## Abstract

The commonly adopted biogeochemistry spin-up process in earth system model is to run the model for hundreds to thousands of years subject to periodic atmospheric forcing to reach dynamic steady state of the carbon-nitrogen (CN) models. A variety of approaches have been proposed to reduce the computation time of the spin-up process. Significant improvement in computational efficiency has been made recently. However, a long simulation time is still required to reach the common convergence criteria of the coupled carbon/nitrogen model. A gradient projection method was proposed and used to further reduce the computation time after examining the trend of the dominant carbon pools. The Community Land Model version 4 (CLM4) with carbon and nitrogen component was used in this study. From point scale simulations we found that the method can reduce the computation time by 20–69 % compared to the fastest approach in the literature. We also found that the cyclic stability of total carbon for some cases differs from that of the periodic atmospheric forcing, and some cases even showed instability. Close examination showed that one case has a carbon periodicity much longer than that of the atmospheric forcing due to the annual fire disturbance that is longer than half a year. The rest was caused by the instability of water table calculation in the hydrology model of CLM4. The instability issue is resolved after we replaced the hydrology scheme in CLM4 with a flow model for variably saturated porous media.

## 20 1 Introduction

The initial starting values of carbon/nitrogen (CN) models are not commonly available, especially for large scale applications, but they have important influence on the subsequent C/N states simulated by the models. Typically, Earth system model (ESM) simulations are initialized in the pre-industrial period to allow sufficient time for the coupled system to respond to the various forcing. Initialization of the CN model is usually achieved by a spin-up run of the CN model given an arbitrary initial condition until an

approximate C equilibrium is reached. This time marching of the model requires several hundreds to thousands of years of model simulations before a dynamic steady state is reached. The length of the transient state to reach a dynamic steady state is dependent on the initial conditions of the system. It has long been recognized that the spin-up process of CN models is time consuming due to the slow turnover rates of the soil carbon pools, which significantly affect the computational efficiency for global modeling. A number of approaches have been proposed in the past to improve upon the explicit forward time integration of ordinary differential equations in their native form and rate parameters for CN models. These approaches include the initialization of soil organic matter carbon pools with observations (Zhang et al., 2002), accelerated decomposition method using a higher decomposition rate for litter and soil carbon pools (Thornton and Rosenbloom, 2005), decelerated bulk denitrification and leaching method (Shi et al., 2013), and semi-analytical steady-state solution for soil organic C and N pools (Xia et al., 2012). Except for the semi-analytical approach, other approaches mentioned above have been summarized and compared in Shi et al. (2013). The semi-analytical model needs initial spin-up values of net primary productivity (NPP), which still requires long simulation time for stabilization because C and N are coupled in CN models.

Recently Koven et al. (2013) used a modified form of the “accelerated decomposition” (hereafter referred as AD approach) by numerically increasing the decomposition rates for the two slowest soil carbon pools (named as Soil3C and Soil4C) to a level so that their turnover rates are similar to the fast pools during the initialization. Numerical evaluation found that the approach significantly reduced the spin-up time (Koven et al., 2013). Figure 1 shows the structure of the soil C pool represented in the CN module of the Community Land Model version 4 (CLM4-CN) (Lawrence et al. 2011). The reason that the AD approach can accelerate the spin-up is because these two slowest pools are essentially decoupled from the rest of the ordinary differential equations, in that all other pools do not need input from them. The approach, however, cannot be applied to the coarse woody debris (CWD) pool even though its turnover rate is on the same order of Soil3C, because it is an input to the litter pools. Changing the rate of CWD

Y. Fang et al.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

will give a different solution of other pools during each integration step using the same initial condition, which will lead to a state far from equilibrium if the state is used in a restart simulation.

In the AD approach, once the solution is obtained from the accelerated run, the state of Soil3C and Soil4C can be analytically solved. From Fig. 1, the flux of Soil3C and Soil4C pools can be described by the following equations:

$$\frac{dC_{\text{Soil3}}}{dt} = -k_{S3}C_{\text{Soil3}} + k_{S2}C_{\text{Soil2}} + k_{L3}C_{\text{Litr3}} \quad (1)$$

$$\frac{dC_{\text{Soil4}}}{dt} = -k_{S4}C_{\text{Soil4}} + k_{S3}C_{\text{Soil3}} \quad (2)$$

where  $k_{L3}$ ,  $k_{S2}$ ,  $k_{S3}$ , and  $k_{S4}$  are the turnover rates of Litter 3, Soil 2, Soil 3, and Soil 4 C pool shown in Fig. 1, respectively.  $C_{\text{Litr3}}$ ,  $C_{\text{Soil2}}$ ,  $C_{\text{Soil3}}$  and  $C_{\text{Soil4}}$  are the amount of C in Litter 3, Soil 2, Soil 3 and Soil 4 C pools, respectively. At the steady state, the left hand side of Eqs. (1) and (2) becomes 0, the amount of Soil3c and Soil4C can then be solved:

$$C_{\text{Soil3}} = \frac{K_{S2}}{K_{S3}}C_{\text{Soil2}} + \frac{K_{L3}}{K_{S3}}C_{\text{Litr3}} \quad (3)$$

$$C_{\text{Soil4}} = \frac{K_{S3}}{K_{S4}}C_{\text{Soil3}} \quad (4)$$

Equations (3) and (4) are applicable regardless whether AD or native run was used (the native run was defined here as the simulations without changing the decomposition rates of Soil3 and Soil4 C pools). Therefore, multiplying Eqs. (3) and (4) by their corresponding accelerator, the results should be close to the native runs. That is

$$C_{\text{Soil3,N}} = \frac{K_{S2}}{K_{S3,N}}C_{\text{Soil2}} + \frac{K_{L3}}{K_{S3,N}}C_{\text{Litr3}} = A_{S3}C_{\text{Soil3}} \quad (5)$$

$$C_{\text{Soil4,N}} = \frac{K_{S3}}{K_{S4,N}}C_{\text{Soil3}} = A_{S4}C_{\text{Soil4}} \quad (6)$$

where „ $N$ “ denotes the native run,  $A$  is the accelerator.

Even with this modified accelerator approach, long simulation time cannot be avoided at dry and cold places because decomposition scaling factor is associated with soil water potential and temperature. Hence we report an approach to further improve the speedup in this study.  
5

## 2 Methods

### 2.1 Model description

Community land model, CLM4, is the land component of the Community Earth System Model (CESM) (Lawrence et al., 2011). Processes simulated in CLM4 include bio-  
10 geophysics (solar and longwave radiation, momentum, heat transfer in soil and snow, hydrology of canopy, soil, and snow, and stomatal physiology and photosynthesis) and biogeochemistry (carbon and nitrogen). The vegetation structures (LAI, SAI and height) in CLM4-CN are represented through the predictive state variables of leaf and stem carbon, which are coupled to simulate fluxes of carbon and nitrogen state variables in  
15 vegetation, litter, and soil organic matter (Lawrence et al., 2011; Thornton and Zimmermann, 2007). The tree, shrub and grass plant functional types (PFTs) are divided into tropical, temperate and boreal climate groupings using the PFT physiology and climate rules of Nemani and Running (1996) and C3/C4 photosynthetic pathways in the case of grasses (Lawrence and Chase, 2007). For this study, we used CLM4-CN in offline  
20 mode, which is not coupled to an atmosphere model.

### 2.2 Gradient projection method

If  $m_c$  is the number of years (one cycle) of atmospheric forcing which will be used repeatedly in the spin-up run, we use a spin-up time of  $[(n + 1)m_c]$  years as a stop point for the accelerated decomposition (AD) run, where  $n = 300/m_c$  is an integer. For example, if the number of years of forcing is  $m_c = 7$ , the stop time will be at year 301.

[Interactive Discussion](#)

At the end of the accelerated run, a dynamic steady state water table should be reached in the soil column. Due to the slow turnover rates, the total soil carbon gradually approaches steady state from one cycle to the next (Fig. 2a). We can approximate C at a future time  $t_n$  (Fig. 2b) using the C gradient between two consecutive cycles expressed in the following equation:

$$C(t_n) = C(t_1) + \frac{C(t_1) - C(t_0)}{m_c} (t_n - t_1) \quad (7)$$

where  $t_0$  is the beginning of the first cycle,  $t_1$  is the beginning of the next cycle, and  $t_1 - t_0 = m_c$ ;  $t_n - t_1 = \tau m_c$ ,  $\tau$  is an integer close to the turnover years (reciprocal of turnover rate) of Soil4 C pool to satisfy the stability requirement of forward time integration.

- We call this method gradient projection (GP) method. We allow  $j_p$  (an integer equals to  $m_c \times (100/m_c + 1)$ ) years of simulation after restart from the accelerated run before using this approach, and also  $j_p$  years of simulation followed by each projection until the solution meets the common convergence criteria of  $0.5 \text{ g m}^{-2}$  for total soil C during two consecutive cycles (Shi et al., 2013; Thornton and Rosenbloom, 2005). During each projection, balance check for C and N is turned off. The GP method is only applied to the dominant C and N pools, i.e., coarse wood debris, dead stem, dead coarse root and Soil4 pool.

### 3 Results

- A total of 38 single point tower sites from the FLUXNET (Baldocchi et al., 2001) were selected to assess the gradient projection method. These sites include temperate, boreal, tropical, and subtropical climatic environments and four ecosystem types (tropical forests, temperate forests, boreal forest, grasslands, and Mediterranean-type ecosystems) (Table 1).

