## Abstract

In this manuscript we describe the experimental procedure employed at the Alfred Wegener Institute in Germany in the preparation of the simulations for the Pliocene Model Intercomparison Project (PlioMIP). We present a description of the utilized community earth system models (COSMOS) and document the procedures which we applied to transfer the Pliocene Research, Interpretation and Synoptic Mapping Project (PRISM) mid-Pliocene reconstruction into model forcing fields. The model setup and spin-up procedure are described for both the paleo and preindustrial (PI) time-slices of PlioMIP experiments 1 and 2, and general results that depict the performance of our model setup for mid-Pliocene conditions are presented. The mid-Pliocene as simulated with our COSMOS-setup and PRISM boundary conditions is both warmer and wetter than the PI. The globally averaged annual mean surface air temperature in the mid-Pliocene standalone atmosphere (fully coupled atmosphere-ocean) simulation is 17.35 °C (17.82 °C), which implies a warming of 2.23 °C (3.40 °C) relative to the respective PI control simulation.

## 1 Introduction

General circulation models of the Earth system provide a suitable tool to understand past climates (e.g. Crowley and North, 1991). They are especially useful since they “can put numbers on ideas” (Ruddiman, 2008). Nowadays, general circulation models are commonly used for the development and testing of physical hypotheses on the quantitative function of the climate system (e.g. Jansen et al., 2007). Their application allows the investigation of the climate’s reaction to changes in boundary conditions, e.g. of orbital forcing and modifications in the distribution of ice sheets. This topic has been studied for the time-slices of the mid-Holocene and the Last Glacial Maximum within the framework of the Paleoclimate Modeling Intercomparison Project (PMIP, e.g. Joussaume and Taylor, 2000). Presently, the quantification of the amplitude

Interactive Discussion

of surface temperature change as a result of anthropogenic emission of infrared-active trace gases has become an important field of research in climate sciences: Simulations of climate scenarios for the IPCC with increased concentrations of atmospheric carbon dioxide are used to retrieve estimates of the changes in climate conditions, such as global mean temperature, that are to be expected in the future (e.g. Meehl et al., 2007). Particular focus is directed at the uncertainties in potential future temperature changes (e.g. Knutti et al., 2008).

The models are in a constant development process and have undergone major improvements since publication of the Intergovernmental Panel on Climate Change (IPCC) Third Assessment Report in 2001 (Randall et al., 2007). Since the design of the models is based on our knowledge about today's climate, it is of particular interest with respect to the investigation of a warming climate to test the climate models on their ability to simulate climate states that differ from present-day conditions. Such quality controls for the reliability of climate simulations have been established in the form of model-data-comparison studies (e.g. Lorenz et al., 2006) and model intercomparison projects (e.g. PMIP, Braconnot et al., 2007). The former type of study investigates whether models generally are capable of satisfactorily simulating the earth's climate. The latter address the question to which extent simulations carried out with different climate models are comparable.

A comparison of output from different climate models representative for the mid-Pliocene time-slice (3.29–2.97 Ma) is undertaken in the Pliocene Model Intercomparison Project (PlioMIP, Haywood et al., 2009, 2010, 2011). Standard climate models, that are widely used in climate research, are exposed to an extensive set of standardized boundary conditions of the mid-Pliocene, that have been retrieved within the framework of the Pliocene Research, Interpretation and Synoptic Mapping Project (PRISM, e.g. Dowsett et al., 1999). The mid-Pliocene is a geological epoch of the earth's recent history during which the continents have already arrived at their present positions, but prevailing climate conditions were still warmer than today. It therefore has been suggested as a potential past analog for future warmer-than-present climates (Jansen

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

et al., 2007), which makes it an ideal testbed for climate models in the context of a warming climate.

This manuscript describes the implementation of the PlioMIP experiments that have been conducted at the Paleoclimate Dynamics section at the Alfred Wegener Institute in Germany. In Sect. 2 we present a description of the utilized climate model, Sect. 3 provides an overview of the setup of both the standalone atmosphere (experiment 1) and coupled atmosphere-ocean (experiment 2) simulations. This background information serves as a prerequisite for the model intercomparison. General results retrieved from our simulations are presented in Sect. 4, and a brief discussion is given in Sect. 5.

## 2 Model description

The simulations described in this manuscript have been carried out using the community earth system models (COSMOS) which have been mainly developed by the Max Planck Institute for Meteorology (MPI) in Hamburg. Our version of COSMOS includes the ECHAM5 atmosphere model, the MPI-OM ocean model, and the land-vegetation model JSBACH.

### 2.1 The atmosphere model ECHAM5

The ECHAM5 model is described in detail by Roeckner et al. (2003). Based on their publication, we give here a summary of the model's properties that might be helpful in the model intercomparison.

ECHAM5 was adapted for climate research from the weather forecasting model of the European Centre for Medium-Range Weather Forecasts (ECMWF). The model is based on a spectral dynamical core and simulates the troposphere and the lower stratosphere up to a pressure level of 10 hPa. The vertical dimension is organized on a hybrid sigma-/pressure-level system. In our model setup we use ECHAM5 in T31/L19 resolution, i.e. there are 19 levels present and triangular truncation of the series of spherical

Interactive Discussion

harmonics is performed at wave number 31. The approximate horizontal resolution is  $3.75^\circ \times 3.75^\circ$ . The time step of the atmosphere simulation is 2400 s.

ECHAM5 uses a semi-implicit time scheme for solving the equations of divergence, surface pressure, and temperature, and a semi-Lagrangian scheme (Lin and Rood, 1996) for passive tracer transport. The model employs a mass flux scheme to simulate cumulus convection. Stratiform clouds are diagnosed by means of schemes for statistical cloud cover and microphysics, also the prognostic equations for water in the fluid, gas and solid phases are considered (Roeckner et al., 2003). The orography as the lower boundary condition for atmospheric circulation in the spectral domain is defined via the surface geopotential. This quantity is calculated from a global distribution of orography and is transformed into the spectral space. Subgrid-scale orographic effects are considered using a parameterization scheme, described by Lott and Miller (1997) and Lott (1999), that relies on the orographic parameters mean and standard deviation of elevation, slope, anisotropy and orientation, as well as the height of orographic peaks and valleys (Roeckner et al., 2003).

A high-resolution ( $0.5^\circ \times 0.5^\circ$ ) hydrological discharge model (HD-model), described in detail by Hagemann and Dümenil (1998a,b) and Hagemann and Gates (2003), closes the hydrological cycle. It simulates the translation and retention of land-bound lateral waterflows, which are separated into overland flow, base flow, and river flow. The sum over these quantities makes up the runoff at each grid cell (Hagemann and Dümenil, 1998b). The HD-model ensures that water flowing into water-sinks over land is redistributed to the ocean. Land ice sheets are not simulated but prescribed in our model setup. Therefore precipitation over glacier cells is transferred toward adjacent ocean points rather than being accumulated as ice volume. Data exchange between the coarse atmosphere grid and the high resolution HD-model is performed via an interpolation scheme.

ECHAM5 can be run standalone (PlioMIP experiment 1) or coupled to an ocean model (PlioMIP experiment 2). In standalone-mode the atmosphere is forced by climatological monthly means of sea surface temperature (SST) and sea ice concentration.

Energy input into the earth system via top of the atmosphere (TOA) insolation is calculated taking into account the prescribed orbital parameters eccentricity, obliquity, length of the perihelion, and the solar constant (e.g. Berger, 1978). The solar constant in our ECHAM5-setup is a fixed parameter. Its value is set to the standard preindustrial (PI) value of  $1365 \text{ W m}^{-2}$  if ECHAM5 runs standalone, and to  $1367 \text{ W m}^{-2}$  if the atmosphere is coupled to an ocean model. Calculation of radiative transfer toward the Earth's surface is performed considering vertical profiles of liquid and solid forms of water. Cloud-water and -ice as well as water vapor are prognostic variables of the atmospheric simulation, while the cloud cover is diagnosed (Roeckner et al., 2003). Adjustable trace gases include carbon dioxide, methane, nitrous dioxide, ozone, and chlorofluorocarbons. Aerosols are prescribed according to a climatology described by Tanré et al. (1984). For the calculation of the energy budget at the surface, the albedo of each grid cell is retrieved by a superposition of prescribed present-day soil albedo and contributions from snow and vegetation. The coupling between land surface and atmosphere is performed via an implicit scheme described by Schulz et al. (2001).

