Abstract. I present a method for developing extensible and modular computational models without sacrificing serial or <sup>35</sup> parallel performance or source code readability. By using a generic simulation cell method I show that it is possible to

- combine several distinct computational models to run in the same computational grid without requiring modification of existing code. This is an advantage for the development and 40 testing of e.g. geoscientific software as each submodel can be developed and tested independently and subsequently used
- without modification in a more complex coupled program. An implementation of the generic simulation cell method presented here, generic simulation cell class (gensimcell), 45 also includes support for parallel programming by allowing model developers to select which simulation variables of
- e.g. a domain-decomposed model to transfer between processes via a Message Passing Interface library. This allows the communication strategy of a program to be formalized 50 by explicitly stating which variables must be transferred between processes for the correct functionality of each sub-
- <sup>20</sup> model and the entire program. The generic simulation cell class requires a C++ compiler that supports a version of the languge standardized in 2011 (C++11). The code is available <sup>55</sup> at https://github.com/nasailja/gensimcell for everyone to use, study, modify and redistribute; those that do are kindly reupper guested to colored and eite this work.
- <sup>25</sup> quested to acknowledge and cite this work.

#### 1 Introduction

Computational modeling has become one of the cornerstones of many scientific disciplines, helping to understand observations and to form and test new hypotheses. Here a computational model is defined as numerically solving a set of mathematical equations with one or more variables using a discrete representation of time and the modeled volume. Today the bottleneck of computational modeling is shifting from hardware performance towards that of software development, more specifically to the ability to develop more complex models and to verify and validate them in a timely and cost-efficient manner (Post and Votta, 2005). The importance of verification and validation is highlighted by the fact that even a trivial bug can have devastating consequences not only for users of the affected software but for others who try to publish contradicting results (Miller, 2006).

Modular software can be (re)used with minimal modification and is advantageous not only for reducing development effort but also for verifying and validating a new program. For example the number of errors in software components that are reused without modification can be an order of magnitude lower than in components which are either developed from scratch or modified extensively before use (Thomas et al., 1997). The verification and validation (V&V) of a program consisting of several modules should start from V&V of each module separately before proceeding to combinations of modules and finally the entire program (Oberkampf and Trucano, 2002). Modules that have been V&V'd and are used without modification increase the confidence in the functionality of the larger program and decrease the effort required for final V&V.

Reusable software that does not depend on any specific type of data can be written by using, for example, generic programming (Musser and Stepanov, 1989). Waligora et al. (1995) reported that the use of object-oriented design and generics of the Ada programming language at Flight Dynamics Division of NASA's Goddard Space Flight Center had increased software reuse by a factor of three and, in addition to other benefits, reduced the error rates and costs substantially. With C++ generic software can be developed without sacrificing computational performance through the use of compile-time template parameters for which the compiler

can perform optimizations that would not be possible other- 120 wise (e.g. Veldhuizen and Gannon, 1998; Stroustrup, 1999). 70

#### **1.1 Model coupling**

Generic and modular software is especially useful for developing complex computational models that couple together several different and possibly independently devel-

oped codes. From a software development point of view code coupling can be defined as simply making the variables stored by different codes available to each other. In this sense  $_{130}$ even a model for the flow of incompressible, homogeneous and non-viscous fluid without external forcing

80 
$$\frac{\partial \boldsymbol{v}}{\partial t} = -\boldsymbol{v} \cdot (\nabla \boldsymbol{v}) - \nabla p; \quad \nabla^2 p = -\nabla \cdot (\boldsymbol{v} \cdot (\nabla \boldsymbol{v}))$$

where v is velocity and p is pressure, can be viewed as a coupled model as there are two equations that can be solved by different solvers. If a separate solver is written for each equation and both solvers are simulating the same volume

with identical discretization, coupling is only a matter of data exchange. In this work the term solver will be used when referring to any code/function/module/library which takes as input the data of a cell and its N neighbors and produces the 140 next state of the cell (next step, iteration, temporal substep,

90 etc.).

