remote Sensing Center and, described in Burgers et al. (1998). We use a localized analysis presented in Sakov and Bertino (2010) to address limitations due to the relative smallness of our ensemble size (25 members) as compared with the size of the state space. This method reduces the spatial domain of influence of observations during the update. Without localized analysis, there are spurious correlations between distant and not physically connected state vector elements (e.g., Houtekamer and Mitchell, 2001; Keppenne and Rienecker, 2002; Anderson, 2007) due to the failure of an ensemble to adequately span the model sub-space (Oke et al., 2007). The chosen localization does not permit observational errors to be correlated. So, we assume independent observational errors.

The analysis update is calculated in the ensemble space (Hunt et al., 2007). Beside reducing the cost of the EnKF, this avoids scaling issues among different variables.

3.1 Formulation of the EnKF

The analysis step for a given member can be written as

$$\mathbf{x}_a = \mathbf{x}_f + \mathbf{K}(\mathbf{d} - \mathbf{H}\mathbf{x}_f) \quad (1)$$

The state vector $\mathbf{x} \in \mathbb{R}^{n \times 1}$ contains all the relevant variables (i.e., all two-dimensional and three-dimensional oceanic variables and all sea-ice variables except for sea-ice temperature and heat content) on all the grid points of the model. Heat content and sea-ice temperature are largely unlinear (L distribution, Lisaeter et al., 2003). An update of their fields by EnKF leads to unphysical behaviour (large melting/formation rate) during the first step of the forecast. Therefore, we decided to exclude these variables from the state vector. n is the dimension of the model state. \mathbf{x}_a is the analyzed state (after data assimilation), \mathbf{x}_f is the forecast state, while $\mathbf{d} \in \mathbb{R}^{p \times 1}$ is a vector containing

the p available observations at that time. The operator $\mathbf{H} \in \mathbb{R}^{p \times n}$ projects the model state into the observational space. This projection ranges from a simple interpolation onto the observational grid to complex transformations of the model variables to some observed quantity. \mathbf{K} is called the “Kalman gain matrix”:

$$\mathbf{K} = \mathbf{P}_f \mathbf{H}^T (\mathbf{H} \mathbf{P}_f \mathbf{H}^T + \mathbf{R})^{-1} \quad (2)$$

$\mathbf{R} \in \mathbb{R}^{p \times p}$ is the observation error covariance matrix. $\mathbf{P}_f \in \mathbb{R}^{n \times n}$ is the model forecast error covariance matrix. This matrix is too large to be computed explicitly in oceanographic applications. The EnKF approximates it by an ensemble of model states $\mathbf{E} \in \mathbb{R}^{n \times m}$, where m is the number of members in the ensemble. The ensemble of anomalies $\mathbf{A} \in \mathbb{R}^{n \times m}$ is defined as

$$\mathbf{A} = \mathbf{E} \left(\mathbf{I} - \frac{1}{m} \mathbf{1} \mathbf{1}^T \right) \quad (3)$$

where $\mathbf{1}$ is a vector with all elements equal to one and \mathbf{I} is the identity matrix. The approximated error covariance matrix \mathbf{P} is then

$$\mathbf{P} = \frac{1}{m-1} \mathbf{A} \mathbf{A}^T \quad (4)$$

Since the assimilation scheme is multivariate, both ocean and sea-ice variables are updated in the analysis step. As a Gaussian distribution of errors is assumed for sea-ice variables, this can lead to non physical states. Consequently, we verify that the sea-ice concentration and thickness as well as the snow thickness are non-negative everywhere (otherwise they are set equal to zero). Furthermore, we impose a maximum value of 1 for sea ice concentration. Also, note that the EnKF is not associated with any freshwater or salt flux towards the ocean. Thus, the EnKF could be a potential mass sink/source in the system. Finally, the sea surface temperature is constrained to be greater or equal to the freezing temperature.

3.2 Ensemble generation

Winds are particularly important for both the motion and surface heat of sea ice budget in both hemispheres (Watanabe and Hasumi, 2005; Bitz et al., 2002). Thus, to generate the ensemble of model states (25 members in our case), we have chosen to perturb only the wind forcing field. This ensures a wide enough dispersion of our ensemble.