## 2.2 The land surface and vegetation model JSBACH

The JSBACH land surface and vegetation model, described by Raddatz et al. (2007), is an extension of the ECHAM5 model. It runs at the same horizontal resolution as the atmosphere model and inherits most of its boundary conditions, including a fixed soil-type distribution and corresponding water storage capacity. Albedo values in the infrared and visible parts of the spectrum are defined separately for soil and vegetation, which allows JSBACH to adjust the surface albedo in case of changes in the prescribed vegetation cover. The state of the land surface is initialized with global distributions of leaf area index, soil wetness, and snow cover taken from the setup of ECHAM5, as well as a surface temperature climatology. In JSBACH, the leaf area index is not a boundary condition but an output of the simulation of land surface conditions.

JSBACH differentiates thirteen different plant functional types (PFTs), of which eight have been in use for the model runs described here (Table 1). These include different

forms of deciduous and evergreen trees, shrubs and grasses. The model is capable of simulating dynamic changes in the vegetation distribution as a result of changes in ambient climatic conditions (Brovkin et al., 2009). A fixed vegetation distribution can be prescribed via the parameters land cover fraction (which defines the relative contribution of a PFT to the vegetated area) and the maximum vegetated cell area-fraction. In case the dynamic vegetation module of JSBACH is used, both fields are simulated rather than being prescribed.

### 2.3 The ocean model MPI-OM

MPI-OM is a hydrostatic, Boussinesq, free surface, primitive equation ocean and sea ice model (Marsland et al., 2003; Jungclaus et al., 2006). The model dynamics are solved on an Arakawa C-grid (Arakawa and Lamb, 1977). In our model setup, MPI-OM is formulated on a bipolar, orthogonal, curvilinear GR30/L40-grid with poles over Greenland and Antarctica (see Fig. 1). The advantage of this setup is an increased resolution at many deep water formation sites, which facilitates a more realistic simulation of the physical processes operating in these regions. The formal horizontal resolution is  $3.0^\circ \times 1.8^\circ$ , with the vertical dimension split into 40 unequally spaced z-coordinate model levels. Ocean bathymetry is resolved on partial grid cells (Marsland et al., 2003) and defined via a global dataset of ocean bottom depth. Flow near the bottom boundary is parameterized by a bottom boundary layer scheme in a similar way as described by Beckmann and Döscher (1997), Lohmann (1998), and Legutke and Maier-Reimer (2002). Eddy-induced mixing is parameterized following Gent et al. (1995). Furthermore an isopycnal diffusion scheme for subgridscale mixing is applied (Marsland et al., 2003). Overturning by convection is implemented via increased vertical diffusion (Jungclaus et al., 2006). MPI-OM includes a dynamic-thermodynamic sea ice model after Hibler (1979) that simulates the distribution and thickness of sea ice considering ambient climatic conditions.

The model is run at a time step of 8640 s, no flux adjustment is applied. Ocean and atmosphere are coupled via the Ocean-Atmosphere-Sea Ice-Soil OASIS3 coupler

(Valcke et al., 2003). One time per model day, OASIS3 performs an exchange of fluxes of energy, momentum and mass between the atmosphere and ocean model. Details of the coupling are described by Jungclaus et al. (2006).

## 2.4 Studies evaluating the climate as simulated with COSMOS components

5 ECHAM5 and MPI-OM have been extensively used in the context of climate and paleo-  
climate research, including simulations for the fourth assessment report of the IPCC. The performance of ECHAM5 and MPI-OM has been examined in various publica-  
tions. The mean ocean circulation and the tropical variability of MPI-OM coupled to  
the ECHAM5 atmosphere model is described by Jungclaus et al. (2006). Roeckner  
10 et al. (2006) investigated the sensitivity of the climate, as simulated with ECHAM5, to  
horizontal and vertical resolution. Wild and Roeckner (2006) described the radiative  
fluxes in the ECHAM5 atmosphere model, Hagemann et al. (2006) evaluated its hy-  
drological cycle. JSBACH has been described by Raddatz et al. (2007) in their study  
on the tropical land biosphere. Brovkin et al. (2009) investigated global biogeophysical  
15 interactions between forest and climate using the dynamic vegetation module. Other  
paleoclimatological studies that employed a COSMOS setup comparable to the one  
used for preparing the PlioMIP simulations are documented for the Holocene (Fischer  
and Jungclaus, 2010; Wei et al., 2012; Wei and Lohmann, 2012; Varma et al., 2012),  
Last Glacial Maximum (Zhang et al., 2012), and the Miocene (Knorr et al., 2011).

## 20 3 Experimental design

In this section we describe our experimental setup and the spin-up of the simula-  
tions of experiment 1 (standalone atmosphere simulation) and experiment 2 (coupled  
atmosphere-ocean simulation). In general, our experimental design follows the PlioMIP  
experimental guidelines (Haywood et al., 2010, 2011). The PI control simulation of

experiment 2 has also been used for PMIP Phase III (PMIP3). For experiment 1 it has been set up specifically for PlioMIP.

### 3.1 PI control simulations

In order to document our setup, we give here an overview on the boundary- and initial-conditions used for the PI control simulation of COSMOS.

Initial climatological snow cover in ECHAM5 is taken from an earlier atmosphere simulation. Soil data flags are prescribed using a data set of Gildea and Moore, described by Henderson-Sellers et al. (1986). Global datasets of soil wetness and the contribution of orography to surface roughness length originate from the ECMWF (United Kingdom). A data set of orography-related parameters, used in a parameterization scheme for the influence of subgrid-scale orographic effects on the surface roughness length, is described by Roeckner et al. (2003). The included parameters, standard deviation of orography, its orientation, slope, and anisotropy, have been derived from topographic gradients relationships (Baines and Palmer, 1990) applied to a highly-resolved present-day orography.

Other boundary conditions are taken from a collection of land surface parameters retrieved from a global distribution of major ecosystems (Hagemann et al., 1999; Hagemann, 2002). This data set includes global distributions of land ice, leaf area index, vegetation ratio, forest fraction, soil albedo, field capacity of soil, land-sea-distribution, and the contribution of vegetation to the surface roughness length. Climatological monthly means of SST and sea ice concentration, that force ECHAM5 in the absence of a coupled ocean model in experiment 1, have been taken from the Atmosphere Model Inter-comparison Project II. A description of the procedure by which these boundary conditions have been generated is given by Taylor et al. (2000). In the coupled atmosphere-ocean PI setup of COSMOS used in experiment 2, the ocean bathymetry and land-sea mask have been generated from the Earth Topography Five Minute Grid (ETOPO5, National Geophysical Data Center 1988; see Jungclaus et al., 2006).

C. Stepanek and  
G. Lohmann[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[I◀](#)[▶I](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

We prescribe uniform and constant volume mixing ratios of 280 ppm carbon dioxide, 270 ppb nitrous oxide, and 760 ppb methane; chlorofluorocarbons are considered to be absent. Height-latitude profiles of ozone are prescribed according to a climatology based on ozone observations (Paul et al., 1998). The solar constant is defined in the standard setup of COSMOS differently for standalone atmosphere and coupled atmosphere-ocean simulations. In experiment 1, the solar constant is set to  $1365 \text{ W m}^{-2}$ , in experiment 2 its value is  $1367 \text{ W m}^{-2}$ . For experiment 1 we perform a sensitivity study by prescribing  $1367 \text{ W m}^{-2}$  as in the coupled model and find only a minor influence on the global climatology (not shown). The Earth's orbit is prescribed by constant values of eccentricity (0.016724), obliquity ( $23.446^\circ$ ), and length of the perihelion ( $282.04^\circ$ ).