> The methods of communicating data between solvers can vary widely depending on the available development effort, the programming language(s) involved and details of the spe-145 cific codes. Probably the easiest coupling method to develop

is to transfer data through the filesystem, i.e. at every step each solver writes the data needed by other solvers into a file and reads the data produced by other solvers from other files. This method is especially suitable as a first version of cou-150 pling when the codes have been written in different programming languages and use non-interoperable data structures. 100

Performance-wise a more optimal way to communicate between solvers in a coupled program is to use shared memory, as is done for example in Hill et al. (2004), Jöckel et al. 155 (2005), Larson et al. (2005), Toth et al. (2005), Zhang and

- Parashar (2006), Redler et al. (2010), but this technique still 105 has shortcomings. Perhaps the most important one is the fact that the data types used by solvers are not visible to outside, thus making intrusive modifications (i.e. modifications to ex-160 isting code or data structures) necessary in order to transfer
- data between solvers. The data must be converted to an in-110 termediate format by the solver "sending" the data and subsequently converted to the internal format by the solver "receiving" the data. The probability of bugs is also increased as 165 the code doing the end-to-end conversion is scattered in two
- different places and the compiler cannot perform static type checking for the final coupled program. These problems can be alleviated by e.g. writing the conversion code in another language and outputting the final code of both submodels 170 automatically (Eller et al., 2009). Interpolation between dif-

ferent grids and coordinate systems that many of the frameworks mentioned previously perform can also be viewed as part of the data transfer problem but is outside the scope of this work.

A distributed memory parallel program can require significant amounts of code for arranging the transfers of different variables between processes, for example, if the amount of data required by some variable(s) changes as a function of both space and time. The problem is even harder if a program consists of several coupled models with different time stepping strategies and/or variables whose memory requirements change at run time. Futhermore, modifying an existing time stepping strategy or adding another model into the program can require substatial changes to existing code in order to accomodate additional model variables and/or temporal substeps.

#### 1.2 Generic simulation cell method

135

A generic simulation cell class is presented that provides an abstraction for the storage of simulation variables and the transfer of variables between processes in a distributed memory parallel program. Each variable to be stored in the generic cell class is given as a template parameter to the class. The variables of each cell instance are grouped together in memory so if several cell instances are stored contiguously in memory (e.g. in an std::vector) a variable will be interleaved with other variables in memory but see Section 8 for a discussion on how this might affect application performance. The type of each variable is not restricted in any way by the cell class or solvers developed using this abstraction, enabling generic programming in simulation development from the top down to a very low level. By using variadic templates of the 2011 version of the C++ standard (C++11), the total number of variables is only limited by the compiler implementation. A minimum of 1024 template arguments is recommended by C++11 (see e.g. Annex B in Du Toit, 2012) and the cell class presented here can itself also be used as a variable thereby grouping related variables together and reducing the total number of template arguments given to the cell class.

By using the generic cell abstraction it is possible to develop distributed memory parallel computational models in a way that easily allows one to combine an arbitrary number of separate models without modifying existing code. This is demonstrated by combining parallel models for Conway's Game of Life (Gardner, 1970), scalar advection and Lagrangian transport of particles in an external velocity field. In order to keep the presented programs succinct, combining computational models is defined here as running each model on the same grid structure with identical domain decomposition accross processes. This is not mandatory for the generic cell approach and, for example, the case of different domain decomposition of submodels is discussed in Section 4.

#### Honkonen: Generic simulation cell method

Section 2 introduces the generic simulation cell class concept via a serial implementation and Section 3 extends it to distributed memory parallel programs. Section 4 shows that it

175

180

195

is possible to combine three different computational models without modifying existing code by using the generic simulation cell method. Section 6 shows that the generic cell implementation developed here does not seem to have an adverse effect on either serial or parallel computational performance. The code is available at https://github.com/nasailja/

- gensimcell for everyone to use, study, modify and redistribute; users are kindly requested to cite this work. The relative paths to source code files given in the rest of the text refer to the version of the generic simulation cell tagged as 1.0
- in the git repository and is available at: https://github.com/ nasailja/gensimcell/tree/1.0/. The presented generic simulation cell class requires a standard C++11 compiler and parallel functionality additionally requires a C implementation of MPI and the header-only Boost libraries MPL, Tribool and TTI.