3.2.1 Wind perturbation

To create a perturbed wind forcing field that is consistent with the spatial structure of the variability of observations, we have selected an approach based on the covariance of the data. We start by gathering samples of data (wind fields in our case) at discrete times. The samples should be sufficiently different so that we can assume the data is not correlated. The sampled data is arranged in a matrix $\mathbf{Y} \in \mathbb{R}^{m \times n}$, where m is the total number of samples and n is the size of each sample (also called the state vector). In the case of our two-dimensional wind field, n is $n_x \times n_y$, where n_x and n_y are the number of grid points along the x - or y -directions, respectively. We extracted the wind field every 11 days, starting on 6 January, over 1950 to 2008, inclusive. This gives us a total of $m = 1947$ atmospheric states that we assume to be independent of each other. As a next step, we find the mean state and subtract it from each row in \mathbf{Y} , thus creating the matrix of anomalies \mathbf{X} . The covariance matrix $\mathbf{\Sigma} \in \mathbb{R}^{n \times n}$ can directly be constructed using $\mathbf{X} \in \mathbb{R}^{m \times n}$ or – to save space and to speed up computations – using $\mathbf{R}_p \in \mathbb{R}^{m \times n}$ obtained from a **QR**-decomposition of $\mathbf{X} = \mathbf{Q}\mathbf{R}_p$, where $\mathbf{Q} \in \mathbb{R}^{m \times m}$ is an orthogonal matrix.

$$\mathbf{\Sigma} = \frac{1}{m} \mathbf{X}^T \mathbf{X} = \frac{1}{m} \mathbf{R}_p^T \mathbf{Q}^T \mathbf{Q} \mathbf{R}_p = \frac{1}{m} \mathbf{R}_p^T \mathbf{R}_p \quad (5)$$

Interactive Discussion

Therefore, a random perturbation $\boldsymbol{p} \in \mathbb{R}^{n \times 1}$ with the same covariance properties as the original data can be created as follows:

$$\boldsymbol{p} = \sqrt{\frac{1}{m}} \mathbf{R}_p^T \boldsymbol{z} \quad (6)$$

where each element of $\boldsymbol{z} \in \mathbb{R}^{m \times 1}$ is sampled from the normal distribution $\mathcal{N}(0, 1)$. To create a perturbed wind field state for a particular ensemble member on that day \boldsymbol{x}_p , one has to add the original wind field state \boldsymbol{x}_o to the perturbation \boldsymbol{p} to get $\boldsymbol{x}_p = \boldsymbol{x}_o + \boldsymbol{p}$. In our case, \boldsymbol{x}_o is the original wind field of a day and \boldsymbol{x}_p the perturbed wind field .

We computed separate covariance matrices \mathbf{R}_p for the zonal and meridional components of the wind field. Nevertheless, to create consistent wind field perturbations, we used the same perturbation vector \boldsymbol{z} for the two components. The scale factor \boldsymbol{p} selected here is 0.5. We did not assume any temporal correlation between the perturbations.

4 Description of the assimilated data

4.1 Synthetic observation data

In order to evaluate the potential of the EnKF data assimilation system in a controlled framework, we first assimilated synthetic sea-ice data. The synthetic dataset was extracted from a simulation with perturbed forcing, supposedly representing sea-ice observations. The snow, ice and water densities were taken equal to 330.0 kg m^{-3} , 915.1 kg m^{-3} and 1023.9 kg m^{-3} , respectively. Localization in time and space are the same as the real sea-ice data described in the next part. To ensure that the EnKF will correct the model ensemble when using real observations, the synthetic data have to be built in such a way that the bias between synthetic data and model output is similar to or larger than the bias between real observations and model output. So,

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[I◀](#)[▶I](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

the synthetic data have been built as for the REF simulation but with the DRAKKAR forcing set 4 (DFS4) described in Brodeau et al. (2010) instead of the NCEP/NCAR forcing set. The simulated ice extent and thickness are underestimated with the DFS4 atmospheric forcing in both hemisphere (not shown), thus the bias between the model ensemble and synthetic data are larger, in both hemispheres, than in the case where real sea-ice observation are used (comparison of green lines in Figs. 2 and 3).

4.2 Real observational data**4.2.1 Sea-ice concentration**

The sea-ice concentration data used in this study come from the OSISAF framework (Eastwood et al., 2010), which provides data and their uncertainties at daily frequency. OSISAF sea-ice concentrations derive from the multi-channel microwave brightness temperatures collected by two satellite instruments: the Scanning Multichannel Microwave Radiometer (SMMR) (1979–1987) and the Special Sensor Microwave/Imager (SSM/I)(1987–2007) (Gloersen et al., 1992; Cavalieri et al., 1997). The nominal resolution of this product is 12.5 km. To avoid indirect data, we excluded gap areas filled through extrapolation (missing orbit, missing scan lines and polar observation hole) as well as areas where a coastal correction is applied. For our analysis, to limit computational cost, data are interpolated on the model grid using a bilinear interpolation scheme.

4.2.2 Total sea-ice freeboard

The total sea-ice freeboard (called hereafter ice freeboard) is the sum of snow depth and sea ice freeboard. Ice thickness can be derived from it if snow depth and density are known. Kwok and Cunningham (2008) estimated the latter using Advanced Microwave Scanning Radiometer (AMSR) sea-ice motion fields, European Centre for Medium-Range Weather Forecasts (ECMWF) snow accumulation and a seasonal

climatology of snow density (Warren et al., 1999). As the determination of snow parameters carry substantial uncertainties, it is recommended to directly assimilate ice freeboard into the model.

