Response to Referee 1

I would like to thank Referee 1 for the time they spent making these thorough comments, which have been very helpful to me in improving the understandability, readability, and presentation of this work.

MAJOR COMMENTS

1. The implementation is of course continuous. However, some users would wonder to what extent they can model very steep gradients in flexural rigidity, and narrow weak zones of very low elastic thickness (major fault zones or crustal discontinuities). The application example contains such weak zone (ridge) but as the author clearly states, it sorts of low pass filter this sharp boundary. It is important to explain to the reader to what extent gflex can approximate major faults or zone of weakness inside the plate and what their response would be. This is particularly important for the non-modellers.

   The low-pass filtering effect that was mentioned early in the paper, in the section on the development of the theory, is a fundamental characteristic of bending of plates of finite thickness. The equations always maintain continuity, even for a plate of 0 thickness – in this case, the flexural solution goes to full local isostatic equilibrium where plate thickness is 0, and then responds accordingly where plate thickness is finite. This is an important distinction between the treatment of a 0-thickness but continuous plate and a true discontinuity, e.g., as given by the 0Moment0Shear (“broken plate”) boundary condition. If the $Te = 0$ condition is in the middle of the load, then the response to the load on either side of it will be continuous with it, creating a cantilever-style condition at the edge of the weak zone. If the $Te = 0$ condition is over a place in which there is no load, then the solution in the rest of the region will be forced to approach this. See the figures below for a better description. One final note is that the finite difference solution requires that the zone of $Te = 0$ be at least 3 cells wide in order to be seen as an isolated block. This is because of numerical diffusion inherent in the solution method and the high order (4) of the PDE. At first glance, this does seem like a disadvantage, or at least that there should be some more flexible way to include a non-straight broken plate condition. However, there are very few (no?) places on Earth’s surface where we truly reach a broken-plate solution, as this implies absolutely no physical interaction between the crust on opposite sides. The closest to this is a rift zone, but even if these have no mantle lithosphere, they have some (thin) crust.

   I have included a paragraph on this in the paper; see the last paragraph in the a new section titled, “Limit as $Te \to 0$.”
Figure 1: 0 elastic thickness in N–S orientation in the middle (E–W) of the array; 0Displacement0Slope boundary conditions elsewhere.
Figure 2: Broken plate on the eastern edge; 0Displacement0Slope boundary conditions elsewhere.
Figure 3: $0$ elastic thickness in N–S orientation on the eastern edge of the array with a broken-plate b.c. on the East. The broken plate b.c. now only applies to the $0$-Te material, which responds to local isostatic equilibrium (here with no load), and the rest of the block must respond to be continuous with this $0$-displacement boundary. Essentially, the $0$-Te section absorbs the effects of the boundary condition locally, and then imposes a $0$-displacement boundary condition on the interior.
2. Delta rho is included in equations 1, 2 and 4. However it is not clear what this term is. It is only until pp. 4258/line 15 that rho_f is mentioned. It would be important to explain the meaning of rho_delta (rho_mantle - rho_filling) and the way it can be used to model different scenarios (marine vs. sedimentary basin, etc.).

This was part of a big oversight on my part! I rearranged some of the paper before submitting, but did not add the descriptions of the variables into the proper sections. I have added the following:

“Here, w is vertical deflection of the plate, q is the applied surface load, and Δρ = ρ_m - ρ_f is the density of the mantle minus the density of the infilling material. This last term represents the feedback by which flexural subsidence can lead a depression to be filled by material, which leads to additional flexural subsidence. This can occur, for example, in a system that is fully underwater (e.g., an underwater volcano load) or one in which the depression is completely filled with sediments. If this infilling material is not uniform in density and/or spatial extent—for example, due to onlap or offlap of water along a shoreline—then one may solve this feedback instead via iteration, by solving for ρ_f = ρ_air ≈ 0 and adding water (or another load) to regions that match certain conditions after every cycle of the iteration.”

3. Can variable rho_f (density of infilling) be modelled in gflex? Page 4260/line 15 says yes, but it is not sure how this can be accomplished. Can variable rho_f be defined as input?