The meteorological forcing, site information such as soil texture, vegetation cover, and satellite-derived phenology at each site are provided by the North American

Carbon Program (NACP) site synthesis team for the sites located in North America and by the Large Scale Biosphere–Atmosphere Experiment in Amazônia Model Intercomparison Project (LBA-MIP) for the sites located in South America. The NACP site synthesis and LBA-MIP datasets are detailed in Schwalm et al. (2010) and at <http://www.climatemodeling.org/lba-mip>. Each site has two runs, one using the AD method and the other using the GP method. The available forcing (Table 1) is applied repeatedly during the simulation for each site.

Table 2 shows the comparison of total simulation years till a certain convergence criterion is met. Three convergence threshold values in  $\Delta C_{TOC}$  (3.0, 1.0, and  $0.5 \text{ g m}^{-2} \text{ yr}^{-1}$ ) were compared. The quality of total soil C is better when the threshold value is smaller (Thornton and Rosenbloom, 2005). The reduction of computation cost is shown in Fig. 3. Figure 3 shows that when high quality solution ( $\Delta C_{TOC} \leq 0.5 \text{ g m}^{-2} \text{ yr}^{-1}$ ) is required, the average total reduction in computation cost is 40 %. Average 23 % of computation time is reduced for achieving the low quality solution ( $\Delta C_{TOC} \leq 3 \text{ g m}^{-2} \text{ yr}^{-1}$ ).

Note that the computation cost reduction for sites US-Me2, RJA, US-IB1 and US-SO2 is not shown in Fig. 3. Site US-Me2 met the convergence criteria before the GP method is applied. Sites RJA and US-IB1 show oscillation and site US-SO2 shows a carbon periodicity much longer (81 years) than that of the atmospheric forcing (9 years) (Fig. 4). Therefore, the GP method failed at those three sites.

We first checked whether the oscillation and longer periodicity were caused by fire disturbance. However this can only explain the oscillation at site US-SO2. The annual fire disturbance at site US-SO2 is longer than half a year, while it is less than a month at the other two sites. In the original CLM4, soil water is calculated first for the top ten soil layers (3.8 m below the ground surface) and one aquifer layer using water content based formulation for water mass conservation and groundwater table as bottom boundary condition (Oleson et al., 2010); the Niu et al. (Niu et al., 2005, 2007) parameterizations are then used to simulate groundwater-soil water interaction and update the water table depth. If the water table is below 3.8 m, groundwater does not contribute to

the soil moisture in the overlaying soil layers. We found that after a hundred years, the water table calculation scheme in CLM4 has resulted in significantly different evolution of water table depth from one cycle to the next when repeatedly forcing the model with atmospheric data at sites RJA and US-IB1. The issue has also been found previously and effort has been made to eliminate the oscillations (Oleson et al., 2010), but such oscillations can still occur under specific conditions such as at RJA and US-IB1. When we turned off the groundwater component, i.e., applying zero flux boundary condition at the bottom of the soil column, we did not see oscillations in SOC at RJA and US-IB1. In Niu et al. (2007) groundwater model, after solving the mass conservation equations in the top ten layers, water is then moved around to account for recharge and subsurface runoff and in the meantime satisfy two conditions for water content in each layer, i.e., the water content has to be greater than the minimum content and smaller than the effective porosity of the layer. This approach will cause local mass conservation error, and the error is large when recharge or subsurface runoff is high. The water content formulation itself has been previously shown to cause solution instability for soils near saturation (Hills et al., 1989). Instead of solving the soil water and groundwater separately, we use a flow model for variably saturated porous media, STOMP (Subsurface Transport Over Multiple Phases) (White and Oostrom, 2000), to see if it can resolve the oscillation in the total soil C.

The STOMP simulator was developed to predict non-isothermal hydrological flow and reactive transport in variably saturated subsurface environments. In STOMP, the nonlinear equations describing mass conservation are discretized spatially on structured orthogonal grids using the integral finite difference approach and discretized temporally using first-order backward Euler differencing. Newton–Raphson iteration is used to resolve the nonlinearities from the constitutive equations that relate the primary and secondary variables. Detailed information regarding STOMP, such as user's guide, theory guide and code availability can be found at <http://stomp.pnnl.gov>. For each soil column, the number of vertical grids used for STOMP is 15 and it is the same as that in CLM4. In CLM4, the top ten grids (3.8 m below ground) are used in the soil water scheme.