#### 2 Serial implementation

Lines 1..30 in Figure 1 show a serial implementation of the generic simulation cell class that does not provide support for MPI applications, is not const-correct and does not hide implementation details from the user but is otherwise complete. The cell class takes as input an arbitrary number of template parameters that correspond to variables to be stored in the cell. Variables have to only define their type through

- the name data\_type. When the cell class is given one variable as a template argument the code on lines 3..11 is used. The variable given to the cell class as a template parameter is stored as a member of the cell class on line 4 and access to it is provided by the cell's [] operator overloaded for the variable's class on lines 6..10<sup>1</sup>. When given multiple vari-
- <sup>205</sup> ables as template arguments the code on lines 13..30 is used which similarly stores the first variable as a private member and provides access to it via the [] operator. Additionally the cell class derives from itself with one less variable on line 19. This recursion is stopped by eventually inherit-
- 210 ing the one variable version of the cell class. Access to the private data members representing all variables are provided by the respective [] operators which are made available to outside of the cell class on line 23. The memory layout of variables in an instance of the cell class depends on the com-
- piler implementation and can include, for example, padding between variables given as consecutive template parameters. <sup>225</sup> This also applies to variables stored in "ordinary" structures and in both cases if, for example, several values must be stored contiguously in memory a container guaranteeing this
  should be used such as std::array or std::vector.

```
1 template <class... Variables> struct Cell;
2
   template <class Variable> struct Cell<Variable> {
3
4
     typename Variable :: data_type data;
5
6
      typename Variable::data_type& operator[](
        const Variable&
7
      ) {
8
9
        return this->data:
10
      }
   };
11
12
13

35
     Mass_Density, Momentum_Density, Total_Energy_Density
36
37
38
  struct HD_State { using data_type = HD_Conservative; };
struct HD_Flux { using data_type = HD_Conservative; };
39
40
   using Cell_T = Cell<HD_State, HD_Flux>;
41
42
43
   int main()
44
      Cell_T cell;
      cell[HD_Flux()][Mass_Density()]
45
        = cell [HD_State()] [Momentum_Density()] [0];
46
```

```
47 }
```

230

**Listing 1.** Brief serial implementation of the generic simulation cell class (lines 1..30) and an example definition of a cell type used in a hydrodynamic simulation (lines 32..47).

Lines 32..47 in Figure 1 define a cell type for a hydrodynamic simulation and a program assigning a value from one variable of a cell to another variable of the same cell. The variables of hydrodynamic equations are defined on lines 32..34 and a cell type consisting of those variables is defined on lines 35..37. In order to store both the current state of the simulation and the change in state variables from one time step to the next, two variables are defined on lines 39 and 40 representing the current state and fluxes into and out of each cell. The final type stored in each cell of the simulation grid consists of the state and flux variables defined on lines 39..41.

<sup>&</sup>lt;sup>1</sup>Future versions might implement a multi argument () operator returning a tuple of references to several variables' data

#### 4

#### **3** Parallel implementation

In a parallel computational model variables in neighboring cells must be transferred between processes in order to cal-290 culate the solution at the next time step or iteration. On the other hand it might not be necessary to transfer all variables in each communication as one solver could be using higher order time stepping than others and require more iterations

for each time step. Or, for example, when modeling an in-compressible fluid the Poisson's equation for pressure must
 be solved at each time step, i.e. iterated in parallel until some norm of the residual becomes small enough, during which time other variables need not be transferred. Model variables
 can also be used for debugging and need not be transferred

between processes by default. The generic cell class provides support for parallel pro-

grams via its get\_mpi\_datatype() member function which returns the information required to transfer one more variables stored in the cell via a library implementing the Message