The vegetation in the PI control simulation of experiment 2 evolves freely as simulated by the dynamic vegetation module of JSBACH. For experiment 1 we prescribe a fixed PI vegetation retrieved from a 50-yr-average of an equilibrium vegetation distribution, generated by the dynamic vegetation module of JSBACH in a fully coupled atmosphere-ocean-vegetation simulation (Wei et al., 2012). This experimental procedure guarantees that an equilibrated (since fixed) vegetation is present during the comparably short integration time.

### 3.2 Mid-Pliocene simulations

The setup of the mid-Pliocene simulations of experiments 1 and 2 is based on the preferred mid-Pliocene data set. We preserve the land-sea-mask of the PI control simulations for the mid-Pliocene, with the exception of a closure of the Hudson Bay, and adjustments at the western Antarctic. The rationale behind this decision is that changes in the land-sea distribution of the mid-Pliocene with respect to present day are rather small and difficult to be implemented in the ocean model that runs on a rather coarse and irregular grid (Fig. 1). As a result of this approach, some areas in the western Antarctic are flat (0 m elevation) but still belong to the land surface. In the ocean model, we add at some locations in the Western Antarctic ocean points of a uniform depth

of 500 m to include some more features of the reconstructed land-sea mask. Ocean gateways present in the PI setup are unaltered in the mid-Pliocene simulation, i.e. the Central American Seaway and the Eastern Tethys Seaway are closed, the Bering Strait and the Drake Passage are open (Fig. 1a and b).

To generate a mid-Pliocene land-elevation we employ an anomaly method (e.g. Haywood et al., 2010): We calculate the difference between the mid-Pliocene elevation reconstruction (file topo\_v1.1.nc, Sohl et al., 2009) and the PRISM3 modern topography (modern\_topo.nc, Edwards, 1992). This mid-Pliocene elevation anomaly is interpolated to T31-resolution and added to the elevation of the PI control setup. At some locations, this procedure generates artifacts in the form of a resulting negative elevation over land. These artifacts are removed by prescribing at affected grid cells the mid-Pliocene elevation reconstruction rather than the elevation generated with the anomaly method. The actual topographic boundary condition of ECHAM5, the surface geopotential, is calculated by multiplying the gravitational acceleration ( $9.81 \text{ m s}^{-2}$ ) to the mid-Pliocene elevation, followed by a smoothing to the spectral domain.

The parameterization of the subgrid-scale orography of ECHAM5 is adjusted to ensure consistency with the modified mid-Pliocene elevation. For the PI setup of ECHAM5, the input parameters for the parameterization scheme have been retrieved using algorithms that rely on a highly resolved topography (see Sect. 3.1), which in general is not available from elevation reconstructions. We therefore interpolate the mid-Pliocene elevation of the atmosphere model to a higher resolution ( $0.5^\circ \times 0.5^\circ$ ) prior to calculation of the subgrid-scale orography parameters. It is inevitable, that the precision of the subgrid-scale orography parameterization is lower in the mid-Pliocene setup than in the PI setup.

As a boundary condition for the land-based mid-Pliocene cryosphere we extract the glacier distribution from the vegetation reconstruction (file biome\_veg\_v1.3.nc, Salzmann et al., 2008a,b; Hill et al., 2007) and interpolate it to T31-resolution. To generate the mid-Pliocene SST forcing for experiment 1 we subtract from the monthly mid-Pliocene reconstruction (file PRISM3\_SST\_v1.1.nc, Dowsett, 2007; Robinson et al.,

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

2008; Dowsett and Robinson, 2009; Dowsett et al., 2009) the modern SST distribution (file PRISM3\_modern\_SST.nc), interpolate the resulting mid-Pliocene SST anomaly to T31-resolution, and add it to the standard PI SST forcing of ECHAM5. At locations where the mid-Pliocene temperature reconstruction does not match to the ECHAM5 land-sea-mask, the SST reconstruction is extrapolated.

Mid-Pliocene sea ice forcing is generated considering the PRISM3 mid-Pliocene SST anomaly in T31-resolution and the PI ECHAM5 sea ice distribution. Our method assumes that at any location a warming of the PI ocean surface will fully remove the sea ice cover. We determine the sign of the mid-Pliocene SST anomaly, and at locations where this sign is positive we remove sea ice from the monthly PI sea ice forcing. By this method we retrieve a mid-Pliocene sea ice distribution that is consistent with the SST-forcing. The resulting Arctic Ocean is nearly ice-free in summer (Fig. 2a), maximum sea ice cover is found in January (Fig. 2b).

In order to generate the mid-Pliocene deep ocean temperature initialization, we add the anomaly between the ocean temperature reconstruction (file Global\_dot\_v2.0.nc, Dowsett et al., 2009) and the present day ocean temperature field (file lev\_94\_dec\_1.nc, Levitus and Boyer, 1994) to a PI ocean state of the MPI-OM model (Wei et al., 2012). The resulting mid-Pliocene ocean temperature is gridded on the native MPI-OM GR30/L40 resolution. For technical reasons, the gridding algorithm has to be applied on temperature data in  $1^\circ \times 1^\circ$  resolution with 33 layers. Therefore, two interpolation steps were necessary to generate the mid-Pliocene deep ocean temperature initialization – a first interpolation of mid-Pliocene ocean temperature anomalies and the PI temperature state of the MPI-OM model to  $1^\circ \times 1^\circ$  and 33 layers, and a subsequent interpolation to the GR30/L40 grid.

In the mid-Pliocene simulation of experiment 2 the HD-model is adjusted to the modified topography. This facilitates the fact that the hydrological cycle is closed, and that runoff to the ocean is simulated realistically. The mid-Pliocene  $0.5^\circ \times 0.5^\circ$  elevation of the HD-model is generated using a topography anomaly procedure that is similar to the one applied for ECHAM5 as described above, i.e. by adding the  $0.5^\circ \times 0.5^\circ$  interpolated

mid-Pliocene elevation anomaly to the PI elevation of the HD-model. The high resolution glacier mask is generated by  $0.5^\circ \times 0.5^\circ$  interpolation of the mid-Pliocene land ice distribution of the atmosphere model. The land-sea-mask is taken from the HD-model's PI setup and the Hudson Bay is closed manually. Mid-Pliocene land-sea-mask, elevation and glacier mask of the HD-model are used to calculate additional parameters. In Fig. 3a and b we show as an example the river direction data sets of the PI control and mid-Pliocene setup.

According to the PlioMIP protocol, a fixed vegetation-reconstruction has to be prescribed for mid-Pliocene simulations. In order to pin JSBACH to the vegetation reconstruction, its dynamic vegetation module is disabled. The standard PI vegetation is replaced by the mid-Pliocene vegetation reconstruction. Unfortunately, the treatment of vegetation in JSBACH is not directly comparable to the information provided by the PRISM3 reconstruction data set. Generation of the mid-Pliocene vegetation forcing therefore is performed in a two-step approach. First, we apply a calibration method to transform each PRISM3 biome into a form that is compatible to JSBACH. Second, we use this information to produce the global mid-Pliocene vegetation forcing for JSBACH.

In order to understand the calibration procedure, it is helpful to recite how vegetation is represented in JSBACH. Internally, vegetation cover is defined using a small number of PFTs (Table 1). The vegetation at a specific grid cell is defined by a set of two parameters: The first parameter defines the density of vegetation cover via the maximum vegetated fraction of a grid-cell, the second parameter provides information on the relative abundance of each PFT. For each grid cell of the land surface, the first parameter is a single rational number with a value in the range  $[0, 1]$ . Since at every grid-cell in principle several or even all of the eight PFTs may be present, the second parameter consists of a set of eight rational numbers in the range  $[0, 1]$  that add up to 1.

The calibration procedure relies on the assumption that modern observed biome distribution and PI control JSBACH vegetation cover are compatible and represent similar information. We generate global masks in T31-resolution that identify locations where a specific observed modern biome (file BAS\_Observ\_BIOME.nc) is present. These binary

masks are multiplied to a 50 yr-average PI vegetation cover as simulated by JSBACH (Wei et al., 2012). The intention is to retrieve a JSBACH vegetation distribution that corresponds to a specific biome. These vegetation distributions, consisting of relative PFT-abundances and vegetation densities for all locations that coincide with the location of a specific biome, are then averaged to retrieve a typical PFT-combination and vegetation density that represent this biome.

