## Abstract

In the case of infinite plane-parallel single- and double-layered cloud, the solar irradiance at ground level computed by a radiative transfer model can be approximated by the product of the irradiance under clear atmosphere and a modification factor due to cloud properties and ground albedo only. Changes in clear-atmosphere properties have negligible effect on the latter so that both terms can be calculated independently. The error made in using this approximation depends mostly on the solar zenith angle, the ground albedo and the cloud optical depth. In most cases, the maximum errors (percentile 95 %) on global and direct surface irradiances are less than 15 $W m^{-2}$ and less than 2–5 % in relative value. These values are similar to those recommended by the World Meteorological Organization for high quality measurements of the solar irradiance. Practically, the results mean that a model for fast calculation of surface solar irradiance may be separated into two distinct and independent models, possibly abaci-based, whose input parameters and resolutions can be different, and whose creation requires less computation time and resources than a single model.

## 1 Introduction

Solar radiation drives weather and climate and takes part in the control of atmospheric chemistry. The surface solar irradiance (SSI) is defined as the power received from the sun on a horizontal surface at ground level. Under concern here is the SSI integrated over the whole spectrum, i.e. between 0.3 µm and 4 µm, called total or broadband SSI.

Numerical radiative transfer models (RTM) simulate the propagation of radiation through the atmosphere and are used to calculate the SSI for given atmospheric and surface conditions. RTMs are demanding regarding computer time and in this respect are not appropriate in cases where operational computations of the SSI are performed such as at the Deutscher WetterDienst (Mueller et al., 2009), the Royal Netherlands Meteorological Institute (KNMI) (Deneke et al., 2008; Greuell et al., 2013), the MINES

GMDD
7, 2007–2032, 2014

ParisTech (Blanc et al., 2011) or prepared within the MACC European project (Granier et al., 2010). Several solutions have been proposed in order to speed up calculations of the SSI, such as abaci – also known as look-up tables (LUT) – (Deneke et al., 2008; Huang et al., 2011; Mueller et al., 2009; Schulz et al., 2009).

The present work contributes to the research of fast calculations of the SSI under all sky conditions. It does not propose a new model but an approximation that can be adopted by models for calculations of the SSI. More precisely, it examines whether in the case of infinite plane-parallel single- and double-layered cloud, the SSI computed by a RTM can be approximated by the product of the SSI under clear-sky and a modification factor due to cloud properties and ground albedo only. If this approximation is accurate enough, i.e. if the modification factor does not significantly change with clear-atmosphere properties, it would be possible to construct two independent models, possibly LUT-based models – for example, one for clear-sky conditions, and the other for cloudy conditions. Recently, for example, Huang et al. (2011) used such an approximation with a very limited justification. This article aims at holding this justification by (1) exploring the influence of the properties of the clear atmosphere on the SSI in cloudy atmosphere, (2) proposing a general equation that decouples the effects of the clear atmosphere from those due to the clouds, and (3) computing the errors made with this approximation.

## 2 Objective of the article

Let $G$ denote the SSI for any sky. $G$ is the sum of the beam component $B$ of the SSI – also known as the direct component – and of the diffuse component $D$, both received on a horizontal surface. In the present article, following the RTM way of doing, $B$ does not comprise the circumsolar radiation. Let note $G_c$, $B_c$ and $D_c$ the same quantities but for clear-sky. The ratios $K_c$ and $K_{cb}$ are called clear-sky indices (Beyer et al., 1996):

GMDD
7, 2007–2032, 2014

$$K_c = G/G_c \quad (1)$$
$$K_{cb} = B/B_c$$

$K_c$ is also called cloud modification factor in studies on UV or photosynthetically active radiation (Alados et al., 2000; Parisi et al., 2007).

