## Abstract

In this study we present a dynamic model evaluation of the chemistry transport model LOTOS-EUROS (LOng Term Ozone Simulation - EUROpean Operational Smog) to analyse the ability of the model to reproduce observed non-linear responses to emission changes and interannual variability of secondary inorganic aerosol (SIA) and its precursors over Europe from 1990 to 2009. The 20 year simulation was performed using a consistent set of meteorological data provided by RACMO2 (Regional Atmospheric Climate MOdel). Observations at European rural background sites have been used as reference for the model evaluation. To ensure the consistency of the used observational data stringent selection criteria were applied including a comprehensive visual screening to remove suspicious data from the analysis. The LOTOS-EUROS model was able to capture a large part of the seasonal and interannual variability of SIA and its precursors' concentrations. The dynamic evaluation has shown that the model is able to simulate the declining trends observed for all considered sulphur and nitrogen components following the implementation of emission abatement strategies for SIA precursors over Europe. Both, the observations and the model show the largest part of the decline in the 1990's while smaller concentration changes and an increasing number of non-significant trends are observed and modelled between 2000-2009. Furthermore, the results confirm

1 former studies showing that the observed trends in sulphate and total nitrate concentrations from  
2 1990 to 2009 are lower than the trends in precursor emissions and precursor concentrations. The  
3 model well captured these non-linear responses to the emission changes. Using the LOTOS-EUROS  
4 source apportionment module trends in formation efficiency of SIA have been quantified for four  
5 European regions. The exercise has revealed a 20-50% more efficient sulphate formation in 2009  
6 compared to 1990 and an up to 20% more efficient nitrate formation per unit nitrogen oxide  
7 emission, which added to the explanation of the non-linear responses. However, we have also  
8 identified some weaknesses to the model and the input data. LOTOS-EUROS underestimates the  
9 observed nitrogen dioxide concentrations throughout the whole time period, while it overestimates  
10 the observed nitrogen dioxide concentration trends. Moreover, model results suggest that the  
11 emission information of the early 1990's used in this study needs to be improved concerning  
12 magnitude and spatial distribution.

14

## 15 **1 Introduction**

16 Atmospheric input of sulphur and nitrogen components may decrease biodiversity in vulnerable  
17 terrestrial and aquatic ecosystems through eutrophication and acidification of soils and fresh water  
18 (Bobbink et al., 1998). The major sources of sulphur and reactive nitrogen in the atmosphere are  
19 sulphur dioxide ( $\text{SO}_2$ ) and nitrogen oxide ( $\text{NO}_x$ ) emissions from fossil fuel combustion and ammonia  
20 ( $\text{NH}_3$ ) emissions from agricultural activities. Although these gases may themselves be removed from  
21 the atmosphere by dry deposition or rainout, they are the precursor gases for SIA (sulphate ( $\text{SO}_4^{2-}$ ),  
22 nitrate ( $\text{NO}_3^-$ ) and ammonium ( $\text{NH}_4^+$ )). The latter provides a means for long-range transport of  
23 reactive nitrogen on a continental scale causing negative ecosystem impacts far away from their  
24 major source areas. In addition, SIA contributes a large portion of particulate matter concentration  
25 throughout the European domain (Putaud et al., 2010). Especially ammonium nitrate ( $\text{NH}_4\text{NO}_3$ )  
26 concentrations are shown to be particularly enhanced during days with PM10 concentrations up or  
27 above the EU (European Union) daily limit value (e.g. Weijers et al., 2011). Moreover, SIA are  
28 involved in climate change by affecting the radiation balance of the earth (Forster et al., 2007).  
29 Recent studies show that short term climate mitigation aimed at reducing black carbon may be  
30 effective, provided that the climate impact of the co-emitted SIA precursors does not cause a net  
31 cooling impact (Bond et al., 2013). Hence, a thorough understanding of the SIA budget is required to

1 inform policy makers and to devise mitigation strategies that are effective for biodiversity, climate  
2 change and human health.

3 To combat the adverse impacts on biodiversity and human health a series of international  
4 conventions and agreements were implemented. The Convention on Long-range Transboundary Air  
5 Pollution was adopted in 1979 and the related Gothenburg Protocol establishing emission ceilings for  
6 sulphur oxides (SO<sub>x</sub>), NO<sub>x</sub>, volatile organic compounds (VOCs) and NH<sub>3</sub> for 2010 negotiated by the  
7 EU Member States together with Central and Eastern European countries, the United States and  
8 Canada was accepted in 1999 (UNECE, 1999). The National Emissions Ceiling Directive (NECD  
9 2001/81/EC) was introduced in 2001 (EC, 2001) setting national emission ceilings for the EU  
10 countries for 2010 and 2020. The implemented mitigation measures have led to significant emission  
11 reductions (Grennfelt and Hov, 2005). According to the European Environmental Agency (EEA)  
12 (2012), SO<sub>x</sub> emissions have decreased by 75%, NO<sub>x</sub> emissions by 42% and NH<sub>3</sub> emissions by 28% in  
13 the EEA-32 group of countries from 1990-2010. As part of the conventions air pollution monitoring  
14 networks have been implemented over Europe providing a long-term observation facility to be able  
15 to assess the effectiveness of the implemented air quality management. Although the substantial  
16 emission reductions of SO<sub>x</sub>, NO<sub>x</sub> and NH<sub>3</sub> are largely reflected in the trends of pollutant  
17 concentrations and wet deposition fluxes, the responses were found to be non-linear (e.g. Lövblad et  
18 al., 2004; Fagerli and Aas, 2008; Tørseth et al., 2012; Harrison et al., 2014). These studies  
19 highlighted that for SIA and its precursors the implemented emission mitigation measures did not  
20 completely meet the expected concentration reduction. Hence, understanding of the non-linear  
21 responses is important to be able to provide robust policy support.

22 Chemistry transport models (CTMs) are used to analyse potential emission reduction strategies and  
23 quantify their effectiveness. Before the CTMs can be used to inform policy development they need to  
24 be evaluated. Dennis et al. (2010) introduced a comprehensive evaluation framework in which four  
25 types of model evaluation are identified: operational, diagnostic, dynamical and probabilistic  
26 evaluation. Operational model evaluations have been performed within a huge number of studies  
27 using standard statistical and graphical analysis to determine how the model results compare with  
28 observations (e.g. Appel et al., 2011, Thunis et al., 2012). Diagnostic model evaluation, focussing on  
29 the description of an individual process or component in the model has also been subject of many  
30 studies (e.g. Fahey and Pandis, 2003; Redington et al., 2009; Banzhaf et al., 2012). Recently,  
31 probabilistic or ensemble based evaluation has gained popularity as the ensemble mean of a group of  
32 models shows mostly the best model performance in comparison to observations (Vautard et al.,

1 2007; McKeen et al., 2005). Dynamic model evaluations, in which the ability of the modelling  
2 system to capture the observed responses to changes in emissions or meteorology is analysed, have  
3 only been performed in a few studies so far (e.g. Berglen et al., 2007).

4 CTMs need to be able to capture non-linear responses of the emission-concentration and emission-  
5 deposition relationship as well as interannual variability over the last 15-20 years to provide  
6 confidence in the use of CTMs for regulatory purposes (Civerolo et al., 2010). Colette et al. (2011)  
7 investigated the capability of six state-of-the-art chemistry transport models to reproduce air quality  
8 trends and interannual variability of ozone (O<sub>3</sub>), nitrogen dioxide (NO<sub>2</sub>) and PM<sub>10</sub> for the time  
9 period of 10 years from 1998-2007. They concluded that the models captured most of the important  
10 features to justify their implementation for future projections of air quality provided that enough  
11 attention is given to their underestimation of interannual variability. Fagerli and Aas (2008) found  
12 that the EMEP (European Monitoring and Evaluation Programme) model's response for nitrogen in  
13 air and precipitation to emission changes over Europe from 1980-2003 is reasonable. The results  
14 indicated a lack of trends in total nitrate (TNO<sub>3</sub>: sum of aerosol nitrate and gaseous nitric acid)  
15 concentrations despite NO<sub>x</sub> emission reductions and it was concluded from the model simulations  
16 that this non-linear behaviour can partly be attributed to a shift in the equilibrium between nitric acid  
17 (HNO<sub>3</sub>) and NH<sub>4</sub>NO<sub>3</sub> towards particulate phase, which was caused by SO<sub>2</sub> emission reductions.  
18 However, the model simulations could not be performed using a consistent meteorological data set  
19 for all simulated years. Civerolo et al. (2010) performed an 18-year CMAQ (Community Multi-scale  
20 Air Quality) simulation (1988-2005) over the north-eastern United States enabling the investigation  
21 of spatial patterns and seasonal variations, but also on long-term trends of SO<sub>4</sub><sup>2-</sup> and NO<sub>3</sub><sup>-</sup> in the  
22 presence of emissions changes and meteorological variability. The results suggested that the  
23 modelling system largely captured the long-term trends in sulphur and nitrogen compounds. While  
24 the seasonal changes in sulphur compounds were also captured, the model did not reproduce the  
25 average seasonal variation or spatial patterns in NO<sub>3</sub><sup>-</sup>.

26 Former studies suggest that the non-linear response of pollutant concentrations to emission changes  
27 can be attributed to the differing magnitude of emission reduction for the different substances  
28 (Løvblad et al., 2004; Fagerli and Aas, 2008) inducing shifts in the atmospheric chemistry and  
29 equilibrium between gas- and particulate phase, which determine the gas to particle conversion.  
30 These non-linearities have been also identified in short term modelling studies that focus on the  
31 sensitivity of SIA formation to precursor emission reductions (e.g. Erisman and Schaap, 2004;  
32 Redington et al., 2009; Derwent et al., 2009; Banzhaf et al., 2013). State of the art labelling

1 approaches (Yarwood et al., 2007; Wagstrom et al., 2008) can be applied to track the source  
2 allocation for secondary aerosols and its precursor gases to study the response of atmospheric  
3 chemistry to emission changes. However, long-term simulations including a source apportionment  
4 have not yet been performed due to the high computational burden. Kranenburg et al. (2013)  
5 introduced a source apportionment module for the operational CTM LOTOS-EUROS, which enables  
6 long-term simulations with source attribution to investigate possible trends in the gas to particle  
7 formation efficiency that accompanied the changes in emission levels over time. We aim to evaluate  
8 the LOTOS-EUROS model for its ability to model the trends in SIA concentrations and, at the same  
9 time, investigate the non-linearity in SIA formation.