This biome representation is used in a second step to create the mid-Pliocene vegetation forcing: We interpolate the PRISM3 vegetation-reconstruction (file biome\_veg\_v1.3.nc, Salzmann et al., 2008a,b; Hill et al., 2007) to T31-resolution, and replace every biome by the corresponding PFT-combination and vegetation density. Land areas in our mid-Pliocene setup, that have no counterpart in the vegetation reconstruction due to small inconsistencies between the land-sea-masks, are initialized with vegetation parameters of a nearby location.

The resulting mid-Pliocene vegetation forcing is illustrated at the example of the density of grass- and forest-types. Forested areas are depicted for PI control (Fig. 4a) and mid-Pliocene (Fig. 4b), the grass cover is shown for PI control (Fig. 4c) and mid-Pliocene (Fig. 4d). The shown forest and grass fractions are calculated for each grid cell by summing over the contributing PFTs in the JSBACH vegetation forcing and weighting this value by the vegetation density. The forest fraction incorporates JSBACH PFTs 1, 2, 3 and 4, which comprise different types of forest. The grass fraction includes shrubs, tundra, C3, and C4 grasses, i.e. JSBACH PFTs 5, 6, 7 and 8 (Table 1).

It is evident, that the vegetation forcing is modified in the mid-Pliocene simulation especially over Greenland, Antarctica, northern Africa, and continental northern high-latitudes (Fig. 4). Throughout the latter, more forest emerges at the expense of the density of grass cover. On Greenland, both forest and grass vegetation are introduced as a result of the reduction of the prescribed ice-sheet. The loss of ice cover on Antarctica is balanced by the emergence of a grass-dominated vegetation. Grasslands are expanding over Europe, where forest becomes rarer. In northern Africa, both grass and forest cover are expanding towards the Mediterranean Sea, grass being the dominant

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

vegetation cover around the area of the present-day Sahara. In the southern part of Africa and the northern part of South America, forest cover decreases while the grass cover becomes more dense. On the Australian continent a displacement of the grass cover toward the south-west is evident, opposed by a north-eastward shift of the forest cover. In summary, the vegetation forcing for the mid-Pliocene simulation exhibits more grass cover than the PI control simulation, with the obvious exception of the continental northern high latitudes, where forest becomes more abundant.

Orbital and radiative forcing in the mid-Pliocene simulations are identical to the PI control setup with the exception of carbon dioxide. Its concentration has been changed to a uniform and constant volume mixing ratio of 405 ppm. This value is in agreement with paleo-reconstructions of carbon dioxide, which suggest for the Pliocene values between approximately 360 ppm (Kürschner et al., 1996) and 425 ppm (Raymo et al., 1996).

### 3.3 Model spin-up and calculation of climatologies

The simulations of experiment 1 are integrated for 50 model years, of which the first 20y are considered as a spin-up. It is evident that the atmosphere relaxes within a very short time of less than 10 yr after applying the modifications in climate forcing (Fig. 5a). Experimental climatologies for the PlioMIP project are retrieved by calculating the multi-year monthly average over the last 30 yr of the simulations.

Simulations of experiment 2 are integrated for  $\approx 1000$  model years, the last 30 yr of the time-integration are used for the calculation of experimental climatologies for the PlioMIP project. The initial ocean state for the PI control simulation is retrieved from a spin-up generated for the Millenium Experiment (Jungclaus et al., 2010), which has been integrated further for about 3000 yr in a standalone ocean simulation. Preparation of the initial ocean state for the mid-Pliocene simulation is described in Sect. 3.2. At the end of the mid-Pliocene simulation, the upper ocean is nearly in an equilibrium state, both with respect to temperature and salinity distribution. On the other hand the deep ocean at 2200 m still shows a drift (Fig. 5b). This suggests that the deep ocean in

our mid-Pliocene simulation is not completely adjusted to the model forcing. Previous paleoclimatic simulations with COSMOS show that in the given model configuration the deep ocean requires a simulation time of the order of 5000 yr for complete relaxation. Such long-term integrations are not feasible within the frame of our contribution to PlioMIP.

## 4 Results

In this section we present general results of our PI and mid-Pliocene simulations of PlioMIP experiments 1 and 2. We first give an overview of a selection of global and zonal average climatological parameters of the simulations, and discuss subsequently in more detail anomalies that result from the implementation of mid-Pliocene boundary conditions into our climate model.

### 4.1 Global averages and zonal profiles of general climatological parameters of the simulations

In Table 2 we present an overview on fundamental physical parameters that characterize the PI control and mid-Pliocene climates of experiments 1 and 2. The radiative balance of the simulations is illustrated by the TOA energy imbalance, i.e. the residuum that appears when summing over the TOA global average up- and downward radiation in the short- and longwave spectral bands. In experiment 2 there are residual net energy inputs into the climate system of slightly more than  $1.5 \text{ W m}^{-2}$  for PI control and mid-Pliocene. In experiment 1, the climate in the mid-Pliocene simulation appears to be slightly farther from radiative equilibrium with a persisting net energy gain of  $3.5 \text{ W m}^{-2}$ , while the PI control simulation shows a small TOA net energy export of  $\approx 0.4 \text{ W m}^{-2}$ . Since the atmosphere is well-equilibrated during the last 30 yr of experiment 1 (Fig. 5a), net energy fluxes are unlikely to be caused by remaining energy buffers in the model climate (like the deep ocean in experiment 2), but are presumably inherent features of

Interactive Discussion

the model forcing. The signs of the residual energy fluxes suggest that the prescribed SST is slightly too warm (too cold) in the PI control (mid-Pliocene) simulation of experiment 1 with respect to radiative equilibrium in ECHAM5.

The PI annual globally averaged precipitation amounts to  $P = 2.83 \text{ mm d}^{-1}$  in experiment 1 and  $P = 2.72 \text{ mm d}^{-1}$  in experiment 2. Annual globally averaged surface air temperatures  $T$  of the PI control simulations of experiment 1 and 2 are  $T = 15.12^\circ\text{C}$  and  $T = 14.42^\circ\text{C}$ , respectively. Jones et al. (1999) estimate from a global SAT database  $T = 14.0^\circ\text{C}$  for the period from 1961–1990. Our PI control climate therefore seems to be comparably warm. Since we are mainly interested in analyzing the differences between PI and mid-Pliocene simulations, we do not consider the potential deviation of our PI climate from an ideal reconstructed PI climatology to be of relevance for this study.

The mid-Pliocene simulations generally are warmer and wetter than the respective PI control simulations. Warming and intensification of precipitation are stronger in the coupled atmosphere-ocean setup of experiment 2. Here, we find  $\Delta T = 3.40^\circ\text{C}$  and  $\Delta P = 0.19 \text{ mm d}^{-1}$ , compared to  $\Delta T = 2.23^\circ\text{C}$  and  $\Delta P = 0.10 \text{ mm d}^{-1}$  in experiment 1. The amplitude of  $\Delta T$  that we observe in both experiments is in agreement with estimates from proxy records, which suggest a mid-Pliocene global temperature anomaly of about  $2^\circ\text{C}$  to  $3^\circ\text{C}$  with respect to PI (e.g. Jansen et al., 2007). The warming observed in our simulations exhibits a strong latitudinal dependency. The zonally averaged SAT anomaly over land is below  $\Delta T = 5^\circ\text{C}$  in low and mid-latitudes (where it is strongest in the coupled atmosphere-ocean simulation), but exceeds this value close to the poles. We observe an asymmetry between the Northern and Southern Hemisphere in that the warming is more pronounced in northern high-latitudes, where temperatures rise from  $-20^\circ\text{C}$  to well above  $-10^\circ\text{C}$  (Fig. 6a). Warming of ocean SAT behaves similarly, with the obvious exception that the amplitude is generally smaller than over land (Fig. 6b). Since warming is most pronounced in high-latitudes, the global meridional temperature gradient of both experiments is reduced in the mid-Pliocene. The smallest equator-pole temperature spread is observed in experiment 1 where SST is prescribed

and follows the reconstruction. The fully coupled atmosphere-ocean simulation cannot reproduce such a low meridional temperature gradient (Fig. 6c). A major cause is a comparably warm equatorial ocean, and a temperature regime in the northern North Atlantic Ocean and neighboring areas of the Arctic that is cooler than suggested by proxy reconstructions: This mismatch between simulated and reconstructed SST is evident from the zonal average temperature profiles of the mid-Pliocene simulations depicted in Fig. 6b. The temperature profile of the coupled simulation does not show the warm peak at around 65°N and the comparably low temperatures at low latitudes, which in the standalone atmosphere simulation are present due to the prescribed mid-Pliocene temperature reconstruction (Dowsett, 2007; Robinson et al., 2008; Dowsett and Robinson, 2009; Dowsett et al., 2009).