The indices $K_c$ and $K_{cb}$ concentrate the cloud influence on the downwelling radiation and are expected to change with clear-atmosphere properties $P_c$ since the clouds and other atmospheric constituents are mixed up in the atmosphere. Equation (1) can be expanded:

$$G = G_c(\theta_S, \rho_g, P_c) K_c(\theta_S, \rho_g, P_c, P_{cloud}) \quad (2)$$
$$B = B_c(\theta_S, P_c) K_{cb}(\theta_S, P_c, P_{cloud})$$

where

- $\theta_S$ is the solar zenith angle,
- $\rho_g$ the ground albedo,
- $P_c$ is the set of 7 variables governing the optical state of the atmosphere in clear-sky: (i) total column contents in ozone and (ii) water vapour, (iii) elevation of the ground above mean sea level, (iv) vertical profile of temperature, pressure, density, and volume mixing ratio for gases as a function of altitude, (v) aerosol optical depth at 550 nm, (vi) Angström coefficient, and (vii) aerosol type,
- $P_{cloud}$ is the set of variables governing the optical state of the cloudy atmosphere: (i) cloud optical depth ($\tau_c$), (ii) cloud phase, (iii) cloud liquid water content, (iv) droplet effective radius, and (v) the vertical position of the cloud.

The objective of this article is to quantify the error made in decoupling the effects of the clear atmosphere from those due to the clouds in cloudy sky, i.e. if changes in $P_c$

GMDD
7, 2007–2032, 2014

are neglected in $K_c$, respectively $K_{cb}$ in Eq. (2). This is equivalent to say that the first derivative $\partial K_c/\partial P_c$, resp. $\partial K_{cb}/\partial P_c$, is close to 0. In that case, Eq. (2) may be replaced by the following approximation:

$$G \approx G_c(\theta_S, \rho_g, P_c) K_c(\theta_S, \rho_g, P_{c0}, P_{cloud}) \quad (3)$$
$$B \approx B_c(\theta_S, P_c) K_{cb}(\theta_S, P_{c0}, P_{cloud})$$

where $P_{c0}$ is an arbitrarily chosen but typical set $P_c$. The objective is now to quantify the error made when using Eq. (3) instead of Eq. (2).

## 3 Method

The methodology used for assessing Eq. (3) is of statistical nature. For a given condition related to the position of the sun, the ground albedo and the clouds ($\theta_S$, $\rho_g$, $P_{cloud}$), several sets of clear-sky properties $P_c$ are randomly built. Each 4-tuple ($\theta_S$, $\rho_g$, $P_{cloud}$, $P_c$) is input to a RTM to compute $G$, $B$, $D$, $K_c$ and $K_{cb}$. The variances of the $K_c$ and $K_{cb}$ series are then computed. The lower the variance, the lower the changes in $K_c$ or $K_{cb}$ with respect to the changes in $P_c$ and the more accurate the approximation given by the Eq. (3). The errors made on the retrieved $G$ and $B$ when using Eq. (3) are quantified.

The RTM libRadtran version 1.7 (Mayer and Kylling, 2005) is used with the DISORT (discrete ordinate technique) algorithm (Stamnes et al., 1988) to solve the radiative transfer equation. libRadtran needs input data of the atmosphere and surface properties. When not provided, data are replaced by standard assumptions. Atmosphere and clouds are assumed to be infinite plane-parallel.

Table 1 reports the range of the ten values taken respectively by $\theta_S$ and $\rho_g$. For computational reasons, $\theta_S$ is set to 0.01°, respectively 89° in place of 0°, resp. 90°.

Cloud properties input to libRadtran are $\tau_c$, phase – water or ice clouds –, heights of the base and top of cloud, the cloud liquid content and effective radius of the droplets. Default values in libRadtran for cloud liquid content and droplet effective radius are

GMDD
7, 2007–2032, 2014

used: 1.0 g m$^{-3}$ and 10 µm for water cloud, and 0.005 g m$^{-3}$ and 20 µm for ice cloud. The cloud properties are linked together. Table 2 presents the typical height of the base of cloud, geometrical thickness, and $\tau_c$ for the different cloud types and is established after Liou (1976), Rossow and Schiffer (1999).

Ten values of $\tau_c$ are selected in this study for water clouds, and ten others for ice clouds (Table 3, left column). Ranges of $\tau_c$ are related to types of clouds to reproduce realistic conditions. Each $\tau_c$ defines a series of 7 couples cloud base height-thickness for water clouds and 3 for ice clouds (Table 3).

According to Tselioudis et al. (1992), 58 % of the clouds are single-layered and 28 % are double-layered. The results presented hereafter are for single-layer; the case of double-layered clouds is briefly discussed at the end of Sect. 4 as results are similar in both cases.