10 In this study a model run of 20 years from 1990 to 2009 was performed with a horizontal grid  
11 resolution of  $0.50^\circ$  longitude x  $0.25^\circ$  latitude over Europe using the CTM LOTOS-EUROS (section  
12 2.1.1). The model explicitly accounts for cloud chemistry and aerosol thermodynamics. The model  
13 run is based on emissions for 1990, 1995, 2000, 2005 and 2010 provided by the International Institute  
14 for Applied Systems Analysis (IIASA) (section 2.1.2) and a consistent 3 hourly meteorological data  
15 set from 1990 to 2009 obtained from the regional climate model RACMO2 (section 2.1.2) of the  
16 Royal Netherlands Meteorological Institute (KNMI). The modelled concentrations of SIA and its  
17 precursors are compared to observations at rural background sites (section 2.2). By means of an  
18 operational (section 3.1) and a dynamic evaluation (section 3.2) we identify shortcomings and  
19 limitations of the model system and input data that need to be improved or considered when using the  
20 applied set up for future emission scenarios. In order to enable the analysis of trends in gas to particle  
21 conversion and residence time of the involved species the source apportionment module of LOTOS-  
22 EUROS (section 2.1) has been used to trace the amount of SIA formed per unit emission of  $\text{SO}_2$ ,  $\text{NO}_x$   
23 and  $\text{NH}_3$  for 4 different regions over Europe from 1990-2009 (section 3.3). The results are discussed  
24 and conclusions are drawn in section 4.

25

## 26 **2 Methods and data**

27 This investigation focuses on SIA and its precursors ( $\text{SO}_2$ ,  $\text{NO}_x$  and  $\text{NH}_3$ ) over the time period 1990  
28 to 2009. Although the focus is on this 20 year long period we have also investigated the trends in  
29 concentrations for the shorter time periods 1995-2009 and 2000-2009 because emission reductions  
30 did not proceed linearly and in line with each other from 1990-2009. By considering several time  
31 periods we could assess the sensitivity of the trend to the different time periods. Furthermore, the

1 amount of available observations increased for the later periods, which made a broader assessment of  
2 the results possible.

3 In the following subsections the applied model and model set-up, the used observations and the  
4 statistic tools we have used to evaluate the model and calculate and assess the observed and modelled  
5 trends are described.

6

## 7 **2.1 Simulation description**

### 8 **2.1.1 Model description LOTOS-EUROS**

9 LOTOS-EUROS is a 3D chemistry transport model. The off-line Eulerian grid model simulates air  
10 pollution concentrations in the lower troposphere solving the advection-diffusion equation on a  
11 regular lat-lon-grid with variable resolution over Europe (Schaap et al., 2008). In this study, model  
12 version 1.8 was used.

13 The vertical transport and diffusion scheme accounts for atmospheric density variations in space and  
14 time and for all vertical flux components. The vertical grid is based on terrain following vertical  
15 coordinates and extends to 3.5 km above sea level. The model uses a dynamic mixing layer approach  
16 to determine the vertical structure, i.e. the vertical layers vary in space and time. The layer on top of a  
17 25 m surface layer follows the mixing layer height, which is obtained from the meteorological input  
18 data that is used to force the model. The height of the two reservoir layers is determined by the  
19 difference between model top at 3.5 km and mixing layer height. If the mixing layer extends near or  
20 above 3.5km, the top of the model exceeds the 3.5 km according to the above-mentioned description.  
21 The horizontal advection of pollutants is calculated applying a monotonic advection scheme  
22 developed by Walcek et al. (2000).

23 Gas-phase chemistry is simulated using the TNO CBM-IV scheme, which is a condensed version of  
24 the original scheme (Whitten et al, 1980). Hydrolysis of N<sub>2</sub>O<sub>5</sub> is explicitly described following  
25 Schaap et al. (2004). LOTOS-EUROS explicitly accounts for cloud chemistry computing SO<sub>4</sub><sup>2-</sup>  
26 formation as a function of cloud liquid water content and cloud droplet pH as described in Banzhaf et  
27 al. (2012). For Aerosol chemistry LOTOS-EUROS features the thermodynamic equilibrium module  
28 ISORROPIA2 (Fountoukis and Nenes, 2007). Dry Deposition fluxes are calculated following a  
29 resistance approach as described in Erisman et al. (1994). Furthermore, a compensation point  
30 approach for NH<sub>3</sub> is included in the dry deposition module (Wichink Kruit et al., 2012). The wet

1 deposition module is based on precipitation rates using simple scavenging coefficients for the below  
2 cloud scavenging of gases (Schaap et al, 2004) and particles (Simpson et al, 2003).

3 In LOTOS-EUROS, the temporal variation of the emissions is represented by monthly, day-of-the-  
4 week and hourly time factors that break down the annual totals for each source category. An included  
5 biogenic emission routine is based on detailed information on tree species over Europe (Koeble and  
6 Seufert, 2001). The emission algorithm is described in Schaap et al. (2009) and is very similar to the  
7 simultaneously developed routine by Steinbrecher et al. (2009). Sea salt emissions are described  
8 using Martensson et al. (2003) for the particles  $<1\mu\text{m}$  and Monahan et al. (1986) for the coarser  
9 particles.

10 LOTOS-EUROS includes a source apportionment module, which enables tracking the source  
11 contribution of a set of sources through the model system. The emissions can be categorized in  
12 several source categories (e.g. countries or sector) and labelled accordingly before the model is run.  
13 The total concentration of each substance for each time step and in each grid cell is modelled as  
14 before, but next to this, the fractional contribution of each label to every species is calculated. During  
15 each process, the new fractional contribution of each label is defined by calculating a weighted  
16 average of the fractions before the process and the concentration change during the process. The  
17 labelling routine is only implemented for chemically active tracers containing C, S or N (reduced and  
18 oxidized) atoms, as these are conserved and traceable. The source apportionment module is  
19 extensively described in Kranenburg et al. (2013).

20 The LOTOS-EUROS model has participated in several international model inter comparison studies  
21 addressing  $\text{O}_3$  (Hass et al, 1997; Van Loon et al, 2007; Solazzo et al., 2012a) and particulate matter  
22 (Cuvelier et al, 2007; Hass et al, 2003; Stern et al, 2008; Solazzo et al., 2012b) and shows  
23 comparable performance to other European models.

24

### 25 2.1.2 Model setup

26 A model run of 20 years from 01.01.1990 to 31.12.2009 has been performed on a domain covering  
27 Europe ( $35^\circ\text{N}$ - $70^\circ\text{N}$ ;  $10^\circ\text{W}$ - $40^\circ\text{E}$ ) with a horizontal resolution of  $0.50^\circ$  longitude x  $0.25^\circ$  latitude on a  
28 rectangular regular latitude-longitude grid (ca.  $25 \times 25 \text{ km}^2$ ). As described above the lowest dynamic  
29 layer is the mixing layer, taken from the meteorological input.

30 The simulation was forced with a consistent meteorological data set from 1990 to 2009 obtained from  
31 the regional climate model RACMO2 (Lenderink et al., 2003; Van Meijgaard et al., 2008) of the

1 KNMI. At the boundaries the simulation was driven by meteorology from ERA-Interim reanalysis  
2 (Dee et al., 2011). Nudging of meteorological data has not been performed for the model runs and  
3 RACMO2 is only constrained by the lateral boundary conditions. RACMO2 has a horizontal  
4 resolution of  $0.44^\circ$  with 114 points distributed from  $25.04^\circ\text{W}$  to  $24.68^\circ\text{E}$  longitude and 100 points  
5 from  $11.78^\circ\text{S}$  to  $31.78^\circ\text{N}$  latitude in the rotated grid. The South Pole is rotated to  $47^\circ\text{S}$  and  $15^\circ\text{E}$ . In  
6 the vertical, 40 pressure levels were used. As described in Manders et al. (2012) the horizontal  
7 projection of RACMO2 fields on the LOTOS-EUROS grid was carried out by bi-linear interpolation.  
8 The vertical projection of RACMO2 profiles on the much coarser LOTOS-EUROS vertical grid was  
9 achieved by mass-weighted averaging of those RACMO2 model layers that were fully or partially  
10 contained in each of the LOTOS-EUROS model layers. At the applied resolution RACMO2 uses a  
11 model time step of 15 min and output for coupling with LOTOS-EUROS was generated every three  
12 hours. RACMO2 has been included in ensemble studies with other regional climate models  
13 (Kjellström and Giorgi, 2010; Kjellström et al., 2010; Vautard et al., 2013; Kotlarski et al., 2014) and  
14 has been successfully applied to force LOTOS-EUROS in earlier studies (Manders et al., 2011;  
15 Manders et al., 2012; Mues et al., 2013).

16 Lateral boundary conditions in LOTOS-EUROS were taken from climatological background  
17 concentrations for gases and aerosols. For a number of components we follow the EMEP method  
18 (Simpson et al., 2003) based on measured data, in which simple functions were derived to match the  
19 observed distributions. Some aerosol species are set to constant at the boundaries.  $\text{NH}_3$  boundary  
20 conditions are neglected.  $\text{SO}_4^{2-}$  is assumed to be fully neutralised by ammonium. Nitrate values are  
21 assumed to be included in those of  $\text{HNO}_3$  (derived following Simpson et al. (2003)) and are zero as  
22 well. The climatology fields did not include windblown dust going back to 1990. Hence, dust from  
23 e.g., wind erosion, agricultural land management and resuspension by road transport has been  
24 neglected, as it does not contribute to the here investigated substances. For  $\text{O}_3$  we have used the  
25 climatological dataset by Logan (1999), derived from  $\text{O}_3$  sonde data. For the interpretation of the  
26 model results we need to keep in mind that there are no trends in boundary conditions considered  
27 over the investigated 20 year period.