- 250 stored in the cell via a library implementing the Message Passing Interface (MPI) standard. An implementation of MPI 305 is not required to use the generic simulation cell class, in that case (if the preprocessor macro MPI\_VERSION is not defined when compiling) support for all MPI functionality will
- not be enabled and the class will behave as shown in Section 2. Transferring variables of a standard type (e.g. float, long 310 int) or a container (of container of ...) of standard types (array, vector, tuple) is supported out of the box. The transfer of one or more variables can be switched on or off via a function
- overloaded for each variable on a cell-by-cell basis or for all cells of a particular cell type at once. This allows the commu-315 nication strategy of a program to be formalized by explicitly stating which variables in what part of the simulated volume must be transferred between processes at different stages of
   execution for the correct functionality of each solver and the

entire program. 320 The transfer of variables in all instances of a particular type of cell can be toggled with its set\_transfer\_all() function and the set\_transfer() member can be used to toggle the trans-

- 270 fer of variables in each instance of a cell type separately. The former function takes as arguments a boost::tribool value and 325 the affected variables. If the triboolean value is determined (true of false) then all instances behave identically for the affected variables, otherwise (a value of boost::indeterminate)
- 275 the decision to transfer the affected variables is controlled on a cell-by-cell basis by the latter function. The functions 330 are implemented recursively using variadic templates in order to allow the user to switch on/off the transfer of arbitrary combinations of variables in the same function call.
- <sup>280</sup> The get\_mpi\_datatype() member function iterates through all variables stored in the cell at compile-time and only add vari-<sup>335</sup> ables which should be transferred to the final MPI\_Datatype at run-time.

Figure 2 shows a parallel implementation of Conway's Game of Life (GoL) using the generic simulation cell class. To simplify the implementation the game grid is 1-340 dimensional, periodic in that dimension and with one cell per process. A version of this example with console output is available at examples/game\_of\_life/parallel/no\_dccrg.cpp. When run with 11 processes the program prints:

.0000000000	
0.00000000.	
.0.000000.0	
0.0.0000.0.	
.0.0.00.0.0	
0.0.0.0.0.	
.0.00.0	
0.00.	
.00	
0	

Lines 6..10 define the model's variables and the cell type used in the model grid. The first parameter given to the cell class on line 9 is the transfer policy of that cell type with three possibilities: 1) All variables are always transferred, 2) None of the variables are transferred and 3) Transfer of each variable can be switched on and off as described previously. In the first two cases all variables of a cell instance are laid out contiguously in memory while in the last case a boolean value is added for each variable that records whether the variable should be transferred from that cell instance. Lines 13 and 14 provide a shorthand notation for referring to simulation variables. Lines 16..23 initialize MPI and the game. The [] operator is used to obtain a reference to variables' data e.g. on line 22. Line 25 switches on the transfer of the Is\_Alive variable whose information will now be returned by each cells' get\_mpi\_datatype() method on lines 28..30. Lines 27..58 of the time stepping loop transfer variables' data based on the MPI transfer information provided by instances of the generic simulation cell class. In this case only one variable is transferred by each cell hence all cells return the address of that variable (e.g. line 4 in Figure 1), a count of 1 and the equivalent MPI data type MPI CXX BOOL.

Figure 3 shows a program otherwise identical to the one in Figure 2 but which does not use the generic simulation cell class. Calls to the MPI library (Init, Isend, Irecv, etc.) are identical in both programs but there is also a fundamental difference: In Figure 3 the names of variables used in the program cannot be changed without affecting all parts of the program in which those variables are used, whereas in Figure 2 only lines 13 and 14 of the main function would be affected. This holds true even if the solver logic is separated into a function as shown in Figure 4. If the names of the one or more simulation variables are changed the function on lines 1..9 would not have to be changed, instead only the function call on lines 18..22 would be affected. In contrast all variable names in the function on lines 11..16 would have to be changed to match the names defined elsewhere. It should be noted that the serial functionality of generic cell class is available for std::tuple in the newest C++ standard approved on

Subsequent examples use the DCCRG library (Honkonen et al., 2013) for abstracting away the logic of transferring neighboring cells' data between processes, i.e. lines 27..58 and 61..62 in Figure 2. DCCRG queries the data to be transferred from each cells' get\_mpi\_datatype() function as needed, i.e. when a cell considers the cell of another process as a neighbor or vice versa, and passes on that information to the MPI transfer functions.