Ice freeboard data used here are provided by the National Snow Ice Data Center (Yi and Zwally, 2010). Those are available only for the Arctic below 86° N. The data span six ICESat laser campaigns (see Table 1). Before calculating the ice freeboard, data with elevation varying more than plus or minus 4 m are not used. A zero ice freeboard is assigned to areas where ice concentration is less than 20%. This is an empirical limit to avoid the ice freeboard contamination introduced by open ocean water waves.

As for sea-ice concentration data, ice freeboard data are interpolated on the model grid each day. Uncertainties on ice freeboard data are assumed equal to the standard deviation of all data available in each model grid cell.

5 Impact of the assimilation of synthetic sea-ice data

In experiments with synthetic sea-ice data assimilation, all the components of the system are known in contrast to the real case in which only some observed variables are available. Furthermore, we know that the data are compatible with the model physics. As we have access to the full state vector, we can evaluate with those synthetic data the improvement brought by data assimilation of an observed variable such as ice concentration on an another one, namely ice volume for which adequate observations are missing. We take profit here of the advantages to assess the quality of the data assimilation procedure, the sensitivity of ice thickness to assimilation of ice concentration as well as the potential improvement due to the assimilation of ice freeboard.

5.1 Experimental setup

The assimilation experiments cover the period 2005–2007. An ensemble of 25 members were used. Each member was forced with a slightly different wind field (see

Interactive Discussion

Sect. 3.2). Initial conditions for each member were taken from the REF simulation. Assimilated data were the synthetic observations described in the previous section. The assimilation scheme was called each day.

Three experiments were performed (see Table 2):

- “FREE” where winds were perturbed but no data was assimilated;
- “IC” where sea-ice concentration data were assimilated;
- “FB” where both sea-ice concentration and ice freeboard data were assimilated.

All the discussion below is about the ensemble mean of each simulation.

5.2 Results

The FREE simulation shows, in comparison to synthetic observations, large discrepancies in Arctic sea-ice extent (up to 3 millions km² at the beginning of September, Fig. 2a) and volume (up to 12 000 km³ in August, Fig. 2b). In the SH, differences between synthetic observations and FREE are also large (Fig. 2). As expected, IC exhibits a sea-ice extent that is closer to synthetic observations than FREE. The Root Mean Squared Error (RMSE) of sea-ice extent decreases by 85 % in IC and FB in the NH, and by 87 % in the SH (Table 3). The RMSE of sea-ice volume also decreases in IC (by 66 % compared to FREE). As in the NH, both sea-ice extent and volume are close to the synthetic observations due to the assimilation procedure. The RMSE of sea-ice extent decreases by 85 % and the RMSE of sea-ice volume decreases by 87 %. These improvements in sea-ice extent and volume at the end of summer period are seen during all the simulated period (Fig. 2). The adjustment of the sea-ice volume ends after the first summer in both the NH and SH (Fig. 2). It is the time needed to transform the multiyear sea ice in FREE, which is seasonal in synthetic observations in seasonal sea-ice in FREE.

Assimilating both ice concentration and ice freeboard (FB simulation) does not further affect the ice extent (Table 3). This is due to the spatial coverage of ice freeboard

data, which do not reach the ice edge (data are automatically excluded if sea-ice concentration is lower than 20 %). However, the ice volume is improved in FB as compared with IC. The RMSE is decreased (as compared with FREE) by 71 % in FB, instead of 66 % in IC, at the beginning of October. It is worth noticing that the improvement due to ice freeboard assimilation in October–November and in March–April on sea-ice volume remain throughout the year (Fig. 2). The largest improvements are seen during the two first ice freeboard measurement campaigns (ON05 and FM06). These improvements are accompanied by some discontinuity (Fig. 2) clearly due to the lack of data during several months.

These results show that the data assimilation method brings the modelled ice extent and volume closer to the synthetic data than in the FREE run in both hemispheres (Fig. 2). The next part of this study examines if our conclusions remain valid when using real observations.

6 Impact of the assimilation of real sea-ice data

6.1 Experimental setup

Two simulations were carried out to highlight the utility of sea-ice concentration and ice freeboard data assimilation in the case where real observations are used: an experiment with assimilation of real sea-ice concentration data (IC) and a simulation with assimilation of both real sea-ice concentration and ice freeboard data (FB) (Table 2). The reference simulation (FREE) is the same as in the previous section. All these simulations cover the period 2005–2007. The model setup, the initial conditions, the forcing fields, the model parameters, the assimilation method, the ensemble size and the generation of the ensemble were the same as in the experiments conducted with synthetic data (Sect. 5). The only difference between the previous experiments and these ones are the type of data used. In the previous section, the data are synthetic observations, while here real sea-ice concentration and freeboard data are used.