28 The emissions applied in this study were provided by IIASA. The data was generated using RAINS  
29 (Regional Air pollution INformation and Simulation) model output for 1990-2000 and GAINS  
30 (Greenhouse gas and Air pollution INteractions and Synergies) model output for 2000-2010. A  
31 description of the RAINS model and the GAINS model can be found in Amann et al. (1999) and  
32 Amann et al. (2011), respectively. Annual total emissions were provided per country, per sector and

1 per SNAP (Selected Nomenclature for Air Pollutants) code for 1990, 1995, 2000, 2005 and 2010. A  
2 linear interpolation was performed to fill in the emissions of the years within the delivered ones.  
3 Figure 1a shows the trends in SO<sub>2</sub>, NO<sub>x</sub> and NH<sub>3</sub> emissions in the EU-27 member States including  
4 Norway and Switzerland (= EU-27+) for 1990 to 2010 in % with 1990 as reference derived from the  
5 applied final emission inventory. The corresponding absolute annual total emissions of SO<sub>2</sub>, NO<sub>x</sub> and  
6 NH<sub>3</sub> of the EU27+ member States for 1990, 1995, 2000, 2005 and 2010 are presented in Table S1 in  
7 the Supplement. The emissions have decreased over Europe for all considered components. The slope  
8 of the decrease in Figure 1a has been computed using a standard linear least square method. Most  
9 emission reduction was achieved for SO<sub>2</sub> with a negative trend of -3.9% a<sup>-1</sup> (a: annum) leading to a  
10 decrease of more than 70% from 1990 to 2010. NO<sub>x</sub> emissions have been decreased by somewhat  
11 less than 50% in the same time period (-2.52% a<sup>-1</sup>) followed by NH<sub>3</sub> emissions with a decrease of  
12 somewhat less than 20% from 1990 to 2009 (0.85% a<sup>-1</sup>). In Figure 1a we present results for the  
13 emission trends since 1990 for the EU-27+ member States as a whole. While it is known that  
14 emission changes from 1990 to 2009 differed significantly from region to region, precise information  
15 on the spatial distribution of the emissions for the early 90s is lacking. Although EMEP provides  
16 information on changes in the emission distribution from the early 1990s onwards we used the TNO  
17 MACC (Monitoring Atmospheric Composition and Climate) (Denier van der Gon et al., 2010;  
18 Pouliot et al., 2012) spatial distribution of emissions for the year 2005 for the entire time period of  
19 investigation. We believe that current emission allocation proxies are more reliable than the ones  
20 used in the 1990s. Furthermore, the EMEP emission information for the 1990s is only available on a  
21 resolution of 150x150 km<sup>2</sup>, which is much lower than the resolution of the applied MACC  
22 distribution and is therefore not expected to provide an improvement. Annual emissions from  
23 international shipping per sea and per sector were provided by the Centre on Emission Inventories  
24 and Projections (CEIP). Figure 1b shows the trends in SO<sub>2</sub> and NO<sub>x</sub> International Shipping emissions  
25 for 1990 to 2010 in % with 1990 as reference. Included are the Baltic Sea, the North-East Atlantic  
26 Ocean, the North Sea, the Mediterranean Sea and the Black Sea. NO<sub>x</sub> emissions have increased over  
27 the whole time period 1990 to 2009 for all seas while SO<sub>2</sub> emissions have increased for the North-  
28 East Atlantic Ocean, the Mediterranean Sea and the Black Sea. In the Sulphur Emission Control  
29 Areas of the North Sea (“NOS” in Figure 1b) and the Baltic Sea (“BAS” in Figure 1b) SO<sub>2</sub> emissions  
30 have increased from 1990 to 2005 and decreased thereafter due to improved fuel quality. The  
31 absolute annual total emissions of SO<sub>2</sub> and NO<sub>x</sub> (summed over all included seas listed above) for  
32 1990, 1995, 2000, 2005 and 2010 are given in Table S1 in the Supplement.

1 In order to analyse the trends in gas to particle conversion and residence time of the involved species  
2 the LOTOS-EUROS source apportionment module was applied. We defined 5 labels for tracking 10  
3 kilo tons (ktons) of SO<sub>2</sub>, NO<sub>x</sub> and NH<sub>3</sub> emissions from either one of these. The labels were defined to  
4 represent the following geographical areas:

- 5 1. The Netherlands and Belgium
- 6 2. Baltic Sea (international shipping)
- 7 3. Czech Republic
- 8 4. Romania
- 9 5. Rest

10 Ten ktons of precursor emission were chosen, as it is certainly smaller than the single country annual  
11 total emissions for 2009. Note that the 10 ktons are chosen arbitrary as tracking any other fraction of  
12 the emissions would give the same results due to the labelling approach used (Kranenburg et al.,  
13 2013). In practice, for each year the 10 ktons are normalized to the total emissions. The obtained  
14 fraction is applied to all emissions in the country and allocated to the respective label. Together with  
15 the simulation of each substance in each grid cell on hourly basis, the fractional contribution of each  
16 of the above labels to every substance, including SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup>, is calculated. By means of  
17 the latter the amount of SIA formed from the 10 ktons of precursor gases can be derived for each  
18 label and possible trends in gas to particle conversion within the time period 1990 to 2009 can be  
19 analysed.

20

## 21 **2.2 Observations**

22 In the following subsections we describe the in-situ surface observations that were used to evaluate  
23 the LOTOS-EUROS model and to derive the observed trends in SIA and its precursors  
24 concentrations (Section 2.2.1) and the observations used to compare to the meteorological input data  
25 provided by RACMO2 (Section 2.2.2).

### 26 **2.2.1 Species concentrations**

27 The European EMEP observational network is devised for trend assessment (EMEP/CCC, 2001;  
28 Hjellbrekke and Fjæraa, 2011). The EMEP data is validated through a quality assurance/quality  
29 control process involving the individual institutions responsible for the different sites and the EMEP-

1 CCC as documented by several reports available on the EMEP website ([www.emep.int](http://www.emep.int)). Data was  
2 downloaded from the EBAS repository (<http://ebas.nilu.no/>, download in autumn 2012). However,  
3 only a few selected stations per country are included in the network. In addition to the EMEP sites,  
4 the stations of AirBase (European AIR quality database), the public database of the EEA, were added  
5 to the observational data set (<http://airbase.eionet.europa.eu/>, download in autumn 2012). The latter  
6 are not specifically devised for trend assessment but have been used in several studies on long-term  
7 trends (e.g. EEA, 2009; Colette et al., 2011; Wilson et al., 2012). The data reported to AirBase are  
8 quality controlled and checked prior to submission by the countries that provide the data.

9 This study is aimed to investigate the transboundary trend of concentrations in the European  
10 background following emission changes all over Europe from 1990-2009. Hence, only rural  
11 background stations are included in the applied observational data set. The analysis is based on daily  
12 observations. The consistency of the observational data set used for the trend assessment and the  
13 operational and dynamical model evaluation was ensured by the implementation of three selection  
14 criteria derived from the guidelines of the EEA (EEA, 2009; Colette et al., 2011):

- 15 1. The annual coverage of data must be larger than 75 %
- 16 2. With criterion No. 1 fulfilled, at least 80% of the annual time series must be available
- 17 3. Passing a visual screening of the data

18 For each time period (1990-2009, 1995-2009 and 2000-2009) a separate data subset of stations within  
19 the model domain (35°N-70°N; 10°W-40°E) was built based on the selection criteria described  
20 above. As we also address relative trends within this study we consider it important to have the first  
21 year of each time period covered. Hence, only stations that could provide the requested 75% data  
22 coverage for the first year of the time period were included in the corresponding subset.

23 Finally, a visual screening of the time series of daily observations for all species and at all stations  
24 that had passed the selection criteria described above was performed. Surprisingly many defective  
25 time series have been identified. The corresponding stations have been removed from the subsets.  
26 The most frequently reasons for removal from the data set were high detection limits throughout the  
27 time series leading to disappearing concentration regimes, high amounts of implausible outliers/peaks  
28 and constant value signals over long time periods. The data reliability is further discussed in section  
29 4.

30 It was found that due to a lack of data the analyses of NH<sub>3</sub> observations could not be included in the  
31 study. However, total ammonia (TNH<sub>4</sub>: sum of aerosol ammonium and gaseous ammonia)

1 observations were included in the trend assessment as considerably more stations with  $\text{TNH}_4$   
2 observations than with  $\text{NH}_4$  observations were available. The latter was also the case for  $\text{TNO}_3$  and  
3  $\text{NO}_3$ . Hence, the considered observed components within this study are  $\text{SO}_2$ ,  $\text{SO}_4^{2-}$ ,  $\text{NO}_2$ ,  $\text{TNO}_3$  and  
4  $\text{TNH}_4$ . In the Supplement, Figure S1 to Figure S3 show maps of the locations of the observational  
5 sites used for the analysis for the different components and the different time periods. Table 1  
6 summarizes the number of stations for the different species and subsets before and after the visual  
7 screening. The number of discarded stations is highest for  $\text{SO}_2$  and  $\text{NO}_2$ . For both components a large  
8 part of the considered stations are from AirBase passing through a less stringent quality control  
9 process than EMEP stations.

10 Due to a lack of long-term monitoring sites within Great Britain, France, Spain and the  
11 Mediterranean region within the monitoring networks used in this study the majority of sites for  $\text{SO}_2$   
12 and  $\text{NO}_2$  observations is located within central Europe accompanied by several sites in northern and  
13 eastern Europe. For both components no southern European station and in the case of  $\text{NO}_2$  no  
14 western European station was available for comparison for the 20 years period. For the time period  
15 1995-2009 an increasing number of eastern and western European stations and in the case of  $\text{SO}_2$  one  
16 southern European station passed the selection criteria. For  $\text{TNO}_3$  and  $\text{TNH}_4$  additionally to the lack  
17 of long-term observations in southern and western Europe, a lack of observations in central Europe  
18 was found and the few available sites are located in northern and eastern Europe. Stations in  $\text{NH}_3$  hot  
19 spot regions like e.g. the Netherlands or the Po valley did not pass the data selection criteria for any  
20 of the time periods. Also for  $\text{SO}_4^{2-}$  no southern European station was available for 1990-2009. The  
21 available stations are distributed over Western, Eastern and Northern Europe with most stations being  
22 located in Northern Europe. For 1995-2009 central and eastern European stations and one southern  
23 European station could be included in the analysis. We would like to stress that the stations at which  
24  $\text{SO}_2$  and  $\text{SO}_4^{2-}$  concentrations are investigated may partly differ.

25 Finally, for the time period 2000-2009 few southern European stations could be included in the  
26 analysis of all considered components. Furthermore, Figure S4 in the Supplement shows for each  
27 component those stations that pass the data selection criteria for all considered time periods.

28

### 29 2.2.2 Meteorological observations

30 Selected parameters of the RACMO2 model are compared to observations to be able to assess the  
31 ability of the model to capture the observed meteorological seasonal, annual and interannual

1 variability. For the evaluation, data of the European Climate Assessment and Dataset (ECA&D)  
2 project (Klok and Klein Tank, 2009) is applied. The project was initiated by the European Climate  
3 Support Network (ECSN) and is funded by and coordinated at the KNMI. A compilation of daily  
4 observations obtained from climatological divisions of national meteorological and hydrological  
5 services, observatories and research centres throughout Europe and the Mediterranean are included in  
6 the database. The data series of observations is combined with quality control and analysis of  
7 extremes via climate change indices (Klein Tank et al., 2002).

8 Daily observed series of 4 parameters that affect atmospheric chemistry have been extracted from the  
9 dataset for the years 1990 to 2009 for evaluation purposes: Temperature (at 2 meter), relative  
10 humidity (at 2 meter), wind speed (at 10 meter) and precipitation. For each parameter a selection of  
11 stations was extracted so that, if available, central, northern, eastern, southern and western European  
12 stations were included in the analysis to also enable a regional consideration. For relative humidity  
13 no northern European stations could be included and western European stations were rare concerning  
14 observations of relative humidity and wind speed. In total 206 stations were selected for the  
15 evaluation of modelled temperature, 113 stations for the evaluation of modelled relative humidity,  
16 246 stations for the evaluation of modelled wind speed and 240 stations for the evaluation of  
17 modelled precipitation. The observed station data is compared with model data at the nearest  
18 gridpoint.