The hydrological cycle is enhanced in our mid-Pliocene simulations, especially in high-latitudes. In both experiments we find increased precipitation poleward of 50°N, which in experiment 2 is at the expense of precipitation in the subtropics at around 30°N and 30°S (Fig. 6d). The sign of anomalous tropical precipitation differs between experiments 1 and 2: in experiment 2 rainfall increases, especially north of the equator by about 1 mm d<sup>-1</sup>. In experiment 1 equatorial precipitation weakens.

## 4.2 Spatially and seasonally resolved mid-Pliocene anomalies of atmospheric quantities

A seasonally resolved consideration of global SAT anomaly maps for experiment 1 (Fig. 7) and experiment 2 (Fig. 8) allows us to identify regions and seasons where temperature is affected strongest by the implementation of mid-Pliocene forcing. The most pronounced annual average warming occurs in polar regions (Figs. 7a and 8a), especially over areas where strong changes of albedo and orography have been implemented, i.e. over Greenland and Antarctica. High-latitude warming is strongest in the respective local winter season (DJF (JJA) for the Northern (Southern) Hemisphere, Figs. 7b, c and 8b, c). Polar warming in the Northern Hemisphere is most pronounced in experiment 2, where temperature anomalies of more than 10°C extend over North-

America and Eurasia. Throughout the latter, the pronounced warming crosses 60° N in the center of the continent. Additionally the Weddell-Sea warms strongest in experiment 2. At some locations there is an obvious deviation of the simulated mid-Pliocene SST from proxy evidence. Strong temperature anomalies over the northern North Atlantic Ocean and the Nordic Seas, that are inherent to the forcing of experiment 1, cannot be reproduced by the fully coupled atmosphere-ocean simulation (compare Figs. 7b and c to Figs. 8b and c). Instead, a pronounced warming of more than 4 °C, that is absent in the temperature reconstruction, is simulated in the northern North Pacific Ocean. In general, regions where a slight cooling or a moderate warming of less than 2 °C is observed in experiment 1 are less common in experiment 2. This is evident over large parts of the ocean between 60° S and 30° N, and over land at the Rocky Mountains, the northern Andes, Africa, the Tibetan Plateau and Australia.

Spatially resolved anomalies of precipitation (i.e. the sum over convective and large scale rainfall) are shown in Fig. 9 and 10. We consider anomalies of the annual mean (Figs. 9a and 10a), boreal winter (DJF, Figs. 9b and 10b), and boreal summer (JJA, Figs. 9c and 10c). The high-latitude trend towards more precipitation observed in the precipitation profiles of the mid-Pliocene simulations (Fig. 6d) is evident in the summer and winter seasons and the annual mean. Over North-America we find a dipole of increased precipitation at the Rocky Mountains and reduced rain in the east of the land mass. This dipole structure is strongest in the winter season, and more pronounced if SST is prescribed. South-America receives less precipitation on average, but local summer rainfall increases in the northern part of the continent. Drying of the Tibetan Plateau occurs in particular in experiment 2. Precipitation over the equatorial Eastern Pacific Ocean, the Atlantic Ocean, and the Indian Ocean shifts northward. This effect is most pronounced in experiment 2 and explains the strong increase in rainfall north of the equator as depicted in Fig. 6d. The decrease in tropical precipitation, observed in experiment 1, is mainly located over the equatorial Atlantic Ocean, the Pacific Ocean, and especially the Indian Ocean.

## PlioMIP AWI

C. Stepanek and  
G. Lohmann[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

At some locations the treatment of SST (prescribed or simulated) seems to be critical with respect to mid-Pliocene precipitation anomaly. The strong year-long increase in precipitation over the northern North Atlantic Ocean in experiment 1 can only be reproduced for boreal winter in the fully coupled atmosphere-ocean simulation. A strong increase of rainfall over the North Pacific Ocean on the other hand is only observed in experiment 2. These differences in precipitation between experiments 1 and 2 coincide with temperature anomalies at respective locations. In experiment 2 a decrease of rainfall dominates in mid-latitudes of the Western Pacific Ocean, while precipitation increases at the equator. Under the influence of the mid-Pliocene SST-reconstruction in experiment 1, the dominant anomaly-pattern is an increase of rainfall over Australia and a decrease at the equator. In experiment 1, the landmasses of the Indian subcontinent and the Arabian Peninsula gain more precipitation, especially during the boreal summer season. In the fully coupled simulation of experiment 2 a general drying is observed at this location. This hints to differences in the behavior of the mid-Pliocene monsoon between experiments 1 and 2.

### 4.3 Mid-Pliocene anomalies of oceanic quantities

In the coupled atmosphere-ocean simulation of experiment 2 the sea surface can evolve freely according to the physics of our climate model. As a result, the SST of the mid-Pliocene simulation does not necessarily follow the reconstruction, which is clearly the case in our simulations as previously discussed. Global maps of absolute SST of the PI control and mid-Pliocene simulations show that in the mid-Pliocene the equatorial warm pools of the Atlantic Ocean, the Pacific Ocean, and the Indian Ocean have increased maximum temperatures and extent (compare Fig. 11a and b). Such a near-equator warming is not supported by the reconstruction (see Fig. 2). A plot of temperature anomalies between mid-Pliocene and PI control confirms observations of SAT that have been described above: In the Indian Ocean sector of the Southern Ocean a warming of more than 3°C is apparent. A substantial ocean surface warming occurs also in the North Atlantic Ocean and extends into the Norwegian Seas and the Barents

Sea (Fig. 11c). The Pacific Ocean warms especially in northern and western regions. Warming of the North Atlantic Ocean and adjoint regions is supported by the SST reconstruction, but comparably weak in our simulation. In the Eastern Pacific Ocean the warming is also smaller than expected. The simulated temperature increase in the North Pacific Ocean on the other hand seems to be stronger than reconstructed.

We observe a widespread retreat of sea ice in the mid-Pliocene simulation (Fig. 11). Especially in the Atlantic Ocean sector of the Southern Ocean, the Weddell-Sea, the Indian Sector of the Pacific Ocean, the Barents Sea, Kara Sea, Bering Sea, Chukchi Sea, and the Beaufort Sea a substantial loss of ice cover is evident (compare Fig. 11a and b). In the Pacific Ocean sector of the Southern Ocean the position of the sea ice border is rather unchanged, but the density of sea-ice is decreased. Large areas of the Arctic Ocean are still covered by sea ice, but its density is also substantially decreased with respect to the PI control simulation.

Ocean surface salinity in the PI control simulation is characterized by high concentrations in the Atlantic Ocean, especially in the mid-latitude evaporation regions, the Mediterranean Sea and the Red Sea. The Baltic Sea, the Hudson Bay, the North Pacific Ocean and the Arctic Ocean are comparably fresh. These general oceanographic patterns are also found in the mid-Pliocene simulation (compare Fig. 12a and b), but the contrast between high- and low-saline regions intensifies (Fig. 12c): salinity increases in the Mediterranean Sea and the Atlantic Ocean, while the Arctic Ocean and large parts of the Pacific Ocean freshen. An exception to this rule are regions in the western North Pacific Ocean, where salinity increases at an amplitude that is comparable to patterns found in the Atlantic Ocean.