Figure 5 shows the variables and time stepping loop of a parallel advection program using the generic simulation cell class and DCCRG library, the full program is available at examples/advection/parallel/main.cpp. The solver function(s) use a first order donor cell algorithm and are implemented similarly to lines 1..9 in Figure 4, i.e. each function takes the required data as arguments and as template arguments the variables to use when calculating the solution. Internally the functions call the [] operator of each cell with instances of the variables given as template arguments to access the required data. Computation is overlapped with communication by solving cells without neighbors on other processes (lines 16..21) while data transfers are ongoing (lines 14 and 23).

```
template < class IA, class LN, class C> void solve (
1
     C& cell, const C& neg, const C& pos
2
3
   ) {
     constexpr IA is_alive{};
4
     constexpr LN live_neighbors{};
 5
6
      if (neg[is_alive]) cell[live_neighbors]++;
7
     if (pos[is_alive]) cell[live_neighbors]++;
9
   }
10
   template<class C> void solve_no_gensimcell(
11
     C& cell, const C& neg, const C& pos
12
13
   )
     -{
      if (neg.is_alive) cell.live_neighbors++;
14
     if (pos.is_alive) cell.live_neighbors++;
15
16
   }
17
   solve <
18
19
     Is_Alive, Live_Neighbors
   >(
20
21
     cell, neg_neigh, pos_neigh
22
   );
23
24
   solve_no_gensimcell(
25
     cell, neg_neigh, pos_neigh
26
```

**Listing 4.** Functions for calculating the number of live neighbors for the program shown in Figure 2 on lines 1..9 and the program in Figure 3 on lines 11..16. Lines 18..26 show the function calls as they would appear in the respective main programs.