19

### 20 **2.3 Statistical measures and methods for evaluation and trend assessment**

21 For the evaluation of the used meteorological input provided by RACMO2 and the resultant  
22 concentrations simulated by LOTOS-EUROS three statistical measures have been applied to assess  
23 the ability of the models to reproduce the observed values:

24

25 1. Correlation coefficient  $r$

$$26 \quad r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2}}$$

Equation 1

27

1        2. Root mean square error (RMSE)

2        
$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (x_i - y_i)^2}$$
        Equation 2

3  
4        3. Bias

5        
$$BIAS = \frac{1}{n} \sum_{i=1}^n (x_i - y_i)$$
        Equation 3

6  
7        where  $x$  is the model output vector and  $y$  its observation counterparts. Each vector has  $n$  elements and  
8         $\bar{x}$  and  $\bar{y}$  represent their mean value. The correlation coefficient (Equation 1) has been applied to  
9        assess the simulated temporal variability and the RMSE (Equation 2) and bias (Equation 3) to assess  
10       the simulated absolute values. The evaluation of RACMO2 and LOTOS-EUROS fields is based on  
11       daily averages.

12       The trends in concentrations are computed using annual averages based on daily data. The slope is  
13       calculated using a standard linear least square method. Within this study we computed only linear  
14       trends and the computation of non-linear trends (Konovalov et al., 2010) or piecewise linear trends  
15       (Carslaw et al., 2011) has not been performed. To assess the significance of the trend a Mann-  
16       Kendall test at the 95% confidence level is performed (Kendall, 1976; Hipel and McLeod, 2005).

17  
18       **3 Results**

19       **3.1 Evaluation of model results**

20       **3.1.1 Evaluation of meteorological fields**

21       The applied meteorological input data has been compared to observations to be able to assess the  
22       ability of RACMO2 to reproduce the observed meteorological annual, interannual and seasonal  
23       variability. In order to limit the length of this article only an abridgement of the performed evaluation  
24       is shown here. Four parameters that considerably impact atmospheric chemistry are shown:  
25       Temperature (at 2 meter), relative humidity (at 2 meter), wind speed (at 10 meter) and precipitation.  
26       The evaluation is based on daily data for the 20 years period. Table 2 summarizes the number of

1 stations, the mean correlation coefficient, the observed mean and RMSE and bias. As an example  
2 Figure 2 shows the 60-days moving average of the four parameters averaged across all available  
3 German stations from 1990-2009. The 60-days moving average was chosen to be able to plot the  
4 whole time series in one graph and, at the same time, to be able to see variability in the time series.

5 As the mean correlation coefficient of 0.97 in Table 2 shows the model captures very well the  
6 temporal distribution of temperature for the considered time period. Figure 2a shows that the  
7 interannual variability (presented here for 66 German stations) is simulated fairly well too. Warm  
8 summers like in 2003 and 2006 and cold winters like the one in 1995/1996 are well reproduced by  
9 RACMO2. However, the bias and also the corresponding graph in Figure 2 indicate a slight  
10 underestimation of the temperature during wintertime in central Europe. The performance of the  
11 model has also been assessed regionally for Northern, Eastern, Southern, Western and Central  
12 Europe separately (not shown here). The underestimation during wintertime was found to be most  
13 distinct for southern and least distinct for northern Europe, which is consistent with findings in van  
14 Meijgaard et al. (2012) and Kotlarski et al. (2014).

15 As Figure 2b illustrates, RACMO2 captures the interannual variability of the relative humidity at 61  
16 German stations less well than that of the temperature (Figure 2a). A regional assessment of the  
17 model performance over Europe has revealed that the latter is most evident at southern European  
18 stations. Also, the model overestimates the relative humidity during wintertime at a large number of  
19 sites in Europe. The latter was again found to be most distinct at southern European stations and may  
20 be connected to the underestimation of the temperature during wintertime. Relative humidity is a  
21 difficult quantity to evaluate, in particular in areas or during episodes with high values of relative  
22 humidity (>95%). However, a mean correlation coefficient of 0.66 at 113 European stations (see  
23 Table 2) indicates that the observed temporal variability is satisfactorily simulated by the model.

24 The temporal variability of the wind speed is also satisfactorily simulated with a mean correlation  
25 coefficient of 0.68 over 246 European stations (see Table 2). Figure 2c displays the mean 60 days  
26 moving average of wind speed for 59 German stations for the investigated time period. The graph  
27 indicates that although the timing is well simulated the model tends to overestimate the wind speed in  
28 central Europe. In central and eastern Europe the overestimation was found to be present throughout  
29 the whole year. In northern and southern Europe RACMO2 overestimates wind speed solely during  
30 wintertime while it tends to slightly underestimate wind speed during summertime.

31 Figure 2d shows the mean 60 days moving average of precipitation for 1990-2009 at 66 German  
32 stations. The figure shows that the interannual variability is modelled satisfactorily in central Europe

1 although it is slightly underestimated. Dry years like 1996, 2003 and 2006 are well reproduced by the  
2 model. RACMO2 underestimates summertime precipitation in southern Europe while it tends to  
3 overestimate wintertime precipitation in northern and central Europe, which was also found by van  
4 Meijgaard et al. (2012) and Kotlarski et al. (2014). Generally, moving from daily to monthly or  
5 annual precipitation sums (not shown here) RACMO2 results compare better to the observed values.  
6 Mean correlation coefficient, RMSE and bias have been calculated at 240 European stations (see  
7 Table 2). The mean correlation of 0.48 indicates that considering the high temporal variability of  
8 precipitation RACMO2 simulates the observed timing reasonably well.

9 For the CTM calculation it is more important to capture the occurrence of precipitation than to  
10 capture its intensity and duration with the meteorological driver as wet deposition is a very efficient  
11 removal process. Therefore, at each of the 240 stations it was investigated on which percentage of  
12 days of the 20 years period the model is able to simulate the observed rain occurrence (rain: yes; rain:  
13 no). In the following a correct modelled rain:yes or rain:no is referred to as ‘hit’. To account for  
14 unphysical small amounts of drizzle that often occur in climate models, daily accumulated  
15 precipitation below 0.5mm was considered as no rain. The results are summarised in Table 3. At 205  
16 out of 240 stations the model is able to correctly simulate the rain occurrence on more than 70% of  
17 the days from 1990-2009.

18 Although some shortcomings in the meteorological input fields were found the outcome of the  
19 evaluation of RACMO2 has shown that the model is capable of satisfactorily reproducing the  
20 observed magnitudes and meteorological annual, interannual and seasonal variability of the  
21 investigated parameters.

22

### 23 3.1.2 Concentrations in air

24 The summary of the statistical evaluation based on daily pairs of observed and measured  
25 concentrations at the stations that have been selected to be used for the trend assessment (see Section  
26 2.2.1) is given in Table 4 for the 1990-2009, 1995-2009 and 2000-2009 time periods. For the  
27 validation of the model more sites become available for the later time periods. To be able to compare  
28 the model performance for different time periods Table 5 shows the statistical evaluation for 1990-  
29 2009 and 2000-2009 when using the same subset of stations per component for both time periods (i.e.  
30 considering only those stations that passed the selection criteria presented in Section 2.2.1 for both of  
31 these time periods). Figure 3 shows the 60-days moving average concentrations averaged across the

1 selected stations for each component for the time period 1990-2009. Besides the time series the  
2 average seasonal variation is given for this same 20 year time period.

3 The modelled time series of SO<sub>2</sub> presented in Figure 3a shows that LOTOS-EUROS underestimates  
4 the observed SO<sub>2</sub> concentrations in the period 1990-1997, while for later years there appears to be a  
5 small bias at these stations. The latter is also reflected in an improved RMSE and bias (in relation to  
6 the observed mean) for the 2000-2009 time period compared to the 1990-2009 time period when  
7 considering the same subset of stations for both time periods (see Table 5). Throughout the time  
8 series the year-to-year variability is captured well by the model, as is the seasonal variation presented  
9 in Figure 3b. The mean correlation coefficient of 0.6 for SO<sub>2</sub> for 1990-2009 (see Table 4) suggests  
10 that the model is able to reproduce part of the observed day-to-day variability throughout the time  
11 period.

12 Figure 3c and 3d reveal that the concentrations of SO<sub>4</sub><sup>2-</sup> are systematically underestimated by  
13 LOTOS-EUROS throughout the whole time period. The underestimation is most distinct from 1990-  
14 1997, which appears to be related to the underestimation of SO<sub>2</sub> in the same period. Analysis of the  
15 individual sites showed that the sites located in eastern and central Europe largely determine the  
16 underestimation for both components as northern European stations show much better comparison.  
17 We speculate that the models' underestimation of SO<sub>2</sub> and SO<sub>4</sub><sup>2-</sup> concentrations in the 1990s could be  
18 connected to the lack of a good representation of the change in emission structures in the power  
19 sector in eastern and parts of central Europe in the 1990s as a consequence of the fall of the Berlin  
20 wall and political changes associated with the liberalisation of the Eastern Bloc's authoritarian  
21 systems as discussed below. A striking feature in the comparison for SO<sub>4</sub><sup>2-</sup> is the inability of the  
22 model to reproduce the magnitude of several spring episodes that occurred in e.g. 1996, 2003 and  
23 2006. Although for some of these episodes the model is able to capture the timing, it is not able to  
24 reproduce the peak values. These episodes are characterized by very stable conditions across central  
25 Europe and some have been studied in detail (e.g. Stern et al., 2008; Banzhaf et al., 2013). A model  
26 comparison by Stern et al. (2008) has shown that also other state of the art models were not able to  
27 simulate the peak values in early spring 2003. It is unclear if the underestimation is connected to a  
28 lack of SO<sub>2</sub>-to-SO<sub>4</sub><sup>2-</sup> conversion or an overestimation of turbulent mixing leading to too high  
29 deposition and vertical mixing.

30 The mean correlation coefficient of 0.46 (see Table 4) for SO<sub>4</sub><sup>2-</sup> for 1990-2009 indicates that the day-  
31 to-day variability is not very well captured by the model throughout the time period. The mean  
32 correlations for the secondary species SO<sub>4</sub><sup>2-</sup>, TNO<sub>3</sub> and TNH<sub>4</sub> presented in Table 4 and Table 5 with

1 values between 0.4 and 0.5 for the different time periods are lower than those found in former  
2 LOTOS-EUROS model evaluation studies showing mean correlations of 0.5 to 0.7. Further analysis  
3 of the time series has revealed that when correlations are low the modelled temporal distribution at a  
4 station is often shifted by just one day compared to the observed distribution. One possible reason for  
5 the lower correlations compared to former evaluation studies of the model could be that the  
6 meteorological input fields used in this study have been generated without nudging of meteorological  
7 data while the LOTOS-EUROS standard meteorological input includes the assimilation of surface  
8 meteorological data.