The same initial saturation condition as that in CLM4 is prescribed. For the grid at the top, the Neumann boundary condition is used. For the bottom (42 m below ground), a zero flux boundary condition is used. Because the aquifer is unconfined, we use the bottom node pressure to calculate water table depth. Figures 5 and 6 shows the model comparison at the beginning of the first 3 years between the simulations using the original soil hydrology scheme in CLM4 and the simulation after replacing the soil water and groundwater-soil water interaction scheme with STOMP at sites RJA and US-IB1. STOMP results in wetter and cooler soil (Figs. 5b, c and 6b, c).

Figure 7a and b shows the oscillations of water table depth resolved at both RJA and US-IB1. Each cycle of atmospheric forcing at both sites has 3 years. The GP method is successful at those two sites. The little jumps in Fig. 7c and d are where the GP method is applied. Both sites show higher total soil C predicted compared to Fig. 4a and b because of the new flow model. The issue of the original groundwater model in CLM4 might explain why it took so long (> 4000 years) for some of the grids in the global simulation to converge as shown in Shi et al. (2013). In addition, the model is not recommended for sites where the length of fire season is too long. For those sites, the overall time that takes for the spin-up run to steady-state is much shorter compared to others, therefore no improvement on the spin-up time is necessary.

## 4 Conclusions

We described a gradient projection method to further speedup the spin-up process based on the slow nature of soil organic C decomposition. Comparison between our approach and the modified accelerator approach showed that 20–69 % of simulation years can be reduced with our approach. While the approach was specifically evaluated using CLM4CN, it can also be readily applied to other CN models in earth system models. In addition, we also found that the original numerical hydrology scheme, especially the water table calculation in CLM4 creates numerical oscillations in simulated water table, leading to a challenge to achieve the common convergence criteria for

soil C. To resolve the issue, we replaced the hydrological model using a flow model for variably saturated porous media. The new flow model caused about 10 % increase in computation time, but gives more accurate results. Using the new flow model, we also see more C being predicted, which will cause less uncertainty due to numerical schemes.

## Accelerating the spin-up of the coupled carbon and nitrogen cycle model in CLM4

Y. Fang et al.

**Figure 5.** Comparison of water table depth (a), average soil moisture content (b), and average soil temperature (c) using original soil hydrology model and STOMP at site RJA.

Accelerating the  
spin-up of the  
coupled carbon and  
nitrogen cycle model  
in CLM4

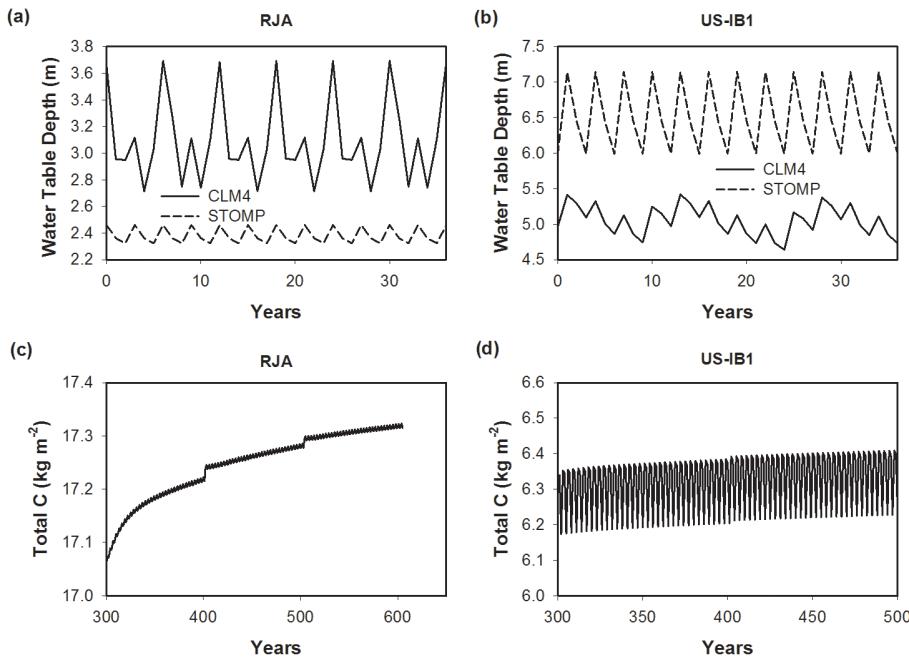

Y. Fang et al.

**Figure 6.** Comparison of water table depth **(a)**, average soil moisture content **(b)**, and average soil temperature **(c)** using original soil hydrology model and STOMP at site US-IB1.

## Accelerating the spin-up of the coupled carbon and nitrogen cycle model in CLM4

Y. Fang et al.

**Figure 7.** Comparison of water table depth simulated by original soil hydrology scheme in CLM4 (solid line) and STOMP (dashed line) at site RJA (a) and site US-IB1(b) at the last 42 years of the simulation; (c) and (d) are total soil carbon at site RJA and US-IB1 using STOMP and the GP method.