It can, but not explicitly so: the quantity ρ_f is a scalar. I have changed the “As Part of a Python Script” section to explain this better than I had before:

“gFlex may also be imported as a Python module to be run either as a standalone simulation or as a component in a multi-model integration effort. This allows it, for example, to be a part of a flexural backstripping toolchain or a model of glacial–isostatic adjustment. A programmatic approach is also useful for scenarios in which material infills a depression, but not over the whole domain and/or not with uniform density. While the flexure equations require that ρ_f be constant, a more flexible way to solve for the effect of infilling material is to compute flexural response with ρ_f = ρ_air ≈ 0, add loads based on some set of rules, and then re-calculate flexure iteratively until convergence is achieved. This can occur in regions with a complex set of sedimentary deposits and/or to be used for for seawater loading across a shoreline.”

4. Figure 5 is rather confusing. It does not completely explain how the different boundary conditions in Figure 4 can be related to different geological processes (line 5 of p. 4255). It is not clear also what the role of figure 5b is (“provides a contrived field of variable elastic thickness”??). Is that the elastic thickness distribution used in
5c and 5d? It does not seem so: for example in 5d the upper right mountain belt load produces more deflection than the lower left one. One would expect the contrary for the elastic thickness distribution in 5b.

I have updated the figure to include all of the available boundary conditions. One of those in the figure had an old name from a development version of the code, and that has been fixed. Panel D does include more subsidence below the lower left mountain belt, as the reviewer noted would be expected, but this was obscured by the shading for the mountain belt. I have therefore replaced it with a pattern of lines that allows the underlying colors to be seen.

5. p. 4255/lines 25 to 29: This sentence is not clear.
The reason for the lack of clarity is because I somehow wrote a sentence that spanned 15 lines! This has now been broken up and re-worded, see the revised third paragraph in Section 2.3. “Boundary Conditions”

6. p. 4256/paragraph lines 13-24: Periodic boundary. Not clear. I read many times this paragraph, but still I don’t understand how to model a continuous mountain belt with the Periodic boundary.
I was concerned that many geologists might not understand what was meant by a periodic boundary condition (I certainly didn’t until I started using numerical methods), so I tried to explain it as a loop. I have added additional words noting that you essentially connect the west and east edges (or north and south edges), and hopefully this provides some additional help. See the revised 6th paragraph in Section 2.3., “Boundary Conditions”, and please let me know if this still is unclear.

MINOR COMMENTS
p. 4246/line 24: change “of Earth” by "of the Earth"
Not changed: generally still correct, and it is better to have it without the article in the context of other planets (e.g., we would say “of Mercury”).

p. 4247/line 9: change "Analytical" by "The analytical"
There is more than one plate-bending theory, so can’t use the article, but the word “analytical” isn’t needed (should just be implied), so I have removed it instead.

p. 4248/line 15: change "and may" by "which could"
This change would imply that boundary conditions relate to the linear response of the analytical solution, but I really want to say that the boundary conditions are applied to the loading scenarios, meaning that I must
Eq. 5: What is kei?

It is a Kelvin function. I didn’t make this clear above, and in fact, I found my description of it unsatisfactory. So I have added some more background about what it actually is, and made clear that the Kelvin function mentioned in the text is kei.

p. 4252-4253: Is the long sentence at the end of p. 4252 and ending at line 4 of p. 4253 necessary? It is rather confusing and in my opinion does not contribute much to the discussion.

It explains the method for efficiently calculating the space-domain analytical solution, so is necessary. I have re-ordered the concepts in the sentence and broken it into multiple sentences for clarity. (It was ordered in a way that worked in my mind at the time, but probably wasn’t the best explanation.) As a result of these changes, I have rewritten the entire paragraph as follows:

“For a given elastic thickness, each flexural response to a line or point load is similar in shape, but different in amplitude. Therefore, I optimize solution speed by pre-calculating the flexural response to a unit load in the center of a template array. This array has twice the linear dimensions of the solution array, and is subsampled and re-scaled to compute the distributed response to each cell in the grid that contains a load. This technique works for all for rectilinear grids with uniform x- and y-grid-spacing, though the x- and y-grid-spacing do not have to be equal to one another. A similar optimization is possible for one-dimensional solutions, but these are so rapid that this has not been found to be necessary. Within gFlex, this solution type is termed “SAS”, which stands for “Superposition of Analytical Solutions”. ”

p. 4260/line 13: “use repeat forward modeling” is awkward. Please consider changing. Also not clear how gflex can be used as a flexural backstripping tool.

In answer to the awkward phrase, I have removed this and rewritten the paragraph to give the more general idea. In answer to the flexural backstripping tool portion, I have included (1) a citation to a paper that provides a general flexural backstripping method, for which gFlex and any other flexural isostatic calculation tool or method would work, and (2) a reference to a newly-accepted paper in which we use gFlex to backstrip a foreland basin and reconstruct the loading history of a mountain belt.
p. 4262/line 15: "presents cause" is awkward.