9 On average, the model underestimates NO<sub>2</sub> concentrations by about 15%. Figure 3e shows that the  
10 overall bias is distinct in the first three years of the time series and becomes small in the years  
11 afterwards. After 2000 the bias between modelled and observed NO<sub>2</sub> starts to increase again and  
12 becomes increasingly larger towards 2009. The seasonal cycle presented in Figure 3f is well  
13 simulated and the interannual variability is satisfactorily reproduced. Also, the temporal correlation  
14 coefficient (>0.6) for these stations throughout the series illustrates that LOTOS-EUROS captures the  
15 day-to-day variability reasonably well. The higher mean correlation coefficients for NO<sub>2</sub> and SO<sub>2</sub>  
16 compared to those of SO<sub>4</sub><sup>2-</sup>, TNO<sub>3</sub> and TNH<sub>4</sub> we attribute to a less strong emission signal in the  
17 secondary species concentrations.

18 At the few northern European sites where long term time series (1990-2009) of TNO<sub>3</sub> concentrations  
19 were available the seasonal cycle and the interannual variability are well simulated by LOTOS-  
20 EUROS (see Figure 3g and h) and the bias is very small. Moreover, some TNO<sub>3</sub> episodes are well  
21 captured by the model. Also for TNH<sub>4</sub> concentrations, presented in Figure 3i, the bias at the few  
22 northern European sites that exhibited time series for 1990-2009 is small. However, a major  
23 shortcoming in the TNH<sub>4</sub> modelling is clearly visible in the average seasonal cycle (see Figure 3j).  
24 The model overestimates TNH<sub>4</sub> concentrations during wintertime (Oct-Jan) and tends to  
25 underestimate during late spring and early summer. Moreover, the maximum concentration is  
26 modelled to be in March, whereas the observed maximum occurs in April. The lack of a good  
27 representation of the seasonal cycle in the NH<sub>3</sub> emissions is a likely cause for this feature.

28

### 29 **3.2 Trends in concentrations**

30 The observed and modelled trends are illustrated in Figure 4 and Figure 5. Figure 4 shows scatter  
31 plots of the observed versus modelled trend for the studied components at the considered stations for

1 the 3 different time periods. It is labelled in the graphs if the observed and/or modelled trends are  
2 significant (method used described in section 2.3): (+) implies that the observed and the modelled  
3 trends are significant, (o) implies that the observed trend is non-significant while the modelled trend  
4 is significant, (o) implies that the observed trend is significant while the modelled trend is non-  
5 significant and (o) implies that the observed and the modelled trends are non-significant. Table 6  
6 summarizes for each component the resultant observed and modelled absolute and relative median  
7 trends for the three considered time periods. For comparison, in Table S2 in the Supplement, the  
8 observed and modelled absolute and relative median trends are also given considering the same  
9 subset of stations (per component) for all time periods to extract the impact of changing number and  
10 location of included sites. However, Table S2 only includes SO<sub>2</sub>, NO<sub>2</sub> and SO<sub>4</sub><sup>2-</sup> as for TNO<sub>3</sub> and  
11 TNH<sub>4</sub> the number of sites (4 and 3, respectively) was considered to be too low for a trend assessment.  
12 Figure 5 shows the observed and modelled trends of the annual mean SO<sub>4</sub><sup>2-</sup>, TNO<sub>3</sub> and TNH<sub>4</sub>  
13 concentrations, their 5<sup>th</sup> and 95<sup>th</sup> percentile and the corresponding trend lines for the 1990-2009 time  
14 period. Solid lines refer to significant trends and dashed lines refer to non-significant trends (only  
15 found for the TNO<sub>3</sub> 5<sup>th</sup> percentile).

### 16 3.2.1 Observed trends

17 Figure 4 illustrates that the observed SO<sub>2</sub>, SO<sub>4</sub><sup>2-</sup> and NO<sub>2</sub> concentrations show significant negative  
18 trends at the majority of stations for the time periods 1990-2009 and 1995-2009. For NO<sub>2</sub> a  
19 significant positive trend for 1995-2009 was observed at two stations located in Estonia at the shore  
20 of the Baltic Sea. For TNO<sub>3</sub> and TNH<sub>4</sub> the majority of trends is significant negative for the 1990-  
21 2009 time period while for 1995-2009 the observed trends are non-significant at all stations (TNO<sub>3</sub>)  
22 or at the majority of stations (TNH<sub>4</sub>). Note that for TNO<sub>3</sub> and TNH<sub>4</sub> the few considered station are  
23 located in northern and eastern Europe due to a lack of long-term observations in the other regions.  
24 The trends in TNO<sub>3</sub> in hot spot areas like the Netherlands may differ. For all components, the relative  
25 amount of stations with non-significant trends increases when moving from 1990-2009 (SO<sub>2</sub>: 0%;  
26 SO<sub>4</sub><sup>2-</sup>: 0%; NO<sub>2</sub>: 11%; TNO<sub>3</sub>: 33%; TNH<sub>4</sub>: 14%) to 1995-2009 (SO<sub>2</sub>: 5%; SO<sub>4</sub><sup>2-</sup>: 18%; NO<sub>2</sub>: 21%;  
27 TNO<sub>3</sub>: 100%; TNH<sub>4</sub>: 50%) to 2000-2009 (SO<sub>2</sub>: 52%; SO<sub>4</sub><sup>2-</sup>: 86%; NO<sub>2</sub>: 72%; TNO<sub>3</sub>: 75%; TNH<sub>4</sub>:  
28 80%). This increasing number of non-significant trends when moving to the later time periods has  
29 also been found when considering the same subset of stations per components for all time periods,  
30 i.e. considering only those stations that fulfilled the selection criteria for all three time periods (not  
31 shown here). For the time period 2000-2009 Figure 4 shows that the observed trends are non-  
32 significant at the majority of stations for all considered components. We would like to stress that this

1 does not necessarily imply that there is no trend present in the data of these stations for 2000-2009  
2 but 10 years may be too short to infer statistically significant trends.

3 Table 6 shows that for all components the observed median absolute negative trends decrease moving  
4 from 1990-2009 to 2000-2009 (absolute decrease in TNO<sub>3</sub> trends in the 3rd decimal place). For SO<sub>2</sub>  
5 and NO<sub>2</sub> the decrease of the observed absolute negative trends from 1990-2009 to 1995-2009 is less  
6 strong than the decrease from 1995-2009 to 2000-2009. Table S2 in the Supplement shows that the  
7 latter features also apply when considering the same, but smaller, subset of stations per components  
8 for all time periods. Furthermore, comparing the observed median relative trends in SO<sub>4</sub><sup>2-</sup>  
9 concentrations to those of SO<sub>2</sub> shows that the trends in SO<sub>4</sub><sup>2-</sup> are lower for all considered time  
10 periods. We are aware that the stations at which SO<sub>2</sub> and SO<sub>4</sub><sup>2-</sup> concentrations are investigated partly  
11 differ. However, the spatial distribution of sites over Europe for SO<sub>2</sub> is comparable with that for  
12 SO<sub>4</sub><sup>2-</sup> (see Figures S1-S4 in the Supplement) and we assume that rural background stations represent  
13 the regional scale atmospheric composition, so that the same conditions are represented by the two  
14 sets. Therefore we think that comparison of the relative trends of both components is maintainable.

15 Finally, the sensitivity of the resultant observed median trends to the selection criteria introduced in  
16 section 2.2.1 has been tested. The results for the 1990 to 2009 time period are presented in the  
17 Supplement showing that increasing the length of the annual time series (at least 80% of the  
18 considered time period was the criterion given in section 2.2.1) has a minor impact on the resultant  
19 median trend.

20

### 21 3.2.2 Modelled trends and comparison to observed trends

22 As the results in Table 6 (and Table S2) show the model is able to well simulate the decrease in the  
23 absolute median negative trend for SO<sub>2</sub>, SO<sub>4</sub><sup>2-</sup> and NO<sub>2</sub> when moving from 1990-2009 to 1995-2009  
24 to 2000-2009. Also, the model is able to reproduce the lower relative trends of observed SO<sub>4</sub><sup>2-</sup>  
25 concentrations compared to those of SO<sub>2</sub>.

26 The model simulates significant negative trends in SO<sub>2</sub>, NO<sub>2</sub> and SO<sub>4</sub><sup>2-</sup> concentrations at most station  
27 locations for 1990-2009 and 1995-2009 (see Figure 4), which coincides with the observed trends for  
28 these time periods. However, the model underestimates the negative trends in concentrations for SO<sub>2</sub>  
29 at several stations and for SO<sub>4</sub><sup>2-</sup> at most stations while it overestimates the negative trends in NO<sub>2</sub>  
30 concentrations at the majority of station locations. For all considered time periods the deviation of the  
31 modelled trends in SO<sub>2</sub>, SO<sub>4</sub><sup>2-</sup> and NO<sub>2</sub> concentrations from the observed trends were found to be

1 most distinct at eastern European stations and stations in north-eastern Germany (e.g. the three  
2 outliers in Figure 4b correspond to trends at two stations in Czech Republic and one station in eastern  
3 Germany) and least distinct at northern European station locations (not shown here). For the time  
4 period 2000-2009 the model well simulates the low negative median trends in  $\text{SO}_2$  and  $\text{SO}_4^{2-}$   
5 concentrations (see Table 6) but Figure 4 reveals that the model simulates significant negative trends  
6 at most station locations while non-significant trends were observed. The latter is also valid for  
7 modelled and observed  $\text{NO}_2$  concentration trends. As for the 1990-2009 and 1995-2009 time periods  
8 the model overestimates the trends in  $\text{NO}_2$  concentrations for the 2000-2009 time period.

9 As Figure 5 a illustrates, the strong observed negative trend in  $\text{SO}_4^{2-}$  concentrations is mostly driven  
10 by the high observed concentrations in the beginning of the 90s. The latter high observed  
11 concentrations could not be reproduced by the model. The 5<sup>th</sup> percentile, which represents the  
12 background concentrations, and its significant negative trend are well captured by the model. The  
13 negative trend of the 95<sup>th</sup> percentile, which represents the high concentration range (the peak  $\text{SO}_4^{2-}$   
14 concentrations), is considerably underestimated by the model. The model satisfactorily captures the  
15 temporal distribution of the interannual variability but there is a substantial negative bias between  
16 modelled and observed value. This shows that the models inability to capture the observed trend in  
17  $\text{SO}_4^{2-}$  is driven by the underestimation of the high range of concentrations.