Inflow of deep water from the South Atlantic Ocean is decreased under mid-Pliocene climate forcing, but the meridional overturning circulation of the upper branch is slightly enhanced in the mid-Pliocene Atlantic Ocean (compare Fig. 13a and b). The maximum of meridional volume transport extends, while the general structure of the Atlantic Ocean meridional overturning circulation (AMOC) is comparable to the PI control run. The globally integrated overturning circulation (GMOC) is more vigorous in the upper

Interactive Discussion

branch of the meridional flow regime of the mid-Pliocene simulation, while the lower branch is nearly in an off-mode (compare Fig. 14a and b). North of 20° N we calculate the Pacific Ocean meridional overturning circulation (which is not explicitly diagnosed in our simulations) by subtracting AMOC from GMOC. We observe that in the mid-Pliocene there is a small formation of intermediate water in the mid-latitude Pacific Ocean between 40° N and 60° N that is not present in the PI control simulation (compare Fig. 15a and b).

## 5 Discussion

In this section we discuss some aspects of the experimental methodology described in Sect. 3, and some of the results presented in Sect. 4.

### 5.1 Experimental methodology

The radiative forcing of experiment 2 differs slightly from the PlioMIP experimental protocol with respect to the value of the solar constant. As described above, the solar constant in our version of the ECHAM5 model is a fixed parameter. In standalone mode its value is set to  $1365 \text{ W m}^{-2}$ , if coupled to an ocean model it is slightly higher ( $1367 \text{ W m}^{-2}$ ). Since all other paleoclimate simulations conducted at our group rely on these standard ECHAM5 parameters, for the sake of comparability we also preserved them in the PlioMIP simulations. Our results of experiment 2 might therefore be based on a slightly different solar constant than those contributed by other PlioMIP groups. As a result of the different implementation of the solar constant, the TOA insolation differs between our experiments 1 and 2. We tested the influence of this difference on the annual global average SAT ( $T$ ) and precipitation ( $P$ ) by setting up a modified standalone atmosphere mid-Pliocene simulation with an increased solar constant ( $1367 \text{ W m}^{-2}$ ). All other settings were identical to our mid-Pliocene simulation of experiment 1. The anomalies  $\Delta T$  and  $\Delta P$  introduced by the change in the solar constant are negligible,

Printer-friendly Version

Interactive Discussion

the values of  $T$  and  $P$  of both mid-Pliocene simulations are identical if rounded to the second decimal place (not shown). We therefore conclude, that the general climatology of experiment 1 is not influenced appreciably by a small modification of the solar constant by  $2 \text{ W m}^{-2}$ , and that our experiments 1 and 2 therefore are comparable.

5 In the PRISM3 topographic boundary condition of the mid-Pliocene a global sea level rise of 25 m due to warming and the related reduction of land ice volume is prescribed (Haywood et al., 2010). Adjusting the land-sea-mask of the ocean model to this change involves an interpolation routine, which leads to strong and undesired alterations of the continental borders and gateways. In the mid-Pliocene simulations of our experiments  
10 we therefore neglected the change in land-sea-distribution resulting from a global sea-level rise, and preserved the PI land sea mask of both the atmosphere and ocean model. Exceptions are the closure of the Hudson Bay and modifications at the West Antarctic.

Another remark is related to the inclusion of mid-Pliocene vegetation into our land  
15 surface and vegetation model JSBACH. A direct transfer of biomes as present in the PRISM3 mid-Pliocene vegetation-reconstruction to JSBACH-PFTs is not possible. Therefore we devised a mapping procedure that has been described in Sect. 3.2. It involves a calibration of each biome to corresponding JSBACH PFT distributions and vegetation densities. Vegetation distributions simulated with the dynamic vegetation  
20 module of JSBACH are biased, in general the grass cover is rather dense on the expense of forest-types – this applies to both our PI control and mid-Pliocene simulations. Furthermore, the biome calibration needed for the mid-Pliocene simulation is performed by calculating one typical value of PFT distribution and vegetation density over a large area. As a result, our mid-Pliocene vegetation reconstruction lacks small  
25 scale variability and is biased towards grass cover. This fact should be kept in mind when comparing results taken from our simulations to those of other groups, who possibly devised other methods for implementing the vegetation reconstruction into their simulations.

For the generation of the mid-Pliocene sea ice forcing of experiment 1 we relied on a procedure in which we removed the PI sea ice cover at locations where the mid-Pliocene SST-reconstruction reports a warming (see Sect. 3.2). This procedure is in agreement with the generation of the mid-Pliocene SST-forcing which relies on temperature anomalies. It assumes that warming in the mid-Pliocene is strong enough to melt all the PI ice at a specific location. This assumption might be justified if an equilibrium climate state is concerned, which certainly is the case for our model forcing fields. An alternative way of generating a mid-Pliocene sea ice reconstruction could rely on the calculation of the lost ice volume under consideration of the amount of energy that is supplied by mid-Pliocene warming. Subtraction of the lost ice volume from the PI sea ice forcing in principle might lead to a different mid-Pliocene sea ice cover at locations where PI sea ice is thick enough to partly survive the heat excess. Unfortunately we do not have information on the thickness of the prescribed PI sea ice distribution (which is a mask that lacks information about the vertical dimension). As a first order approximation we therefore relied on the procedure which assumes an infinite energy supply (or alternatively vanishing ice-thickness). We also tested the equivalence of this approach to the alternative extraction of the sea ice cover directly from the mid-Pliocene temperature reconstruction (i.e. by assuming the presence of mid-Pliocene sea ice wherever the reconstructed SST is at the freezing point of sea water). The differences with respect to our approach are marginal.

## 5.2 Experimental results

When comparing the SAT anomalies of experiment 1 and 2 (Figs. 6, 7, 8), we observe for ocean areas in experiment 2 the lack of specific patterns that are present in experiment 1. Since experiment 1 is forced with the SST-reconstruction, and since local SST and SAT are closely coupled, we can conclude that differences in SAT anomaly-patterns between both experiments identify regions in which our coupled atmosphere-ocean setup is not able to reproduce the mid-Pliocene oceanography as it is interpreted from the geological record. Obvious examples are the North Atlantic Ocean, the south-

eastern Pacific Ocean, and the equatorial regions: our experiment 2 lacks the extreme warmth in the northern North Atlantic Ocean and the Nordic Seas, simulates too low temperatures in the south-eastern Pacific Ocean, and is generally too warm in the tropics. Generally in experiment 2 we are able to create a lower than PI meridional temperature spread. However, we cannot reproduce the low SAT gradient suggested by the mid-Pliocene SST reconstruction and inherent to experiment 1 (Dowsett, 2007; Robinson et al., 2008; Dowsett and Robinson, 2009; Dowsett et al., 2009, see Fig. 6b), which is about 5 °C smaller than our mid-Pliocene simulation of experiment 2. We therefore summarize that our experiment 2 fails to reproduce a number of ocean temperature patterns that are considered to be critical features of the mid-Pliocene, see e.g. Robinson (2009) for a discussion with respect to extreme warmth in the Arctic Ocean.

A model result in which the mid-Pliocene simulations of both experiments agree is the positive precipitation anomaly in high-latitudes, as evident from Fig. 6d. The increase in rainfall is most prominent in the Northern Hemisphere, where it amounts to approximately 0.5 mm d<sup>-1</sup>–1.0 mm d<sup>-1</sup>. The larger part of the excess precipitate is directly lost to the North Atlantic Ocean, but in both the local summer and winter season in experiments 1 and 2 (Figs. 9, 10) a certain amount ( $\approx 1$  mm d<sup>-1</sup> in experiment 2, up to  $\approx 2$  mm d<sup>-1</sup> in experiment 1) predominantly reaches the south-east of Greenland. In our mid-Pliocene setup, Greenland is therefore both wetter and warmer than the corresponding PI control simulations. The potential implications for the state and dynamics of the Greenland ice sheet, which has been prescribed in our simulations, is an interesting question that we will address in a future study.