6.2 Assimilation of real sea-ice concentration data

6.2.1 Northern Hemisphere

As expected, the impact of real data assimilation on sea-ice extent and volume are similar to those obtained with synthetic data. FREE overestimates the mean sea-ice extent, particularly during summer months (Fig. 4) along the Siberian coast and in Baffin Bay. Assimilation of ice concentration data reduces this bias (Figs. 4 and 3) for all seasons, but particularly in summer when the errors of FREE are the largest. During freeze-up, the sea-ice extent in both IC and FREE remain close to each other.

During the first months of 2005 (since May), the Arctic ice volume is similar in IC and FREE (Fig. 5). After the first summer, the sea-ice volume in IC is much lower than in FREE (Fig. 5). This is due to a lowered summer sea-ice extent in IC that induces a large substitution of multiyear sea ice (area cover by sea ice in summer, mainly composed of sea ice thickness greater than 2.50 m, Fig. 4) present in the Beaufort and East Siberian Seas in FREE by a seasonal sea ice (area covered by sea ice in winter and not in summer, mainly composed of sea-ice thickness lower than 2.50 m in winter) in IC (Fig. 4a). In October 2005, the total Arctic sea ice volume in IC is $5 \times 10^3 \text{ km}^3$ smaller than in FREE (40% of Arctic volume in FREE during summer). As compared with the sea-ice volume estimate from Kwok et al. (2009), after 10 months (end of the first summer in the simulations), IC is clearly better during summer (Fig. 5). This change of sea-ice concentration propagates into the multiyear ice. After three years of simulation, the whole sea-ice pack is affected (Fig. 6a, c). Areas where sea ice is seasonal in IC and multiyear in FREE show a lower sea-ice thickness in IC (ice thickness differences up to -2 m). In areas where sea ice is, in both simulations, multiyear (or seasonal), differences are lower in both winter and summer (up to -0.6 m).

Over all the pack and during both winter and summer (Figs. 5, 7 and 8), IC reduces the ice thickness overestimation seen in FREE. However, the decrease of ice thickness in IC is too strong along the ice edge. This is a sign that the model tends to underestimate ice thickness in summer and also to produce a too thin sea ice during the first

winter months on the Siberian side of the Arctic. Several hypotheses can explain this too low ice thickness near the ice edge during summer: either the atmosphere-ice heat flux as derived from the forcing fields is overestimated or the model representation of mass source and sink processes leads to excessive melting. During winter, sea ice in IC is too thick in the Beaufort Sea. In the rest of the sea-ice pack, sea-ice thickness in IC is very close to observations. However, the sharp sea-ice thickness gradient observed is much weaker north of the Canadian Archipelago in all the experiments.

These changes in sea-ice thickness and extent lead to changes in ice production. Thin ice supports stronger conductive heat fluxes than thick ice (Ebert and Curry, 1993; Maykut, 1986). Therefore, the model produces more sea ice in IC than in FREE (Fig. 9) in winter. During the melting period, the sea ice that is thinner in IC than in FREE disappears faster, further enhancing the melting rate because of a more efficient ice-albedo feedback.

As the FREE simulation overestimates the sea-ice extent and thickness during the melting period and in winter, the EnKF tends to keep the model in agreement with observations and to remove the excess of sea ice. However, between July and September, each year, the EnKF creates sea ice. This may seem surprising as FREE still has a too large ice extent at this time when the center of the pack begins to freeze, but the marginal sea-ice zone is still melting. The fact that the EnKF is producing ice means that the ice in the center of the pack does not consolidate fast enough in NEMO-LIM, maybe because of biases in the forcing or because of a too strong positive ice-albedo feedback during summer.

In the present model setup, the EnKF does not conserve oceanic salt in the model, since the ice-ocean freshwater flux associated with the ice growth/melt induced by the filter is not taken into account. Data assimilation leads thus to a net increase in oceanic salt content in IC, as compared to FREE (not shown).

6.2.2 Southern Hemisphere

In the Southern Ocean, FREE overestimates the winter ice extent, while in summer, the agreement with observations is quite good (Fig. 3). However, this agreement in summer is due to a compensation of errors in different regions (Fig. 4c, d). There is an excess of sea ice in the Ross Sea and along Dronning Maud Land Coast and a lack of sea ice at the tip of the Antarctic Peninsula, along the East Coast of Antarctica and in the Bellingshausen Sea in FREE. Assimilation of ice concentration data corrects all these biases. However, some problems persist. Area where ice concentrations are low (below 15%) are missing in both FREE and IC. Summer ice concentrations below 50% are almost absent. During freeze-up, the sea-ice extents of both IC and FREE are similar until the end of June. Afterwards, until the end of winter, IC is clearly more realistic than FREE (Fig. 3).