18 Also for  $\text{TNO}_3$  and  $\text{TNH}_4$  shown in Figure 5b and Figure 5c the deviation from the observed values is  
19 most distinct in the 95<sup>th</sup> percentile while the interannual variability is well simulated by the model.  
20 Figure 4 shows that the model well reproduces the low trends in  $\text{TNO}_3$  concentrations at the majority  
21 of considered sites for all time periods while for  $\text{TNH}_4$  the model tends to underestimate the observed  
22 concentration trends. Furthermore, for both components,  $\text{TNO}_3$  and  $\text{TNH}_4$ , the increased relative  
23 number of non-significant trends when moving from the 1990-2009 to the 2000-2009 time period is  
24 well captured by the model at most stations.

25

### 26 **3.3 Trends in SIA formation**

27 The previous section has revealed that the observed relative trends in  $\text{SO}_4^{2-}$  concentrations are lower  
28 than those of its precursor gas  $\text{SO}_2$ . Furthermore, the analysis of the LOTOS-EUROS simulation has  
29 shown that this non-linear effect was well reproduced by the model. Hence, the LOTOS-EUROS  
30 source apportionment module was used to further investigate the observed and modelled non-  
31 linearity. Therefore 10 kttons of  $\text{SO}_2$ ,  $\text{NO}_x$  and  $\text{NH}_3$  emissions, respectively, have been tracked for

1 1990 to 2009 for 4 different labels, which were chosen to be 4 different regions: The Netherlands and  
2 Belgium (NLBE), the Baltic Sea (BAS), Czech Republic (CZE) and Romania (ROM). By means of  
3 the labelling we can determine how much SIA was formed per unit emission during the time period  
4 from 1990 to 2009. The results of the source attribution are presented in Figure 6. Figure 6a shows the  
5  $\text{SO}_4^{2-}$  concentration (solid lines) formed per unit emission normalized to that of 1990 for the different  
6 labels for 1990 to 2009. A trend line (dashed line) is added for all labels. For all considered regions  
7 the  $\text{SO}_4^{2-}$  formation efficiency increases from 1990 to 2009. Following the Mann-Kendall Test at a  
8 95% confidence level the positive trends are significant for all labels. To investigate if the identified  
9 increase is a matter of climate change we re-run the model for 1990, 1995, 2000 and 2009 using the  
10 emissions for the corresponding year but the meteorology of 2005. The results are added to Figure 6a  
11 as accordingly coloured dots for each label. Most dots are located on or close to the corresponding  
12 trend line. The latter indicates that the increase in  $\text{SO}_4^{2-}$  formation efficiency is induced by the change  
13 in emissions from 1990 to 2009. The increase is most distinct for the region NLBE with a 61% more  
14 efficient  $\text{SO}_4^{2-}$  formation in 2009 compared to 1990 followed by CZE (+60%), BAS (+31%) and  
15 ROM (+28%). The major driver for the increased  $\text{SO}_4^{2-}$  formation efficiency in the model has been  
16 an increasing neutralisation of cloud acidity and thus pH over time as diagnosed from the model run.

17  $\text{SO}_4^{2-}$  formation is a sink for  $\text{SO}_2$  concentrations and therefore the increase in  $\text{SO}_4^{2-}$  formation  
18 efficiency explains that the decrease in  $\text{SO}_2$  concentrations is larger than expected solely from the  
19 decrease in  $\text{SO}_2$  emissions. Figure 6b displays the decrease in  $\text{SO}_2$  quantity per unit  $\text{SO}_2$  emission  
20 showing a negative trend for the time period 1990 to 2009 for all considered labels. However, for the  
21 Baltic Sea (BAS) the trend from 1990 to 2009 is not significant following a Mann-Kendall Test at the  
22 95% significance level.

23 Figure 6c reveals a decrease in  $\text{NH}_4^+$  formation per unit  $\text{NH}_3$  emission for the labels NLBE, CZE and  
24 ROM with a reduction of -22% (ROM) to -33% (NLBE and CZE) for 2009 compared to 1990.  
25 Following a Mann-Kendall Test at the 95% significance level the trend is significant for these labels.  
26 BAS is not included in the figure as there is no  $\text{NH}_3$  emission from shipping on the Baltic Sea.

27 The changes in  $\text{NO}_3^-$  formation efficiency from 1990 to 2009 are lower than for  $\text{SO}_4^{2-}$  and  $\text{NH}_4^+$  (see  
28 Figure 6d). A significant trend has been found for the label NLBE showing an increase in  $\text{NO}_3^-$   
29 formation efficiency with an increase of +22% from 1990 to 2009. In the next section the results of  
30 the labelling exercise are further discussed.

31

## 1 **4 Discussion and Conclusions**

2 In this study we presented a dynamic model evaluation of the LOTOS-EUROS CTM to analyse the  
3 ability of the model to reproduce the non-linear responses to emission changes and interannual  
4 variability of SIA and its precursors over Europe from 1990 to 2009. This study presents the first  
5 evaluation of the model system over such a long time period.

6 With respect to the study design we feel that the simulation of the whole period is a strong point as  
7 opposed to using one or several key meteorological years to study the impact of emission changes as  
8 it is difficult to choose a meteorological year that is representative for an average year throughout  
9 Europe. In addition, through the reanalysis with RACMO2 we have used a consistent set of  
10 meteorological data to drive the model for the whole period. The major activity needed to improve  
11 the study design is associated with the emission information for the early nineties. Improvements are  
12 especially needed for the eastern European countries. Emission estimates for 1990 are relatively  
13 uncertain (Granier et al., 2011) as much of the information currently used to estimate emissions is not  
14 available (at the same quality) for 1990. Moreover, we have simply used the spatial allocation of the  
15 TNO-MACC-2005 dataset and scaled the emission totals per sector back to those of 1990. As a  
16 result, the (spatial) representation of e.g. the industrial infrastructure and location of power plants,  
17 especially in eastern and parts of central Europe in the period 1990-2000 will not be correct as the  
18 infrastructure here during this period still resembled the pre-1990 period. The improvement needed  
19 here is highlighted by the higher underestimation of the pollutants in the first years of the study  
20 period. One could use the spatial allocation of emission inventories built in the nineties to overcome  
21 these problems partly. Making a small compromise on the spatial resolution of the data may not be a  
22 large problem as model resolution does hardly affect the performance of CTMs for regional  
23 assessments (Schaap et al., *in prep.*).

24 In the present model set-up, trends in boundary conditions were not considered, although background  
25 concentrations are expected to change from 1990 to 2009. We believe that the impact of using time-  
26 variant boundary conditions would be most relevant for O<sub>3</sub> levels, which also affect the formation of  
27 SIA. Time-variant lateral boundary conditions could be extracted from a global model simulation.  
28 Hogrefe et al. (2011) studied the uncertainties associated with chemical boundary conditions from a  
29 global model, showing that the representation of the interannual variability of O<sub>3</sub> concentrations was  
30 improved when time-variant boundary conditions were used. However, biases in the global  
31 simulations significantly affected the O<sub>3</sub> simulations throughout the modelling domain with adverse  
32 impact on the simulated O<sub>3</sub> trends.

1 Complementing the EMEP monitoring data with those of AIRBASE has increased the number of  
2 stations with valid time series, especially for the precursor gases. Our visual screening of the  
3 measurement data revealed that a large fraction of the stations with long time series were not useable  
4 as data quality was obviously an issue. The most frequent peculiarities were shifts in the  
5 concentration level, many implausible peaks of short duration, constant value signals over prolonged  
6 time periods or concentration regimes below the detection limit. Most problems were associated to  
7 time series of SO<sub>2</sub>. The number of defective time series was highest for the 1990's and decreases  
8 considerably towards 2009. A lack of a long-term time series for southern and parts of western and  
9 eastern Europe hampered an evaluation across the full European domain. Furthermore, for  
10 concentrations of NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> there is a lack of observations with separation between gas- and  
11 aerosol-phase. Additional efforts for data mining within European countries could yield larger  
12 observational basis for evaluation of the time period. Moreover, generation of a centralized dataset  
13 for the specific purpose of evaluation long-term trends could be a means to improve the data quality  
14 by incorporation of expertise from the data providers.

15 The operational model evaluation showed that the seasonal variability as well as the interannual  
16 variability are satisfactorily simulated for all components. Within a multi-model trend assessment  
17 study Collette et al. (2011) presented the ability of 6 state of the art CTMs to simulate the seasonal  
18 cycle of amongst others SO<sub>2</sub>, SO<sub>4</sub><sup>2-</sup>, NO<sub>2</sub>, TNO<sub>3</sub> and TNH<sub>4</sub> concentrations at European rural  
19 background stations for the time period 1998-2007. A qualitative comparison of our model results to  
20 those presented in Collette et al. (2011) shows that LOTOS-EUROS performs comparatively well in  
21 simulating the observed seasonal cycles. Operational model evaluations within AQMEII (Solazzo et  
22 al., 2013) and EURODELTA (e.g. Vautard et al., 2009; Schaap et al., *in prep.*) showed that LOTOS-  
23 EUROS model skill is in line with those of models like EMEP and CHIMERE. Although LOTOS-  
24 EUROS was able to capture a large part of the observed variability in the considered sulphur and  
25 nitrogen compounds from 1990-2009, some shortcomings have been identified.

26 A systematic underestimation of SO<sub>4</sub><sup>2-</sup> concentrations is observed throughout the whole study. This  
27 could be connected to a lack of good representation of clouds, which is needed for the recently  
28 implemented cloud chemistry scheme (Banzhaf et al., 2012; Wichink Kruit et al., 2012). The method  
29 used to pass the information of the liquid water content vertical distribution from the vertically high  
30 resolved meteorological driver to LOTOS-EUROS running on 5 vertical layers may need further  
31 improvements. Furthermore, uncertainties in NH<sub>3</sub> emissions (magnitude, space and time) may play  
32 an important role as NH<sub>3</sub> provides the neutralising capacity of cloud droplets and constrains cloud

1 water acidity. Cloud pH regulates the oxidation pathways of SO<sub>2</sub> and therewith the formation  
2 efficiency of SO<sub>4</sub><sup>2-</sup> (Fowler et al., 2007). According to EMEP (2009), the uncertainty in magnitude of  
3 annual NH<sub>3</sub> emission totals amounts about ±30% in Europe. Furthermore, the seasonal and diurnal  
4 variation in NH<sub>3</sub> emissions are still uncertain and may differ regionally as a function of climatic  
5 conditions and in time due to changing agricultural practices and regulations (Geels et al., 2012)  
6 which is not accounted for in most state of the art CTMs including LOTOS-EUROS. The  
7 underestimation of springtime episodes for SO<sub>4</sub><sup>2-</sup> connected to stable atmospheric conditions is  
8 observed in several years. It has not yet been solved if the underestimation is induced by a lack of  
9 SO<sub>2</sub>-to-SO<sub>4</sub><sup>2-</sup> conversion or too high deposition and vertical mixing due to an overestimation of  
10 turbulent mixing. In a case study for 2003 this feature was identified to be a common challenge for  
11 European CTMs as meteorological drivers tend to fail to represent these stable weather conditions  
12 satisfactorily (Stern et al., 2008).