For a given cloud phase, there are 1000 (10×10×10) possible combinations of $\theta_S$, $\rho_g$ (Table 1) and $\tau_c$ (Table 3). The selection of a given $\tau_c$ leads to the additional selection of a series of cloud base heights and thicknesses as shown in Table 3, i.e. 7 for water clouds and 3 for ice clouds. At that stage, there are 7000 triplets ($\theta_S$, $\rho_g$, $P_{cloud}$) for water clouds and 3000 for ice clouds.

Each triplet ($\theta_S$, $\rho_g$, $P_{cloud}$) gives birth to 20 4-tuples ($\theta_S$, $\rho_g$, $P_{cloud}$, $P_c$) by adding 20 $P_c$ randomly selected in Table 4. Similarly to what was done by Lefevre et al. (2013) and Oumbe et al. (2011), the selection takes into account the modelled marginal distribution established from observation. More precisely, the uniform distribution is chosen as a model for marginal probability for all parameters except aerosol optical thickness, Angstrom coefficient, and total column ozone. The chi-square law for aerosol optical thickness, the normal law for the Angstrom coefficient, and the beta law for total column ozone have been selected. The selection of these parametric probability density functions and their corresponding parameters have been empirically determined from the analyses of the observations made in the AERONET network for aerosol properties and from meteorological satellite-based ozone products (cf. Table 4). For the sake of

GMDD
7, 2007–2032, 2014

avoiding non-realistic cases, the allocation of the aerosol types is empirically linked to the ground albedo (Table 5).

Each combination ($\theta_S$, $\rho_g$, $P_{cloud}$, $P_c$) is input to libRadtran, yielding $G$, $B$, $D$. In addition, $G_c$ and $B_c$ are obtained by libRadtran using ($\theta_S$, $\rho_g$, $P_c$) as inputs. $K_c$ and $K_{cb}$ are obtained using Eq. (1). A series of 140 000 values for $G$, $B$, $D$, $K_c$ and $K_{cb}$ is thus obtained for water clouds and 60 000 for ice clouds. For each triplet ($\theta_S$, $\rho_g$, $P_{cloud}$), the variances $v(K_c)$ and $v(K_{cb})$ are computed over the 20 values $K_c$ and $K_{cb}$. Since the clouds and other atmospheric constituents are mixed up in the atmosphere, $K_c$, or $K_{cb}$, is expected to change with varying $P_c$. It is observed that $v(K_c)$ and $v(K_{cb})$ are very small, meaning that changes in $K_c$ and $K_{cb}$ with varying $P_c$ are small, thus supporting Eq. (3).

In order to illustrate this and to present this vast amount of results in a synthetic manner, it is firstly observed that these quantities $v(K_c)$ and $v(K_{cb})$ do not vary in a noticeable way with the cloud geometry for a given triplet ($\theta_S$, $\rho_g$, $\tau_c$), i.e. that among the cloud properties for a given phase, the cloud optical depth $\tau_c$ is the most prominent one. As a consequence, it is possible to illustrate the findings by averaging $v(K_c)$ and $v(K_{cb})$ over the cloud geometry properties for each triplet ($\theta_S$, $\rho_g$, $\tau_c$). One obtains mean($v(K_c)$) and mean($v(K_{cb})$). The positive root means of these averages are denoted RM($v(K_c)$) and RM($v(K_{cb})$):

$$\mathrm{RM}(v(K_c)) = \sqrt{\mathrm{mean}(v(K_c))} \qquad (4)$$
$$\mathrm{RM}(v(K_{cb})) = \sqrt{\mathrm{mean}(v(K_{cb}))}$$

RM($v(K_c)$) gives at a glance the influence of $P_c$ on $K_c$ for all cloud geometries. A small RM($v(K_c)$) means that the mean of $v(K_c)$ is small. The variance $v(K_c)$ and consequently RM($v(K_c)$) are linked to $\partial K_c/\partial P_c$. The lower RM($v(K_c)$), the lower the mean of $v(K_c)$, the lower the change in $K_c$ with $P_c$, and finally the lower the error made when using Eq. (3). The same reasoning holds for RM($v(K_{cb})$). RM($v(K_c)$), respectively RM($v(K_{cb})$), can be considered as a measure of the error made on $K_c$, or $K_{cb}$, when using Eq. (3). These

GMDD
7, 2007–2032, 2014

quantities are also expressed relative to the mean $K_c$ and $K_{cb}$ for a given triplet, yielding relative values, noted $r\mathrm{RM}(v(K_c))$ and $r\mathrm{RM}(v(K_{cb}))$.