Sea-ice thickness differences between IC and FREE are large in both winter and summer (Fig. 10). During summer, the ice thickness differences correspond well to the differences in ice edge location (Fig. 4c). During winter, ice thickness is smaller in IC than in FREE almost everywhere (−30 cm), except in the Western Weddell Sea (+40 cm) and near Pridz Bay (+20 cm). Timmermann et al. (2004) in a similar model configuration had a lack of sea ice in these area. However, in the other locations, they found good agreement between the model results and the ASPeCT data (Worby et al., 2008). Therefore, the increase in ice thickness in the Weddell Sea (and Pridz Bay) improves the simulation. In the other areas, sea ice in IC is too thin.

6.3 Assimilation of sea-ice concentration and freeboard

To better constrain the ice thickness, we can also assimilate the ice freeboard in addition to the ice concentration. As shown in Sect. 5, assimilating both variables improves the representation of sea ice volume, as compared with assimilation of ice concentration alone. Ice freeboard data over 2005–2007 is cut into 6 campaigns (Table 1). Each

Interactive Discussion

data campaign does not contain the same number of daily data (interpolated on model grid), from 87 in MJ06 to 378 in MA06 (Fig. 11).

As ice freeboard is a combination of ice thickness and snow depth, the simulated ice freeboard could be realistic for bad reasons (error balance) and improvement on ice freeboard fields could result only from an increased realism of ice thickness or snow depth alone. The comparison of the model mean ice thickness over the Central Arctic (Fig. 11a) shows a large overestimation in all simulations (up to +2 m in FREE and +1.5 m in IC and FB) during winter campaigns and a reasonable agreement during summer campaigns in IC and FB (+25 cm). By contrast, the snow depth is underestimated in all seasons (Fig. 11b). The simulated snow depths are quite similar in IC and FB. Without data assimilation, snow thickness is greater in FREE: +5 % in fall and summer, up to +15 % compared to IC and FB in winter. A comparison between IC and FB indicates that the assimilation of ice freeboard data improves the sea-ice thickness and slightly degrade the snow field. Unexpectedly, overestimation of ice thickness and underestimation of snow depth in FREE lead to a quite realistic ice freeboard, while IC and FB simulate a ice freeboard too small (-5 cm) during fall and summer (Fig. 11c). However, during winter, IC and FB ice freeboards are much more realistic than FREE ice freeboards. The main reason is the large ice thickness error, which is not balanced by the snow depth underestimation.

The mean snow depth, ice thickness and freeboard in IC and FB are qualitatively close to each other. Furthermore, these simulations show the same large scale geographical distribution of ice thickness. However, during ON07, as for the MA07 campaign (Figs. 8, 7), ice is thinner in the centre of the Arctic Basin, by up to 70 cm near the North Pole (unobserved area due to satellite orbit) (Fig. 6b, d). The intrusion of thick sea ice in the Beaufort sea is also less pronounced in FB, which is more realistic.

In winter, sea ice volume in the Arctic Ocean (as defined by Kwok et al., 2009) is closer to observations in FB than in IC (Fig. 5). In fall, the FB ice volume is smaller than observed, while multiyear sea ice is better represented in FB (Fig. 8). This inconsistency is due to an error compensation in IC. In IC, the too thin sea ice close to the

ice edge during the minimum (new ice) is balanced by a thicker multiyear sea-ice in Beaufort gyre. As the new sea-ice close to the ice edge is almost not affected by ice freeboard data assimilation, this error balance is less important in FB.

7 Conclusions

5 The impact of sea-ice concentration and freeboard data assimilation using an Ensemble Kalman Filter is assessed in a global coupled ocean–sea-ice model. To do this, three types of experiments were carried out: one without data assimilation (referred to as FREE), one with ice concentration data assimilation (IC) and one with both ice concentration and freeboard data assimilation (FB). The simulations covered the entirety
10 of the globe, over 2005–2007, with a relatively low spatial resolution (2°).

First, data assimilation experiments using synthetic observations (from a reference simulation, which is considered as the truth) were conducted in order to evaluate the data assimilation system independently of model errors. Both synthetic ice concentrations and freeboards are assimilated each day. As expected, IC sea-ice extent fits very
15 well to synthetic data, in both hemispheres. Assimilating ice freeboard data has been shown to reduce differences in total ice volume, even with the relatively short temporal coverage of the data (February to April and October to November). Ice extent is similar in IC and FB.

20 The second step of the study was to assimilate in the model real data of ice concentration and freeboard. For sea ice concentration, the results are similar to those obtained in previous studies (e.g., Lisaeter et al., 2003). The errors between modelled and observed sea-ice extents are much larger in FREE than in IC in both hemispheres and in both summer and winter. Due to large sea-ice extent differences between IC and FREE, large differences of ice thickness are observed between IC and FREE after the first summer (more than 1 m along the Russian coast). After three years, these
25 discrepancies do not remain confined at the sea-ice edge but propagate to the whole sea-ice pack (about 50 cm over all the thick sea ice). Comparison with ice thickness

Interactive Discussion

reconstruction from ICESat reveals an improvement of the sea-ice thickness field in IC compared to FREE.