#### 4 Combination of three simulations

```
Parallel models implemented using the generic simulation
cell class can be combined without modification into one model by incorporating relevant parts from the main.cpp file of each model. This is enabled by the use of distinct types, or metavariables, for describing simulation variables and for accessing their data as well as by allowing one to easily switch
on and off the transfer of variables' data between processes in a distributed memory parallel program. The time stepping loop of a program playing Conway's Game of Life, solving the advection equation and propagating particles in an external velocity field is shown in Figure 6 and the full program is available at examples/combined/parallel.cpp. Sepa-
```

```
rate namespaces are used for the variables and solvers of
each submodel as e.g. two have a variable named Velocity 395
and all have a function named solve. Variables of the parallel
particle propagation model are shown on lines 1..11. In or-

**Listing 5.** Variables and time stepping loop of a parallel advection program that uses the generic simulation cell class and DCCRG (Honkonen et al., 2013).

ferent processes can be updated (lines 17..19) while the inner simulation cells are solved (lines 21..22). After the amount of incoming particle data is known (line 24) space for that data is allocated (line 25) and eventually received (lines 31..33 and 41). Lines 35..59 solve the parallel game of life and advection problems while finishing up the particle solution for that time step.

All submodels of the combined model run in the same discretized volume and with identical domain decomposition. This is not mandatory though as the cell id list given to each solver need not be identical but in this case the memory for all variables in all cells is always allocated when using variables shown e.g. in Figure 2. If submodels always run in

#### Honkonen: Generic simulation cell method

 Table 1. Summary of application programming interface of generic simulation cell class. Listed functions are members of the cell class unless noted otherwise.

Code	Explanation	Usage example on line # of Listing 2
template <class TP, class Vari- ables&gt;</class 	Transfer policy and arbitrary number of vari- ables to be stored in a cell type given as template arguments	9
operator[] (const Variable& v)	Returns a ref- erence to given variable's data	22
get_mpi_datatype()	Returns MPI trans- fer information for variables selected for transfer	28
set_transfer(const bool b, const Variables& vs)	Switches on or off transfer of given variables in a cell	n/a
set_transfer_all(cons boost::tribool b, const Variables& vs)	t Static class func- tion for switching the transfer of given variables in all cell instances on, off or to be decided on a cell- by-cell basis by set_transfer()	25
Member operators +=, -=, *=, /= and free operators +, -, * and /	Operations for two cells of the same type or a cell and standard types, the operator is applied to each variable stored in given cell(s)	n/a

non-overlapping or slightly overlapping regions of the simulated volume, and/or a method other than domain decomposition is used for parallelization, the memory required for the variables can be allocated at run time in regions/processes where the variables are used. This can potentially be accomplished easily by wrapping the type of each variable in the boost::optional<sup>2</sup> type, for example.

**Listing 7.** Example of one way coupling between the parallel advection and particle propagation models. The clock-wise rotating velocity field of the advection model (line 6) is periodically used by the particle propagation model instead of the counter clock-wise 460 rotating velocity field of the particle propagation model (line 15).

# 5 Coupling models that use generic simulation cell method 465

- In the combined model shown in previous section the submodels cannot affect each other as they all use different variables and are thus unable to modify each other's data. In order to couple any two or more submodels new code must be 470 written or existing code must be modified. The complexity
- 420 of this task depends solely on the nature of the coupling. In simple cases where the variables used by one solver are only switched to variables of another solver, only the template parameters given to the solver have to be switched. 475
- Figure 7 shows an example of a one way coupling of the parallel particle propagation model with the advection model by periodically using the velocity field of the advection model in the particle propagation model. A similar approach could be relevant e.g. in modeling atmospheric trans- 480 port of volcanic ash in velocity fields of a weather predic-
- tion model (Kerminen et al., 2011). On line 6 the particle solver is called with the velocity field of the advection model while on line 15 the particle model's regular velocity field is used. More complex cases of coupling, which require e.g. additional variables or transferring variable data between pro-485
- 435 cesses, are also simple to accomplish from the software development point of view. Additional variables can be freely inserted into the generic cell class and used by new couplers without affecting other submodels and the transfer of new variables can be activated by inserting calls to e.g. the generic

440 cell's set\_transfer\_all() function as needed.

#### 6 Effect on serial and parallel performance

In order to be usable in practice the generic cell class should not slow down a computational model too much and ideally neither serial nor parallel performance should be affected when compared to hand-written code with identical functionality. I test this using two programs: a serial GoL model and a parallel particle propagation model. The tests are conducted on a four core 2.6 GHz Intel Core i7 CPU with 256 kB L2 cache per core, 16 GB of 1600 MHz DDR3 RAM and the following software: OS X 10.9.2, GCC 4.8.4 0 from MacPorts, Open MPI 1.8.4, Boost 1.56.0 and dccrg commit 7d5580a30 dated 2014-01-12 from the c++11 branch at https://gitorious.org/dccrg/dccrg. The programs are compiled with -O3 -std=c++0x. Where available/supported the options -march=native and -mtune=native were found to increase program speed by about 0.2 % with GCC on another machine and 3 % with Clang on the hardware described above.

#### 6.1 Serial performance

445

450

455

Serial performance of the generic cell is tested by playing GoL for 30 000 steps on a 100 by 100 grid with periodic boundaries and allocated at compile time. Performance is compared against an implementation using struct { bool; int; }; as the cell type. Both implementations are available in the directory tests/serial/game\_of\_life. Each timing is obtained by executing 5 runs, discarding the slowest and fastest runs and averaging the remaining 3 runs. As shown in Table 6.1 serial performance is not affected by the generic cell class, but the memory layout of variables regardless of the cell type used affects performance by over 10 %. Column 2 specifies whether is\_alive or live\_neighbors is stored at a lower memory address in each cell. By default the memory alignment of the variables is implementation defined but on the last two rows of Table 6.1 alignas(8) is used to obtain 8 byte alignment for both variables. The order of the variables in memory in a generic cell consisting of more than one variable is not defined by the standard. On the tested system the variables are laid out in memory by GCC in reverse order with respect to the order of the template arguments. Other compilers do not show as large differences between different ordering of variables, with ICC 14.0.2 all run times are about 6 s using either -O3 or -fast (alignas is not yet supported) and with Clang 3.4 from MacPorts all run times are about 3.5 s (about 3.6 s using alignas).

#### 6.2 Parallel performance

490

Parallel performance of the generic cell class is evaluated with a particle propagation test which uses more complex variable types than the GoL test in order to emphasize the computational cost of setting up MPI transfer information in the generic cell class and a manually written reference

**Table 2.** Run times of serial GoL programs using different cell types and memory layouts for their variables compiled with GCC 4.8.4.

Cell type	Memory layout	Run time (s)
generic	bool first	1.422
generic	int first	1.601
struct	bool first	1.424
struct	int first	1.603
struct	bool first, both aligned to 8 B	1.552
struct	int first, both aligned to 8 B	1.522

cell class. Both implementations are available in the directory tests/parallel/particle\_propagation. Parallel tests are compiled with GCC and are run using 3 processes and the final time is the average of the times reported by each process. Similarly to the serial case each test is executed 5 times, outliers are discarded and the final result averaged over the remaining 3 runs. The tests are run on a 20<sup>3</sup> grid without periodic boundaries and RANDOM load balancing is used to emphasize the cost of MPI transfers. The runtime of generic cell class version is 2.2 s and of reference program is 3.1 s.

- The extra time in reference program is spent in MPI regions but more detailed profiling was not done as the point is only to show that the generic simulation cell class does not slow down the parallel program. The output files of the different
- versions are bit identical if the same number of processes is used. When using recursive coordinate bisection load balancing the run times of both are about 0.5 s with the reference program being 10 % slower. A similar result is expected for a larger number of processes as the bottleneck will likely be
  in the actual transfer of data instead of the logic for setting up the transfers.

#### 7 Converting existing software

515

Existing software can be gradually converted to use a generic 530 cell syntax but the details depend heavily on the modularity of said software and especially on the way data in transferred between processes. If a grid library decides what to transfer and where and the cells provide this information via an MPI datatype, conversion will likely require only small changes.

- Figure 8 shows an example of converting a Conway's Game of Life program using cell-based storage (after Figure 535 4 of Honkonen et al., 2013) to the application programming interface used by the generic cell class. In this case the underlying grid library handles data transfers between processes so the only additions required are empty classes for denoting
- $_{525}$   $\,$  simulation variables and the corresponding [] operators for  $_{540}$