## 4 Influence of $P_c$ on clear-sky indices

Relative quantities $r\mathrm{RM}(v(K_c))$ and $r\mathrm{RM}(v(K_{cb}))$ depend on $G$ and $B$. A large $r\mathrm{RM}(v(K_c))$ may not be important if $G$ is very small. To better understand the results, Fig. 1 displays the averages of $G$ and $D$ for $\theta_S = 40^\circ$ as a function of $\rho_g$ and $\tau_c$ for water cloud. The beam irradiance $B$ is not drawn as it does not depend on $\rho_g$; it decreases rapidly as $\tau_c$ increases and the diffuse irradiance $D$ tends towards $G$ as a consequence. As expected, Fig. 1 shows that $D$ increases with $\rho_g$, and that both $G$ and $D$ decrease as $\tau_c$ increases.

Figure 2 exhibits $r\mathrm{RM}(v(K_c))$ for each couple ($\rho_g$, $\tau_c$) for $\theta_S = 40^\circ$ for water cloud (left) and ice cloud (right). Each cell represents the changes in $K_c$ obtained for this $\theta_S$ and this couple ($\rho_g$, $\tau_c$) when the geometrical parameters of the cloud and the other variables in $P_c$ are varying. For both cloud phases, $r\mathrm{RM}(v(K_c))$ increases with $\tau_c$ and ground albedo. As a whole, it is small. It is less than 2 % for the most frequent cases, i.e. $\tau_c \leq 20$ and $\rho_g \leq 0.7$. It can be compared to the maximum relative errors (66 % uncertainty) recommended by the World Meteorological Organization (WMO, 2008) for measurements of hourly means of $G$ or $D$ which are 2 % for high quality, 8 % for good quality, and 20 % for moderate quality.

$r\mathrm{RM}(v(K_c))$ reaches a maximum of 8.5 % for $\tau_c = 70$ and $\rho_g = 0.9$ for water cloud (7.5 % for $\tau_c = 20$ for ice cloud). Large $\rho_g$ and large $\tau_c$ mean more reflected radiation by the ground and more backscattered radiation by clouds. This increases the path of the radiation in the atmosphere, and therefore increases the influence of $P_c$ on $K_c$. As $G$ is small for ($\tau_c = 70$, $\rho_g = 0.9$) (Fig. 1), a maximum of 8.5 % is not important in absolute value since it corresponds to approximately 30 $\mathrm{W\,m^{-2}}$. This high relative

GMDD
7, 2007–2032, 2014

deviation happens only for very high $\rho_g = 0.9$. When $\rho_g \leq 0.7$, the corresponding error on $G$ is less than $10\,W\,m^{-2}$.

The median and percentiles 5 % (P5) and 95 % (P95) of RM($v(K_c)$) for all corresponding couples ($\rho_g$, $\tau_c$) for a given $\theta_S$ are computed and expressed relative to the corresponding mean $K_c$. The results are plotted in Fig. 3 for water cloud (left) and ice cloud (right) as a function of $\theta_S$. For both phases and for $\theta_S$ from 0° to 60°, the relative median is less than 2 %, and the relative P95 ranges between 3.5 % and 5 %. All three quantities increase sharply for $\theta_S > 60°$. The median, respectively P95, reaches a maximum of approximately 8–9 %, respectively 11–12 % for $\theta_S = 80°$. Then, a decrease is observed for $\theta_S > 80°$.

Overall, an increase in $\tau_c$ or $\theta_S$ increases the path of the sun rays in the atmosphere, and therefore the influence of changes in $P_c$ on $K_c$ increases along with $\tau_c$ and $\theta_S$. This increase is compensated by a corresponding decrease in $G$. Since $G_c$ rarely reaches $120\,W\,m^{-2}$ for $\theta_S = 80°$, the error in $G$ corresponding to P95 is less than $15\,W\,m^{-2}$. The diffuse irradiance $D$ and therefore $G$ are strongly influenced by $\rho_g$. In case of large $\rho_g = 0.9$, the error (P95) on $G$ can be large for small $\theta_S$, i.e. $30\,W\,m^{-2}$. One has to be cautious in using Eq. (3) in such extreme cases.