In order to improve the sea-ice thickness field, assimilation of sea-ice concentration data is completed by assimilating both sea-ice concentration and freeboard data.

Comparison with thickness fields available during the ICESat campaign indicates an improvement of the modelled sea-ice thickness and volume in FB as compared to IC. The overestimation of sea-ice thickness in the Beaufort gyre is decreased by 20 cm. However, the improvement on sea-ice volume comes with a worse snow cover and there is no effect on sea-ice extent. This improvement on sea-ice volume is minor compared to the ones obtained in IC as compared to FREE and only concern the Arctic region.

The experiments conducted in this study show that the methodology proposed is adequate to estimate sea-ice extent and volume. If the main error of the model is in the ice extent, the simulation with data assimilation reaches a new equilibrium state after the first summer both in Arctic and in Antarctic. About the assimilation of ice freeboard data, a limitation is the presence of discontinuities in the sea-ice volume during each winter campaign. Furthermore, data used to validate the method come from the same data set used for the assimilation step.

Global sea-ice data assimilation

P. Mathiot et al.

Table 3. Root mean squared error (RMSE) of sea-ice extent and volume between data assimilation experiments using the synthetic data and the synthetic observations themselves in the NH and SH, respectively, at the beginning of October and February. Between parentheses, the reduction of RMSE for each simulation (compared to the FREE simulation).

Experiment	October RMSE (NH)	February RMSE (SH)
Sea-ice extent ($\times 10^6$ km ²)		
FREE	1.51 (n.a.)	3.83 (n.a.)
IC	0.22 (–85 %)	0.51 (–87 %)
FB	0.22 (–85 %)	0.51 (–87 %)
Sea-ice volume ($\times 10^3$ km ³)		
FREE	10.44 (n.a.)	4.25 (n.a.)
IC	3.54 (–66 %)	0.49 (–88 %)
FB	3.54 (–71 %)	0.49 (–88 %)

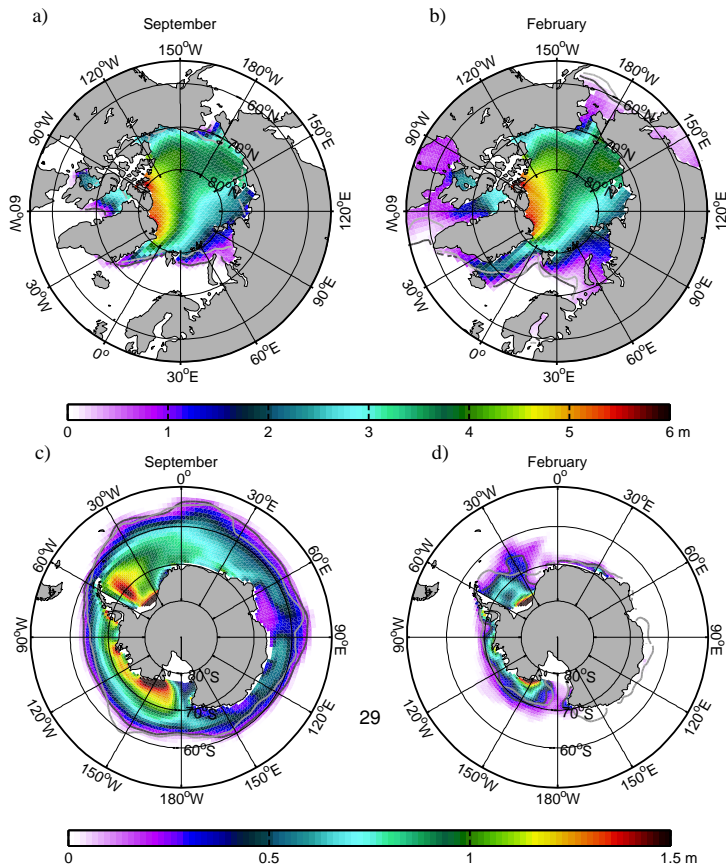

Fig. 1. Simulated mean sea-ice thickness (1979–2005) in September (**a, c**) and in February (**b, d**) in the NH (**a, b**) and SH (**c, d**). The dark and light grey lines correspond to the simulated and observed sea-ice edges (15% limit), respectively. Observation comes from OSISAF (Eastwood et al., 2010).

Global sea-ice data assimilation

P. Mathiot et al.

Fig. 2. Time series of the sea-ice extent **(a)** and volume **(b)** difference compared to synthetic observations for both the NH (full lines) and the SH (dashed lines) over 2005–2007. Green lines represent the FREE run difference, red lines the IC run difference, blue lines the FB run difference and black line the FB-IC difference. Grey shading areas indicate periods when the ice freeboard data are available.