```
1
   struct game of life cell {
2
      int data [2];
3
4
      std::tuple<
5
        void * ,
6
        int.
7
        MPI Datatype
      > get mpi datatype() const {
8
9
        return std::make tuple(
10
           (void*) \& (this \rightarrow data [0]),
11
           1.
          MPI_INT
12
13
        );
14
      }
15
    };
16
   struct Is Alive {};
17
   struct Live_Neighbors {};
18
19
   struct game of life cell compat {
20
21
22
      int& operator [](const Is_Alive&) {
23
        return this \rightarrow data [0];
24
      }
25
26
      int& operator [] (const Live Neighbors&) {
27
        return this -> data [1];
28
      }
    };
29
```

**Listing 8.** An example of converting existing software to use an application programming interface (API) identical to the generic cell class. API conversion consists of adding empty classes for denoting simulation variables on lines 17 and 18, and adding [] operators for accessing the variables' data on lines 22..28. Line 21 is identical to lines 2..14.

accessing the variables' data. With these additions the program can be converted step-by-step to use the generic cell class API and once complete the cell implementation shown in Figure 8 can be swapped with the generic cell.

#### 8 Discussion

The presented generic simulation cell method has several advantages over implementations using less generic programming methods:

 The changes required for combining and coupling models that use the generic simulation cell class are minimal and in the presented examples no changes to existing code are required for combining models. This is advantageous for program development as submodels can be tested and verified independently and also subsequently used without modification which decreases the possibility of bugs and increases confidense in the correct functioning of the larger program. 590

2. The generic simulation cell method enables zero-copy code coupling as an intermediate representation for model variables is not necessary due to the data types of simulation variables being visible outside of each 595 model. Thus if coupled models use a compatible representation for data, such as IEEE floating point, the variables of one model can be used directly by another one without the first model having to export the data to an intermediate format. This again decreases the chance for 600 bugs by reducing the required development effort and by allowing the compiler to perform type checking for the entire program and warn in cases of e.g. undefined behavior (Wang et al., 2012).

Arguably code readability is also improved by making <sup>605</sup> simulation variables separate classes and making models a composition of such variables. Shorthand notation for accessing variables' data is also possible if the reduction in verbosity is deemed acceptable:
 <sup>610</sup>