Our analysis of the meridional overturning circulation in the Atlantic Ocean and the Pacific Ocean shows that under mid-Pliocene conditions our climate model simulates a slight increase in the AMOC with respect to the maximum transport at 1000 m depth, while inflow of deepwater from the South Atlantic Ocean is reduced. At the same time we find formation of a small amount of intermediate water between 50° N and 60° N in the Pacific Ocean. It will be interesting to see whether these details of ocean circulation can be confirmed by other simulations in the framework of PlioMIP. The mechanisms

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

behind the change in meridional volume transport, and the implications for the mid-Pliocene climate of the Northern Hemisphere, certainly deserve a deeper investigation which is beyond the scope of this manuscript.

## 6 Summary

5 We presented the layout of the PlioMIP simulations of experiments 1 and 2 that have been carried out at the Alfred Wegener Institute in Germany, using the Earth system model COSMOS. Our model setup consists of the atmosphere model ECHAM5, the land surface and vegetation model JSBACH, and the ocean model MPI-OM. In the fully coupled atmosphere-ocean simulation of experiment 2 the low-latitude SST, which is influenced by the increased atmospheric concentration of carbon dioxide, is overestimated with respect to experiment 1 and the proxy record. In particular in the Northern Hemisphere, the meridional temperature gradient is therefore larger in experiment 2. Our results suggest that the PI control and mid-Pliocene simulations are in (or close to) an equilibrium state, and that the climatology of atmosphere quantities (e.g. SAT), and presumably near-surface ocean quantities of the coupled atmosphere-ocean simulations, is stable. The TOA energy imbalance is small, i.e. about  $1.6 \text{ W m}^{-2}$  in experiment 2. It is largest in the mid-Pliocene simulation of experiment 1 ( $3.5 \text{ W m}^{-2}$ ). This shows that the energy balance in experiment 1 is not fully consistent with the prescribed SST and the atmosphere model. This is a common problem of uncoupled climate scenarios.

15 Our setup of experiment 2 shows several aspects of the Pliocene oceanographic details when compared to the PRISM3 mid-Pliocene SST-reconstruction (Dowsett, 2007; Robinson et al., 2008; Dowsett and Robinson, 2009; Dowsett et al., 2009), but there are obvious differences, e.g. with respect to tropical SST. A deeper analysis of the mechanisms behind the differences between our model results and the proxy record is beyond the scope of this study.

Despite problems with the reproduction of regional oceanographic features, we can in general reproduce a global mid-Pliocene climatology that is wetter and about 2–3 °C warmer than the PI control simulation, with a strong amplification of warming in high latitudes.

5 *Acknowledgements.* We would like to thank Ulrich Salzmann, Reiner Schnur, Thomas Raddatz and Christian Reick for useful discussions on the implementation of the mid-Pliocene vegetation reconstruction into our simulations. We acknowledge the help from Stefan Hagemann with the preparation of the adjustments of the HD-model for the mid-Pliocene setup, and thank Xu Zhang for making available the model output that has been used to retrieve the PI control climatologies  
10 of experiment 2. Christian Stepanek's work has been financed by a scholarship of the Helmholtz Graduate School for Polar and Marine Research (POLMAR).

C. Stepanek and  
G. Lohmann

**Table 2.** Major annual globally averaged climatological parameters of PI control and mid-Pliocene simulations for the last 30 model years of simulations: The TOA global energy imbalance has been calculated by averaging the sum of TOA downward shortwave radiation, TOA upward shortwave radiation, and TOA upward longwave radiation. Globally averaged SAT are given for the PI control and mid-Pliocene simulations of experiments 1 and 2 as absolute values, for the mid-Pliocene simulations the anomaly  $\Delta T$  with respect to the corresponding control simulation is given in brackets. Global average precipitation is given in units of  $\text{kg m}^{-2} \text{s}^{-1}$  (the internal unit in ECHAM5) and converted to  $\text{mm d}^{-1}$ .

simulation	TOA imbalance/ $\text{W m}^{-2}$	SAT ( $\Delta T$ )/ $^{\circ}\text{C}$	precipitation/ $\text{kg m}^{-2} \text{s}^{-1}$ ( $\text{mm d}^{-1}$ )
PI control experiment 1	−0.36	15.12	$3.28 \times 10^{-5}$ (2.83)
mid-Pliocene experiment 1	3.50	17.35 (2.23)	$3.39 \times 10^{-5}$ (2.93)
PI control experiment 2	1.72	14.42	$3.15 \times 10^{-5}$ (2.72)
mid-Pliocene experiment 2	1.61	17.82 (3.40)	$3.37 \times 10^{-5}$ (2.91)

## PlioMIP AWI

C. Stepanek and  
G. Lohmann

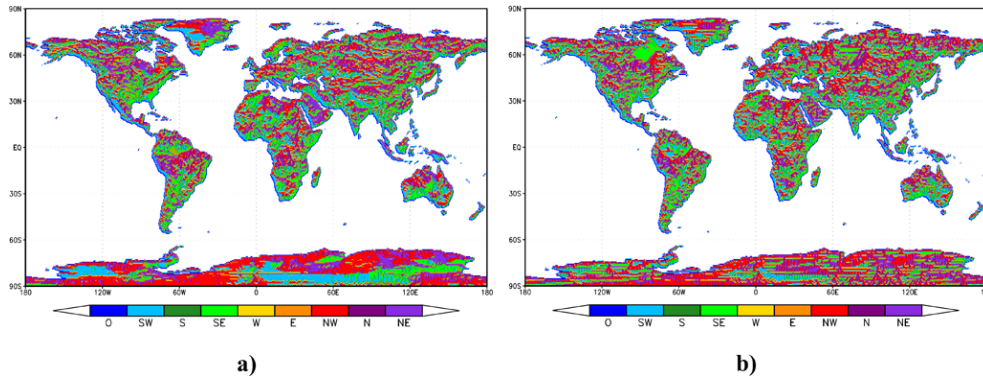

**Fig. 1.** Land-sea distribution on the ocean model grid as used in the PMIP3 PI control simulation **(a)** and the PlioMIP Pliocene simulation of experiment 2 **(b)**. There are two grid poles (white areas) which are located over Greenland and Antarctica. The nominal grid resolution of  $3^\circ \times 1.8^\circ$  of the  $122 \times 101$  grid varies, it is high in polar regions and highest around Greenland. Both land-sea distributions are identical with the exception of the closure of the Hudson Bay and modifications in the West Antarctic in the case of the mid-Pliocene experiment. For clarity, only every second grid line is shown in the graph.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