Global sea-ice data assimilation

P. Mathiot et al.

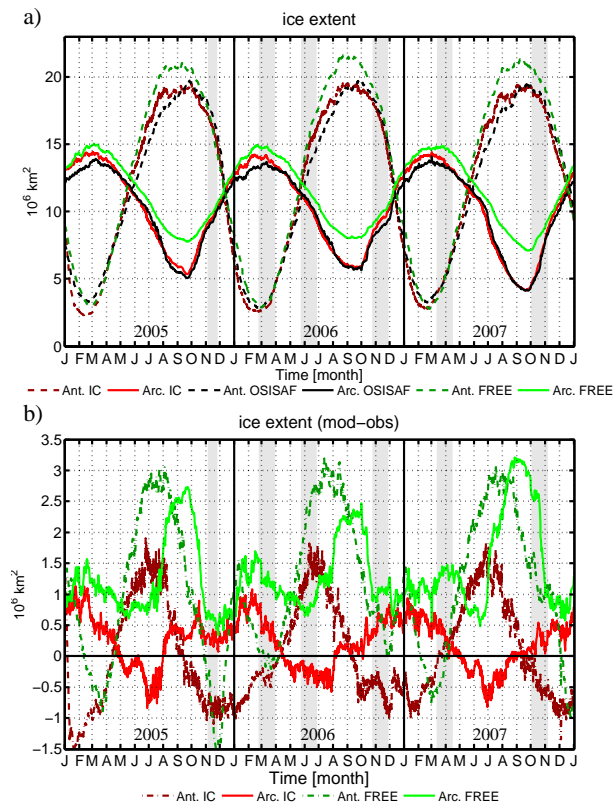

Fig. 3. Times series of sea-ice extent over 2005–2007 **(a)**. The observations are in black. The red lines correspond to the IC run and the green lines to the FREE run. The dashed lines are for the NH and the solid lines for the SH. **(b)** Differences between model and observations are plotted with the same codes. Grey shading areas indicate periods when the ice freeboard data are available.

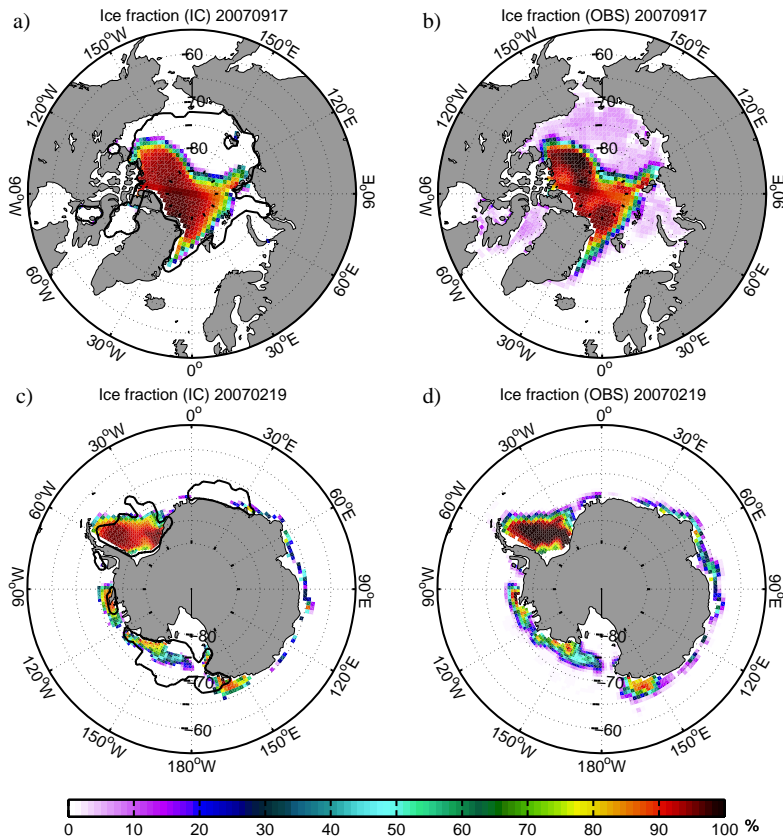

Fig. 4. Sea-ice concentrations during the minimum of sea-ice extent in 2007 in the NH (**a, b**) and SH (**c, d**). Colors show the sea-ice concentration in IC simulation (**a, c**) and in the OBS (**b, d**). The thick black line represents the sea-ice extent in the FREE simulation.

Global sea-ice data assimilation

P. Mathiot et al.

Fig. 5. Time series over 2005–2007 of the sea-ice volume in the Arctic Ocean for the FREE (green line), IC (red line) and FB (blue line) runs. Black lines are the mean sea-ice volume provided by Kwok et al. (2009). The two sea-ice volume estimates (model and obs) are on the domain used in Kwok et al. (2009) (i.e., the Arctic Ocean). Gray areas indicate the periods when ice freeboard data are available.