Similar calculations are made for $K_{cb}$. As expected with a RTM code $K_{cb}$ does not change with ground albedo nor cloud phase; the cloud optical depth is the most prominent variable. Figure 4 exhibits the relative median and percentiles 5 % and 95 % of RM($v(K_{cb})$) for all couples ($\rho_g$, $\tau_c$) as a function of $\theta_S$. The relative median, respectively relative P95, is less than 2 %, respectively 3 % for $\theta_S \leq 60°$. Then, it rises sharply. The relative median, respectively P95, reaches a maximum of approximately 8 %, respectively 17 % for $\theta_S = 80°$. Then, a decrease is observed for $\theta_S > 80°$. Large $\theta_S$ correspond actually to low irradiances. The clear-sky $B_c$ equals $53\,W\,m^{-2}$ for $\theta_S = 80°$, and therefore the corresponding median and P95 errors in $B$ are approximately $4\,W\,m^{-2}$ and $9\,W\,m^{-2}$.

GMDD
7, 2007–2032, 2014

$r\mathrm{RM}(v(K_{cb}))$ has a tendency to increase as $\theta_S$ increases. This increase is compensated by a corresponding decrease in $B$. The clear-sky irradiance $B_c$ rarely reaches $90\,\mathrm{W\,m^{-2}}$ for $\theta_S = 80^\circ$ and the maximum error in $B$ is less than $16\,\mathrm{W\,m^{-2}}$.

If cases of large $\theta_S$ and $\tau_c$ for which the radiation is greatly attenuated are removed by considering only cases for which $G > 100\,\mathrm{W\,m^{-2}}$, the obtained $r\mathrm{RM}(v(K_c))$ and $r\mathrm{RM}(v(K_{cb}))$ are very small, even for large $\theta_S$. For $\theta_S$ equal to 70° and 80°, the medians are approximately 3 % of $K_c$ and $K_{cb}$, and the P95 are 5 % and 7 % respectively.

It is concluded that for all considered cloud properties and $\theta_S$, and for $\rho_g \leq 0.7$, the influence of changes in $P_c$ on $K_c$ and $K_{cb}$ can be neglected. In these cases, Eq. (3) may be adopted with an error (P95) on $G$ and $B$ less than $15\,\mathrm{W\,m^{-2}}$ and most often less than 2–5 % in relative value. These results match the WMO requirements for high quality measurements.

A similar analysis has been made for two-layered clouds with ice cloud topping water cloud. The water and ice cloud properties have been taken from Table 3, where only water clouds with a height top less or equal to 5 km were considered since the minimum height of ice cloud base is 6 km. Accordingly, there were 5 (water cloud) · 3 (ice cloud) cases. Results and conclusions are similar to those for single-layered clouds.

## 5 Practical implications

A first practical interest in adopting Eq. (3) instead Eq. (2) is that two independent models – one for modelling $G_c$ and $B_c$, the other for modelling the effects of clouds – can be used. If the approach selected to assess the SSI is based on a LUT-based model, using Eq. (3) means that two LUT-based models for $K_c$ and $K_{cb}$ can be computed with only one typical set $P_{c0}$, therefore strongly reducing the number of runs of the RTM. One may select the following $P_{c0}$:

GMDD
7, 2007–2032, 2014

- the middle latitude summer from the USA Air Force Geophysics Laboratory (AFGL) data sets is taken for the vertical profile of temperature, pressure, density, and volume mixing ratio for gases as a function of altitude,
- aerosol properties: optical depth at 550 nm is set to 0.20, Angström coefficient is set to 1.3, and type is continental average,
- total column content in water vapour is set to 35 $\mathrm{kg\,m^{-2}}$,
- total column content in ozone is set to 300 Dobson unit,
- elevation above sea level is 0 m.

It has been checked that the difference in $K_c$ and $K_{cb}$ using different typical sets $P_{c0}$ was negligible providing the selected $P_{c0}$ does not include extreme values.