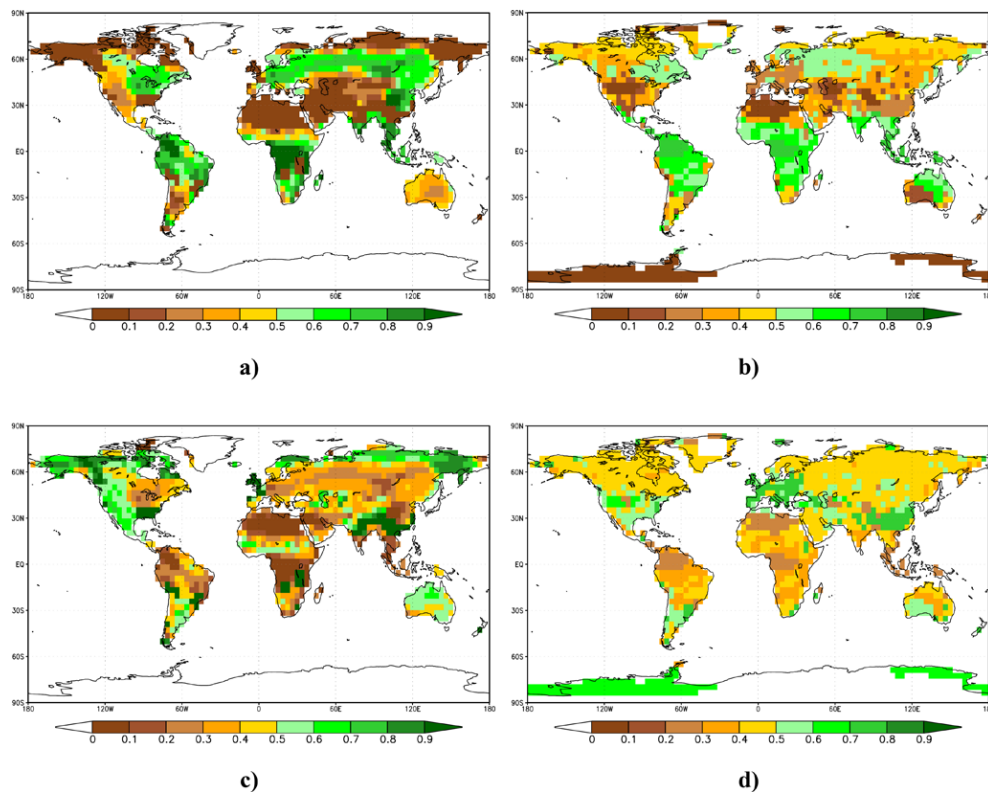

**Fig. 2.** Anomaly between the climatological SST forcings of the mid-Pliocene and PI control simulations of experiment 1 in units of  $^{\circ}\text{C}$ . The grey contours indicate the 90%-isoline of the absolute sea ice cover prescribed for the mid-Pliocene simulation. Shown are the forcings for the months January **(a)** and August **(b)**.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[I◀](#)[▶I](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

**Fig. 3.** River directions in the hydrological model of ECHAM5 ( $0.5^\circ \times 0.5^\circ$ ) for PI control **(a)** and adjusted to Pliocene topography **(b)**. The colors indicate the flow direction at each grid point, ocean is indicated by white. In addition to the four main and diagonal directions, dark blue (O) marks grid cells where the water flow is directly into the ocean (coastal gridpoints).

**Fig. 5. (a)** Evolution of yearly average 2m-temperature in experiment 1. The atmosphere adjusts to the change in climate forcing very fast (cf. the inset that shows a monthly resolved time series of the first 10 simulation years), and reaches an equilibrium state in less than ten years. **(b)** Annual mean North Atlantic Ocean temperature and salinity at 700 m and 2200m in the mid-Pliocene simulation of experiment 2. Starting point of the simulation is a temperature-adjusted PI control state at year 800 of the model time axis (see text for details). Output from model years 600 and 749 is missing, as indicated by the straight progression of the graph.

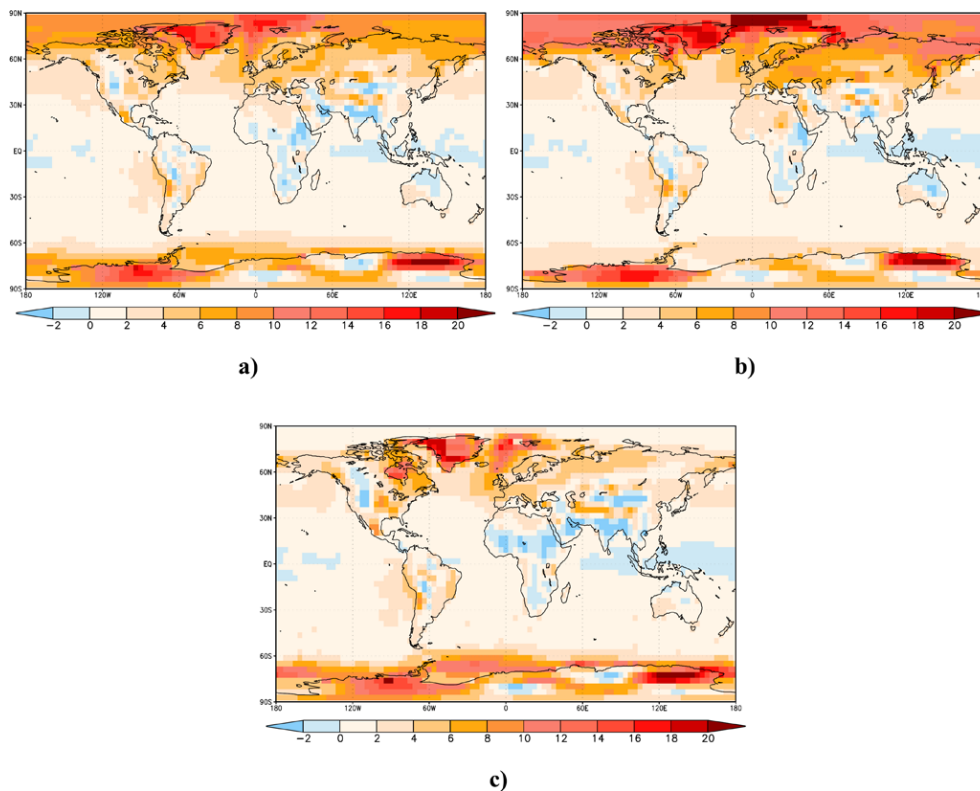

**Fig. 6.** Zonal averages of surface-air temperature in °C for land-areas **(a)**, oceans **(b)**, and land and ocean **(c)**. Shown are absolute values for the PI control and mid-Pliocene simulations of experiments 1 and 2, as well as the respective anomalies. Zonal averages of precipitation for land and ocean **(d)**. All temperatures have been retrieved from a 30 yr climatology.

**Fig. 11.** Annual mean SST in  $^{\circ}\text{C}$  in experiment 2 for the PI control simulation **(a)**, the mid-Pliocene simulation **(b)**, and the anomaly between mid-Pliocene and PI control **(c)**. The expansion of the equatorial warm pool is indicated by the bold grey  $28.5^{\circ}\text{C}$ -isoline **(a,b)**. In addition to the SST fields, we show in **(a,b)** thin grey isolines depicting the absolute values of fractional sea ice cover. The percentage of PI sea ice cover that is still available at a specific location in the mid-Pliocene simulation is indicated by thin grey isolines in **(c)**. All values represent time averages calculated from a 30 yr climatology that has been interpolated to a regular  $360^{\circ} \times 180^{\circ}$  grid.

**Fig. 12.** Annual mean sea surface salinity in psu in experiment 2, calculated from a 30 yr climatology that has been interpolated to a regular  $360^\circ \times 180^\circ$  grid. Shown are the PI control simulation (a), the mid-Pliocene simulation (b), as well as the anomaly between mid-Pliocene and PI control (c).

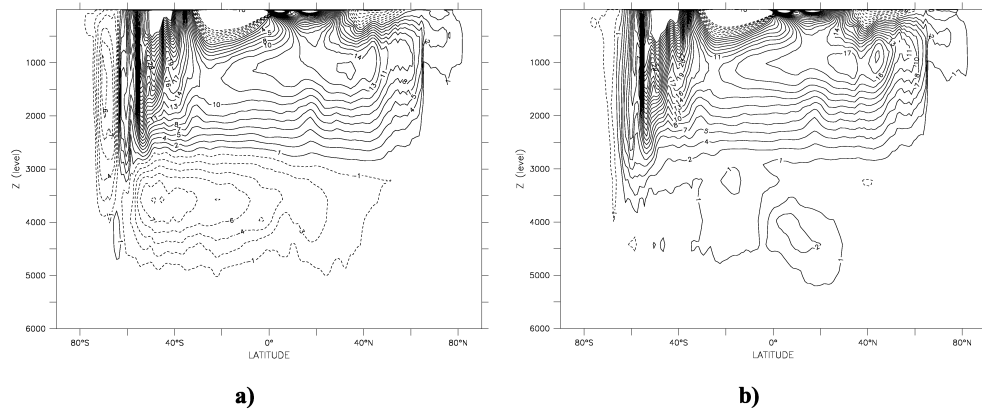

**Fig. 13.** Atlantic Ocean meridional overturning circulation in Sv for PI control **(a)** and mid-Pliocene **(b)** simulations of experiment 2. Overturning rates are time averages that have been calculated from 30 yr climatologies. Positive values represent a clockwise circulation.