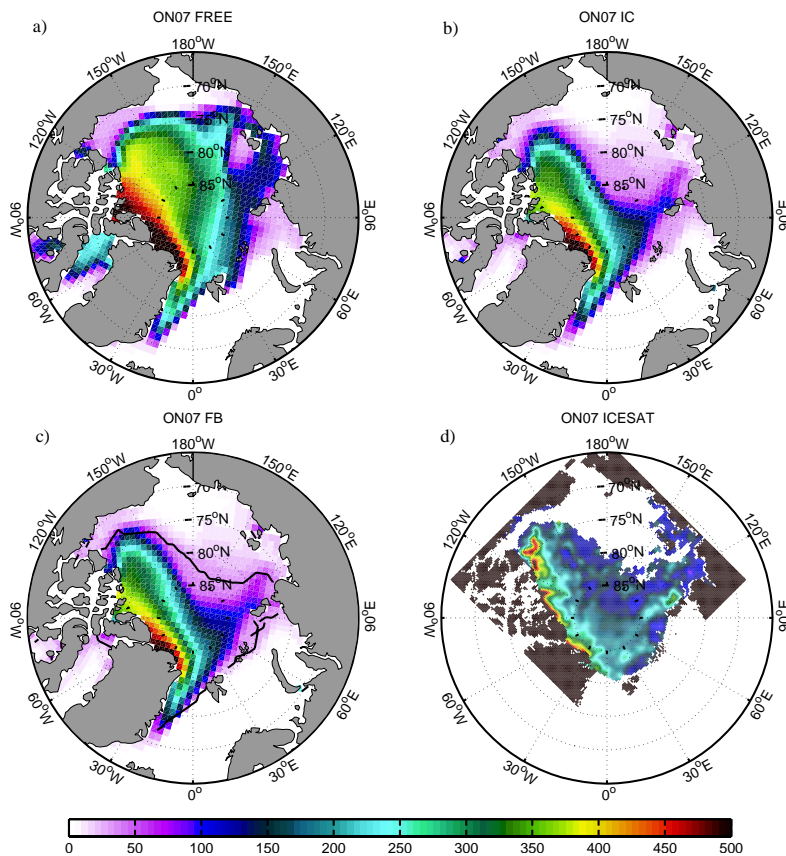

Fig. 8. Sea-ice thickness during the ON07 campaign in the FREE, IC and FB runs (a, b, c, respectively), and in the observations (Kwok et al., 2009). The black line corresponds to the sea-ice edge simulated in FB at the minimum extent (17 September 2007).

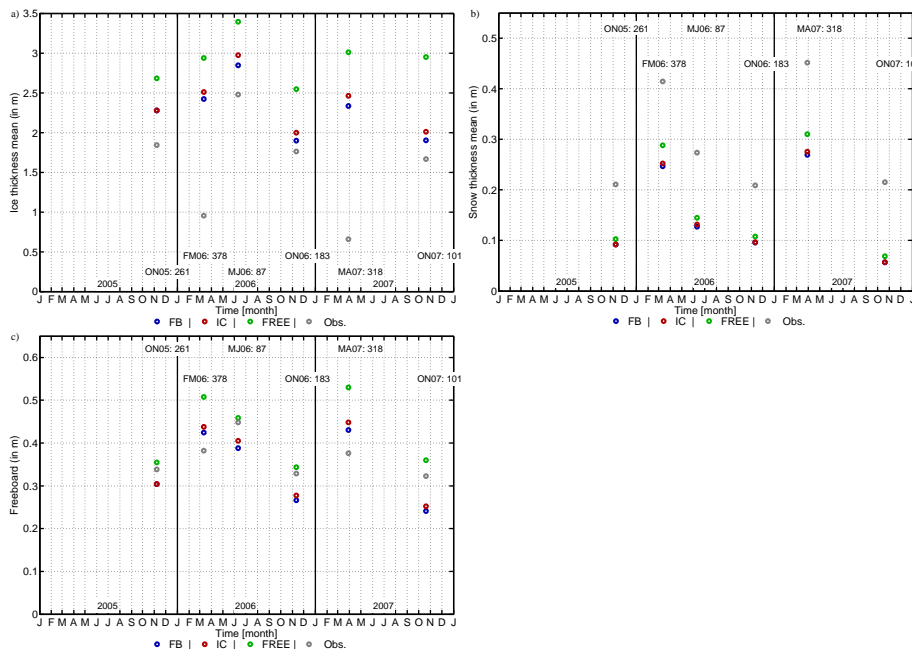

Fig. 11. Mean values of ice thickness **(a)**, snow depth **(b)** and ice freeboard **(c)** (green for FREE, red for IC and blue for FB) in the Central Arctic at the same locations as ICESat observations; observations are in light grey. Snow depth is extracted from ice freeboard data and sea-ice thickness (derived from ICESat freeboard Kwok and Cunningham, 2008). Snow density is assumed constant (330 kg m^{-3}). The numbers at the top of the plot are the mean number of data points available each day during the corresponding ICESat campaign.