As an example, this approach is that used in the MACC/MACC-II (Monitoring Atmosphere Composition and Climate) projects to develop the new Heliosat-4 method for a fast assessment of $G$, $D$ and $B$ (Qu, 2013; Qu et al., 2013). The McClear clear-sky model (Lefevre et al., 2013) is adopted in Heliosat-4 to compute $G_c$ and $B_c$. The McClear abaci are very large since there are 10 dimensions. They concentrate most of the computational resources. It took approximately 6 months in computation time to compute all abaci. On the opposite, the abaci for $K_c$ and $K_{cb}$ have much less dimensions and much less nodes. Computation time was of order of a few hours only. If it were not possible to consider independently the clear-sky conditions and the cloudy conditions, the computation time for abaci combining the dimensions of McClear abaci and those for $K_c$ and $K_{cb}$ would have amounted to years. The immense gain in time justifies the slight loss in accuracy.

Except $\theta_S$ and $\rho_g$, inputs to both models are independent. This is another practical advantage of Eq. (3) since it allows to efficiently coping with the fact that $P_c$ and $P_{cloud}$ may not be available at the same spatial and temporal resolutions. This is exactly the case in the MACC/MACC-II projects. On the one hand, these projects are preparing the operational provision of global aerosol properties forecasts together with physically

GMDD
7, 2007–2032, 2014

consistent total column content in water vapour and ozone (Kaiser et al., 2012; Peuch et al., 2009). These data are available every 3 h with a spatial resolution of approximately 100 km. They are inputs to the McClear model, yielding $G_c$ and $B_c$. On the other hand, these projects are preparing the provision of $P_{cloud}$ at high temporal (15 min) and spatial (3 km at nadir) resolutions from an appropriate processing of images taken by the Meteosat Second Generation satellites. $P_{cloud}$ will be input to the $K_c$ and $K_{cb}$ models. Using Eq. (3) implies that the SSI may be computed at the best available time and space resolutions by resampling $G_c$ and $B_c$, instead of resampling all variables contained in $P_c$.

## 6 Conclusions

This article analyses the influence of the prominent atmospheric parameters on the SSI, with the objective to find a practical way to speed up the calculations with a RTM. The presented results have been obtained by the RTM libRadTran. It has been checked that the results and conclusions do not depend on this model by obtaining similar results with the Streamer RTM (Key and Schweiger, 1998).

It was found that for all considered cloud properties, solar zenith angles and ground albedos, the influence of changes in clear-atmosphere properties on $K_c$ and $K_{cb}$ is generally less than 2–5 %, provided that the ground albedo is less than 0.7. This variation is similar to the typical uncertainty associated to the most accurate pyranometers. In these cases, Eq. (3) may be adopted with an error (P95) on $G$ and $B$ less than 15 $W m^{-2}$.

The longer the path of sun rays in the atmosphere, the greater this variation and the greater the influence of clear-atmosphere properties on the clear-sky indices. The mean error made when using Eq. (3) can reach significant relative values at high $\theta_S$: 4 % at 70° and 8 % at 80°. However, in such cases, the irradiances are very low, and the error on global and direct irradiances expressed as the percentile 95 % (P95) is less than 15 $W m^{-2}$. The P95 can be greater than 15 $W m^{-2}$ when the ground albedo

GMDD
7, 2007–2032, 2014

is greater than 0.7. In that case, one should be cautious in using Eq. (3). Such high albedos are rarely found, they may happen in case of fresh snow.

Like in other RTMs the beam irradiances are modelled by libRadtran as if the sun were a point source. On the contrary, pyranometers measure the radiation coming from the sun direction with a half-aperture angle equal to 2.5° according to WMO standards. The diffuse irradiance in this angular region is called the circumsolar irradiance (CSI). If it were to be compared to measurements, irradiances estimated in this work have to be corrected by adding CSI to $B$, and by removing CSI from $D$. In clear-sky, the CSI correction to $B$ is approximately 1 % of $B$ (Gueymard, 1995; Oumbe et al., 2012). Under cloudy skies, and especially thin clouds, the CSI can be greater than 50 % of $B$. A CSI correction needs to be applied only in cloudy skies. Therefore the CSI can be taken into account a posteriori by correcting $K_c$ and $K_{cb}$ obtained by Eq. (3) with a specific model.