13 Despite the mentioned shortcomings in the representation of the sulphur components, the model  
14 captures the non-linearity observed in the response to the emission changes. Investigating the  
15 observed trends at the EMEP monitoring sites between 1980 and 2009, Tørseth et al. (2012) showed  
16 that SO<sub>2</sub> trends indicate larger reductions than the reductions of SO<sub>2</sub> emissions while those of SO<sub>4</sub><sup>2-</sup>  
17 concentrations are comparatively lower. These findings are very close to our analysis incorporating  
18 AIRBASE stations and earlier analyses by e.g. Løvblad et al. (2004). Fagerli and Aas (2008)  
19 presented an investigation on the observed trends of nitrogen from 1980-2003 at EMEP sites showing  
20 that the trends in TNO<sub>3</sub> concentrations were significantly lower than the trends in precursor  
21 emissions which matches the outcome of the here presented study. Using a source apportionment  
22 module trends in formation efficiency of SIA have been quantified adding to the explanation of the  
23 non-linearities described above. The exercise revealed an increase of SO<sub>4</sub><sup>2-</sup> formation efficiency and  
24 a decrease in NH<sub>4</sub><sup>+</sup> formation efficiency for all regions considered. The major driver for the increased  
25 SO<sub>4</sub><sup>2-</sup> formation efficiency in the model was the increasing neutralisation of cloud acidity and thus  
26 pH over time. The modelled trend is supported by the observed increase in precipitation pH during  
27 the last decades (Løvblad et al., 2004; Tørseth et al., 2012). Hence, the pH dependent aqueous-phase  
28 SO<sub>4</sub><sup>2-</sup> formation by O<sub>3</sub> is more effective (Redington et al., 2009; Banzhaf et al., 2012; 2013). In  
29 addition, the H<sub>2</sub>O<sub>2</sub>/SO<sub>2</sub> ratio increases which also leads to more efficient formation. Finally, the  
30 simultaneous NO<sub>x</sub> and SO<sub>2</sub> emission reductions may lead to increased OH levels, which counteract  
31 the SO<sub>4</sub><sup>2-</sup> reduction as the rate of homogeneous oxidation of SO<sub>2</sub> is increased (Tarrasón et al., 2003;  
32 Derwent et al., 2009). The decrease in NH<sub>4</sub><sup>+</sup> formation efficiency is related to the overall decrease in

1  $\text{SO}_4^{2-}$  concentrations from 1990 to 2009, which leads to less ammonium sulphate ( $(\text{NH}_4)_2\text{SO}_4$ )  
2 formation. The strong decrease in  $\text{SO}_4^{2-}$  concentrations from 1990-2009 increases the availability of  
3  $\text{NH}_3$  for the formation of  $\text{NH}_4\text{NO}_3$  (Tarrasón et al., 2003; Fagerli and Aas, 2008; Harrison et al.,  
4 2014). Hence, this could explain the change in  $\text{NO}_3^-$  formation efficiency for the Benelux region.  
5 Another reason for changes in the  $\text{NO}_3^-$  formation efficiency could be a change in the oxidant levels  
6 (Fowler et al., 2005; Fagerli and Aas, 2008). A decrease in  $\text{NO}_x$  emissions leads to a decrease of  $\text{O}_3$   
7 titration and therewith to an increased rate of  $\text{NO}_2$  to  $\text{NO}_3^-$ -conversion. The increased rate of  $\text{NO}_2$  to  
8  $\text{NO}_3^-$ -conversion could also be induced by higher availability of oxidants that previously were  
9 consumed in the oxidation of  $\text{SO}_2$  or other pollutants. A more detailed budget analysis is advised to  
10 study the changes in chemical regime.

11 Furthermore, LOTOS-EUROS underestimates the observed  $\text{NO}_2$  concentrations on average by 15%  
12 throughout the whole time period. The underestimation is induced by modelled concentrations at  
13 central and eastern European stations while the model performs considerably better at northern  
14 European stations. Part of the underestimation may be explained by the measurement devices used in  
15 the networks. Oxidized nitrogen compounds such as  $\text{HNO}_3$ , PAN (peroxyacyl nitrate) and other  
16 organic nitrates can significantly interfere with the measurements by contributing to the  $\text{NO}_2$  signal  
17 (Steinbacher et al., 2007). In the beginning of the 90s again the uncertainties in the emission input  
18 may explain part of the bias in  $\text{NO}_2$  concentrations. After 2000 the bias increases inducing an  
19 overestimation of the observed negative trend in  $\text{NO}_2$  concentrations by the model. It has been  
20 investigated if the decrease in model performance after 2000 is connected to the increased  $\text{NO}_2/\text{NO}$   
21 ratio of traffic emissions by comparing simulations with 3% and 20% direct  $\text{NO}_2$  emissions from  
22 diesel fuelled vehicles. These runs showed a slight increase in the rural background close to large  
23 cities (up to 2 %), whereas in more remote areas  $\text{NO}_2$  levels declined by about 0.5% due to the faster  
24 oxidation to  $\text{HNO}_3$ . Hence, this effect does not contribute to the mismatch between observed and  
25 modelled trends. The model inter-comparison study by Collette et al. (2011) has shown that 4 out of  
26 6 models underestimate  $\text{NO}_2$  concentrations at European rural background stations for the time  
27 period 1998-2007. Moreover, three of these models also show stronger trends than observed. A  
28 recent study using satellite retrieved  $\text{NO}_2$  columns by OMI and in-situ data for the period 2005-2012  
29 also showed lower trends in observations than in the European emission inventories (Curier et al.,  
30 2014). Hence, more research is needed to assess if the mismatch in the  $\text{NO}_2$  trend is a model issue or  
31 if it can be attributed to too strong declines in the emission data.

1 The implemented emission abatement strategies for SIA precursors have led to concentration  
2 reductions over Europe even though for some secondary species the achieved concentration reduction  
3 is lower than corresponding precursor reductions would suggest. The LOTOS-EUROS model is able  
4 to capture most of the seasonal and interannual variability of SIA and its precursors' concentrations  
5 and their non-linear responses to emission changes for the time period 1990-2009. The largest part of  
6 the decline is observed in the 1990's. Smaller concentration changes and more non-significant trends  
7 are observed and modelled between 2000-2009. The smaller, non-significant trends between 2000-  
8 2009 do not necessarily imply that there is no trend present in the data, but only that we are not sure  
9 at the 95% confidence level (Nuzzo, 2014). It highlights that the validation of emission trends  
10 remains a challenge, in particular the ability to separate relatively smaller trends from interannual  
11 variability (Koumoutsaris et al., 2008; Voulgarakis et al., 2010).

12 This study has revealed many interesting features and resulting research questions that can be  
13 approached making further use of the 20 years model simulation. Specific attention is needed to  
14 address the trends in  $\text{NO}_x$  and tackle the underestimation in  $\text{SO}_4^{2-}$  and other pollutants in eastern  
15 Europe. As a next step we will analyse the ability of the model to reproduce the trends modelled for  
16  $\text{O}_3$  as new analyses have shown shifts in seasonal variability over time (Parrish et al., 2013).  
17 Moreover, trends in wet and dry deposition should be investigated to further complement the budget  
18 analysis. We have found that the trends for SIA are emission-driven. Next, a quantification of trends  
19 induced by meteorological variability as reported by Andersson et al. (2007) is planned. Furthermore,  
20 special attention in further investigations will be given to uncertainties in the emission input by  
21 performing sensitivity studies on emission timing (dependency on meteorology etc.). The here  
22 presented study could be seen as an exploratory exercise for the re-analysis of the 1990-2010 period  
23 with several model systems within the UNECE-EMEP taskforce on measurement and modelling  
24 (TFMM).

25 In short, we presented a successful dynamic model evaluation of the LOTOS-EUROS CTM aimed at  
26 secondary inorganic aerosol formation in Europe between 1990 and 2009. In general, the model is  
27 able to capture the non-linearity as detected in the observations. A source apportionment analysis has  
28 confirmed that changes in the formation efficiency due to changes in the chemical regime are at the  
29 basis of this non-linearity.

1 Table 2. Statistical comparison between measured and modelled meteorological parameters using daily  
 2 observations at European observational sites. The number of considered stations, mean correlation, observed  
 3 mean, RMSE and bias are given.

| Evaluation         | Temperature | Relative humidity | Wind speed             | Precipitation |
|--------------------|-------------|-------------------|------------------------|---------------|
| Number of stations | 206         | 113               | 246                    | 240           |
| Mean correlation   | 0.97        | 0.66              | 0.68                   | 0.48          |
| Observed mean      | 286.06 K    | 78 %              | 3.82 m s <sup>-1</sup> | 1.82 mm       |
| RMSE               | 2.82 K      | 11 %              | 1.87 m s <sup>-1</sup> | 4.52 mm       |
| Bias               | -1.47 K     | 2 %               | 0.35 m s <sup>-1</sup> | 0.04 mm       |

4

5

1 Table 3. Percentage of daily rain occurrence hits of the RACMO2 model from 1990 to 2009 at 240 European  
2 observational stations

---

| Hits                 | # stations |
|----------------------|------------|
| $h < 60\%$           | 0          |
| $60\% \leq h < 70\%$ | 35         |
| $70\% \leq h < 80\%$ | 156        |
| $80\% \leq h < 90\%$ | 48         |
| $h \geq 90\%$        | 1          |

---

3

4

1 Table 4. Statistical comparison between measured and modelled concentrations using daily observations. The  
 2 number of considered stations, mean correlation, observed mean, RMSE and bias are given for each  
 3 component and each time period.

| Period    | Evaluation                         | SO <sub>2</sub> | NO <sub>2</sub> | SO <sub>4</sub> | TNO <sub>3</sub> | TNH <sub>4</sub> |
|-----------|------------------------------------|-----------------|-----------------|-----------------|------------------|------------------|
| 1990-2009 | number of stations                 | 23              | 37              | 15              | 9                | 7                |
|           | mean correlation                   | 0.60            | 0.65            | 0.46            | 0.46             | 0.48             |
|           | observed mean (µg/m <sup>3</sup> ) | 3.86            | 15.97           | 2.77            | 0.56             | 1.35             |
|           | RMSE (µg/m <sup>3</sup> )          | 6.01            | 8.66            | 2.86            | 0.61             | 1.21             |
|           | Bias (µg/m <sup>3</sup> )          | -0.44           | -2.43           | -0.88           | 0.04             | 0.03             |

1 Table 6. Number of stations and derived observed and modelled absolute ( $\mu\text{g m}^{-3} \text{ a}^{-1}$ ) and relative ( $\% \text{ a}^{-1}$ )  
 2 median trends for the considered components and time periods.