```
constexpr Mass_Density Rho{};
constexpr Velocity V{};
cell_data[Rho] = ...;
cell_data[V][0] = ...;
cell_data[V][1] = ...;
...
```

For many intents and purposes the presented cell class acts identically to the standard heterogeneous container std::tuple (see also Section 3 on using tuple as a substitute in serial <sup>620</sup> code) while providing additional syntactical sugar for serial programs and helpful functionality for distributed memory

parallel programs. For example the question of memory layout of simulation

variables, whether each simulation variable should be stored
 <sup>62</sup> contiguously in memory or interleaved with other variables at the same location in the simulated volume, also applies not only when using standard C++ containers but to other programming languages as well. The key factor in this case seems to be the locality principle (Denning, 2005), i.e. that

- all hierarchies of computer (registers, caches, etc.) storage are reused as efficiently as possible while processing. For simulations modeling systems of multiple coupled equations it could well be that storing related variables, representing the same location of the simulated volume, contiguously in
- <sup>585</sup> memory leads to faster execution than storing each variable separately from others. This is because e.g. the smallest unit a CPU cache operates on is of the order of 100 bytes<sup>3</sup> so fetching variables of one neighbor cell could lead to many

more reads from memory if each variable is stored in a separate array instead of being stored close to the neighbor's other variables. It should be quite simple to add the functionality of the cell class presented here to an existing grid library that would store all variables in separate contiguous arrays but this might not result in faster program execution and would violate at least rules 5 and 33 of Sutter and Alexandrescu (2011), namely "Give one entity one cohesive responsibility." and "Prefer minimal classes to monolithic classes". If such functionality is absolutely necessary one could store e.g. one DCCRG grid (which itself stores only one type such as double in each of its own cells) in each variable given to the generic simulation cell class.

Other methods of speeding up a program, such as vectorization and threading, do not seem to be affected by using the generic simulation cell class. For example the run time of a threaded version of the combined parallel program (available in examples/combined/parallel\_async.cpp), that uses std::async to (potentially) launch each solver in a new thread at each time step, is reduced to less than 75 % of the original program on the system described in Section 6.1 when using a 100 by 100 grid without I/O. As different solvers cannot access each other's data they can be run simultaneously in different threads. If submodels are coupled, e.g. as in Figure 7, standard concurrency mechanisms can be used such as std::atomic or std::mutex. Access to entire simulation cells can be serialized with a mutex or it can guard a group of related variables (e.g. one for each of lines 39 and 40 in Figure 1) or single variables.

The possibility of using a generic simulation cell approach in the traditional high-performance language of choice -Fortran - seems unlikely as it currently lacks support for compile-time generic programming (McCormack, 2005). For example a recently presented computational fluid dynamics package implemented in Fortran, using an object oriented approach and following good software development practices (Zaghi, 2014), uses hard-coded names for variables throughout the application. Thus if the names of any variables had to be changed for some reason, e.g. coupling to another model using identical variable names, all code using those variables would have to be modified and tested to make sure no bugs have been introduced.

#### 9 Conclusions

I present a generic simulation cell method which allows one to write generic and modular computational models without sacrificing serial or parallel performance or code readability. I show that by using this method it is possible to combine several computational models without modifying any existing code and only write new code for coupling models. This is a significant advantage for model development which reduces the probability of bugs and eases development, testing and validation of computational models. Performance tests