The presented work has demonstrated that computations of the SSI can be made by considering independently the clear-sky conditions and the cloudy conditions as shown in Eq. (3). a first practical interest is that two independent models may be developed and used, one for clear-sky conditions, and the other for cloudy conditions with their own set of inputs. Another practical interest is that it allows to efficiently coping with cloud and clear-sky variables available at different spatial and temporal resolutions.

These results are important in the view of an operational system as it permits to separate the whole processing into two distinct and independent models, whose input variables types and resolutions may be different. The benefit of this separation is not limited to LUT-based models. For example, one may combine LUT-based models for $K_c$ and $K_{cb}$ with an analytical model predicting $G_c$ and $B_c$ such as the ESRA model (Rigollier et al., 2000) or the SOLIS model (Mueller et al., 2004). When both models are LUT-based, using Eq. (3) means two ensembles of abaci, one for clear-sky and the other for cloudy skies. In doing so, the number of entries for each ensemble is reduced leading to (i) reducing the size of the abaci, (ii) the number of combination between

GMDD
7, 2007–2032, 2014

parameters, and (iii) the total number of interpolations between nodes, thus increasing the speed in computation.

*Acknowledgements.* The research leading to these results has received funding from the European Union's Seventh Framework Programme (FP7/2007-2013) under Grant Agreement no. 218793 (MACC project) and no. 283576 (MACC-II project). MACC and MACC-II are preparatory projects for Europe's Global Monitoring for Environment and Security (GMES) program – recently re-named as the Copernicus programme. The authors thank the team developing libRadtran (http://www.libradtran.org).

**Table 2.** Properties of cloud types. Base height and thickness are from Liou (1976), and cloud optical depth are from Rossow and Schiffer (1999). Cu: cumulus, Sc: stratocumulus, As: altostratus, Ac: altocumulus, Ci: cirrus, Cs: cirrostratus.

| Cloud type | Base height (km) | Thickness (km) | Cloud optical depth |
|---|---|---|---|
| Low cloud (Cu, Sc) | 1.7 | 0.45 | Cu: 0–3.6<br>Sc: 3.6–23 |
| Middle cloud (As, Ac) | 4.2 | 0.6 | Ac: 0–3.6<br>As: 3.6–23 |
| High cloud (Ci, Cs) | 4.6 | 1.7 | Ci: 0–3.6<br>Cs: 3.6–23 |
| Stratus (St) | 1.4 | 0.1 | 23–379 |
| Nimbostratus (Ns) | 1.4 | 4 | 23–379 |
| Cumulonimbus (Cb) | 1.7 | 6 | 23–379 |

GMDD

**Table 4.** Range of $P_c$ values (7 variables describing the clear atmosphere).

| Variable | Range of values |
|---|---|
| Total column content in ozone | Ozone content is: $300 \cdot \beta + 200$, in Dobson unit. Beta law, with A parameter = 2, and B parameter = 2, to compute $\beta$ |
| Total column content in water vapour | Uniform between 0–70, in kg $m^{-2}$ |
| Elevation of the ground above mean sea level | Equiprobable in the set: 0, 1, 2, 3 in km |
| Atmospheric profiles (Air Force Geophysics Laboratory standards) | Equiprobable in the set: Midlatitude Summer, Midlatitude Winter, Subarctic Summer, Subarctic Winter, Tropical, US Standard |
| Aerosol optical depth at 550 nm | Gamma law, with shape parameter = 2, and scale parameter = 0.13 |
| Angstrom coefficient | Normal law, with mean = 1.3 and standard-deviation = 0.5 |
| Aerosol type | Equiprobable in the set of 10 aerosol types proposed in libRadtran: urban, continental average, continental clean, continental polluted, maritime clean, maritime polluted, maritime tropical, desert, antarctic |

GMDD
7, 2007–2032, 2014

**Table 5.** Empirical allocation of aerosol types according to ground albedo.

| Ground albedo | Possible aerosol types |
|---|---|
| < 0.1 | maritime clean, maritime polluted, maritime tropical |
| 0.1–0.2 | continental average, continental clean, continental polluted, urban |
| 0.2–0.25 | continental average, continental clean, continental polluted, urban, desert |
| 0.25–0.4 | continental average, continental clean, desert |
| 0.4–0.5 | continental average, continental clean |
| 0.5–0.9 | continental average, continental clean, antarctic |