| Period    | Evaluation                 | SO <sub>2</sub> | NO <sub>2</sub> | SO <sub>4</sub> | TNO <sub>3</sub> | TNH <sub>4</sub> |
|-----------|----------------------------|-----------------|-----------------|-----------------|------------------|------------------|
| 1990-2009 | number of stations         | 23              | 37              | 15              | 9                | 7                |
|           | Observed abs. median trend | -0.34           | -0.36           | -0.16           | -0.01            | -0.03            |
|           | Modelled abs. median trend | -0.33           | -0.45           | -0.07           | -0.01            | -0.01            |
|           | Observed rel. median trend | -4.88           | -1.85           | -3.55           | -1.57            | -2.18            |
|           | Modelled rel. median trend | -4.16           | -2.44           | -2.36           | -1.33            | -1.61            |
| 1995-2009 | number of stations         | 40              | 64              | 22              | 9                | 8                |
|           | Observed abs. median trend | -0.28           | -0.30           | -0.10           | -0.01            | -0.02            |
|           | Modelled abs. median trend | -0.23           | -0.44           | -0.06           | -0.01            | -0.02            |
|           | Observed rel. median trend | -5.14           | -1.67           | -3.34           | -1.23            | -1.77            |
|           | Modelled rel. median trend | -4.98           | -2.46           | -2.57           | -1.54            | -1.18            |
| 2000-2009 | number of stations         | 60              | 112             | 28              | 16               | 15               |
|           | Observed abs. median trend | -0.13           | -0.14           | -0.05           | -0.01            | -0.02            |
|           | Modelled abs. median trend | -0.12           | -0.28           | -0.05           | -0.01            | -0.01            |
|           | Observed rel. median trend | -4.45           | -1.12           | -2.63           | -1.45            | -0.98            |
|           | Modelled rel. median trend | -5.10           | -2.17           | -2.37           | -1.66            | -0.66            |

Figure 3. Mean 60 days moving average (left panel) and seasonal cycle (right panel) of (a-b) SO<sub>2</sub>, (c-d) SO<sub>4</sub><sup>2-</sup>, (e-f) NO<sub>2</sub>, (g-h) TNO<sub>3</sub> and (i-j) TNH<sub>4</sub> for the time period 1990-2009. The number of considered stations is given in the figure captions.

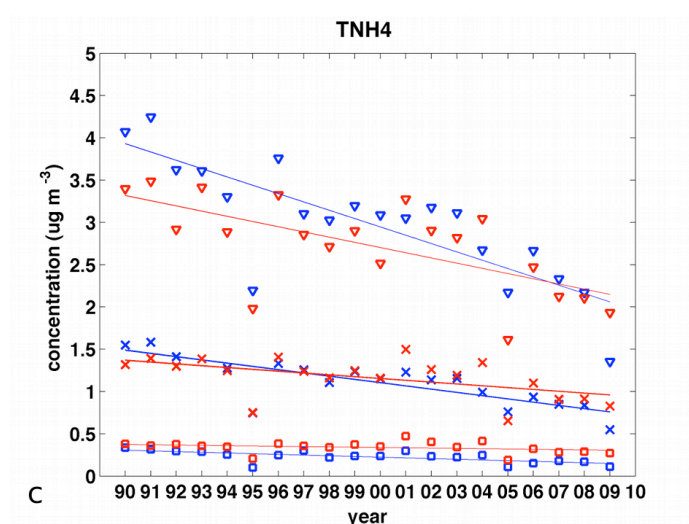

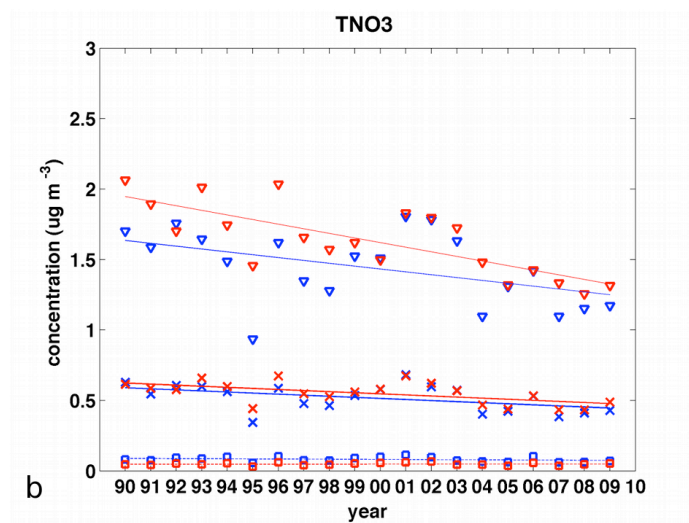

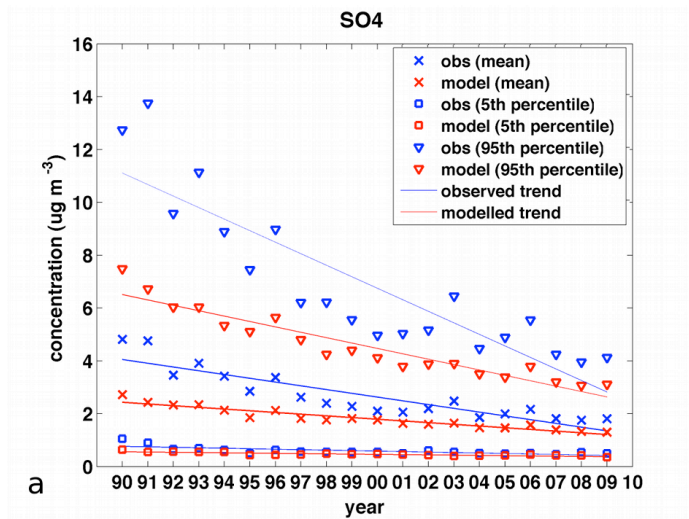

1

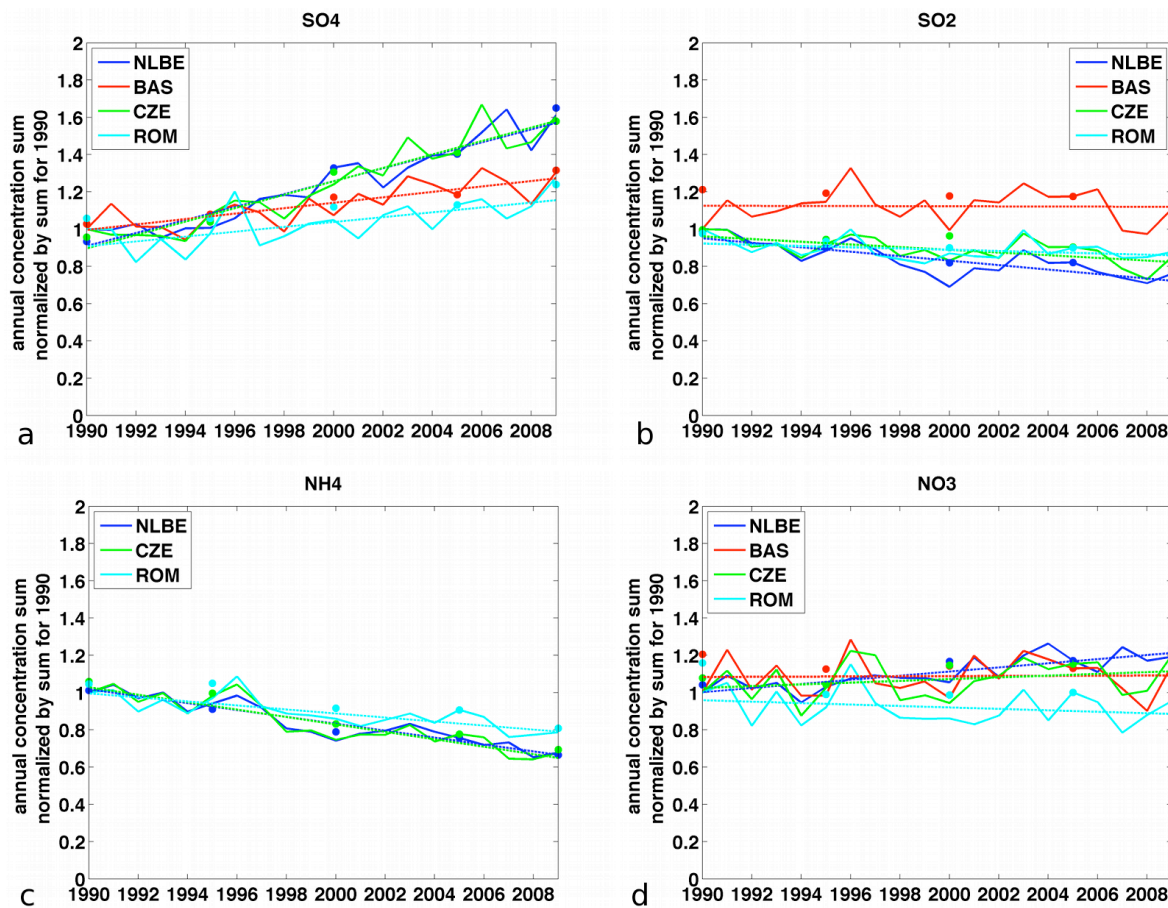

1  
 2 Figure 4. Scatter plots of the observed versus modelled trends for the studied components at the considered  
 3 stations for the three different time periods. At each individual station the marker (described in the legend on  
 4 the top right of the plot) indicates if the observed and/or modelled trend is significant following the Mann-  
 5 Kendall test at a 95% confidence level.

6

1  
 2 Figure 5 Observed (blue) and modelled (red) annual mean (crosses), 5<sup>th</sup> percentile (squares) and 95<sup>th</sup> percentile  
 3 (triangles) and corresponding trend line of (a)  $\text{SO}_4^{2-}$ , (b)  $\text{TNO}_3$  and (c)  $\text{TNH}_4$ . Solid lines indicate a significant  
 4 and dashed lines a non-significant trend.

1  
 2 Figure 6 Amount of (a)  $\text{SO}_4^{2-}$ , (c)  $\text{NH}_4^+$  and (d)  $\text{NO}_3^-$  (solid lines) formed from 10 kt of  $\text{SO}_2$ ,  $\text{NH}_3$  and  $\text{NO}_2$   
 3 emissions, respectively, relative to the amount formed in 1990, for the different labels as indicated by the  
 4 colours, for the entire time period 1990 to 2009. Panel (b) shows the resultant  $\text{SO}_2$  per unit  $\text{SO}_2$  emission for  
 5 each label for the 1990 to 2009 time period. The corresponding trend lines are presented as dashed lines. The  
 6 dots denote results for the runs forced with 2005 meteorology.