It is, and so is much of the sentence. I have rewritten it as follows:

“Earth’s crust at Iceland has been built by the unique intersection of the Iceland hotspot and the Mid-Atlantic Ridge, which together produce a weak lithosphere with spatially-variable elastic thickness, resulting in short-wavelength variability in solid Earth response to loading.”

Figure 5c: What is "Dirichlet0" to the left of the scale bar?

This was an old and poorly-described name for the 0Displacement0Slope boundary; this figure has been updated to fix that.

Figure 6: Caption: Clearly indicate a, b and c: a. before "The ungridded". b. before "The gridded". and c. before "Finite difference"

Thanks for catching this! Done.

Figure 6: scales of x and y axes in a, b and c are quite different. This can be misleading.

They are not only different scales, but they are fundamentally different axes because of the different drivers of compute time for each of the different model runs. While it is nice to put fully-comparable plots above and below each other, I think in this case, the reader will be left to read the axis labels. Figure 7 has a comparison among the different solution types. I have fixed an issue with transparency in both of these figures (6 and 7) and updated the axes labels to be more intuitive.

Figure 7: Put labels to the scale bars, including units (as in Figure 5).

I’m guessing that you mean Figure 8? In which case, done, and thanks for noticing this!

Additional changes:

- Updated overview sketch (Figure 1) for better 3D perspective
- Defined \( T_e \) and \( D \) and their relationship towards the beginning of the paper
- Changed the left-handed coordinate system in the appendix schematic to a right-handed one (oops!)
Response to Referee 2

The author presents a new open source model (gFlex) that can produce analytical and finite difference solutions for lithospheric flexure in 1D and 2D. The software is well described and for sure it will be used by the scientific community. gFlex has been applied to simulate the effects of spatially variable lithospheric thickness on a modelled Iceland ice cup. My only recommendation is to display the results of models having different boundary conditions, since gFlex supports a number of them. In this way it will be fully clear the potentiality of the software.

I appreciate the reviewer’s enthusiasm about this work. To the question about different boundary conditions, I would point the reviewer to Figure 5, which has now been updated to include all available boundary conditions, and now has a hatch pattern instead of a shading beneath loads to better see the local effects on isostasy.
Open-source modular solutions for flexural isostasy: gFlex v1.0

Abstract

Isostasy is one of the oldest and most widely applied concepts in the geosciences, but the geoscientific community lacks a coherent, easy-to-use tool to simulate flexure of a realistic (i.e. laterally heterogeneous) lithosphere under an arbitrary set of surface loads. Such a model is needed for studies of mountain-building, sedimentary basin formation, glaciation, sea-level change, and other tectonic, geodynamic, and surface processes. Here I present gFlex, an open-source model that can produce analytical and finite difference solutions for lithospheric flexure in one (profile) and two (map view) dimensions. To simulate the flexural isostatic response to an imposed load, it can be used by itself or within GRASS GIS for better integration with field data. gFlex is also a component with the Community Surface Dynamics Modeling System (CSDMS) and Landlab modeling frameworks for coupling with a wide range of Earth-surface-related models, and can be coupled to additional models within Python scripts. As an example of this in-script coupling, I simulate the effects of spatially variable lithospheric thickness on a modeled Iceland ice cap. Finite difference solutions in gFlex can use any of five types of boundary conditions: 0-displacement, 0-slope (i.e. clamped); 0-slope, 0-shear; 0-moment, 0-shear (i.e. broken plate); mirror symmetry; and periodic. Typical calculations with gFlex require ≪1 second to ∼1 minute on a personal laptop computer. These characteristics—multiple ways to run the model, multiple solution methods, multiple boundary conditions, and short compute time—make gFlex an effective tool for flexural isostatic modeling across the geosciences.

1 Introduction

Flexure of the lithosphere is a frequently observed processes by which loads bend the elastic outer shell of Earth or other planets (Watts, 2001; Watters and McGovern, 2006). The sources of these loads are wide-ranging (Figure 1), encompassing volcanic islands and seamounts (Watts, 1978; Watts and Zhong, 2000), mountain-belt-forming thrust sheets their associated subsurface loads (Karner and Watts, 1983; Stewart and Watts, 1997), sedimen-
tary basins (Watts et al., 1982; Heller et al., 1988; Dalca et al., 2013), continental ice sheets (Le Meur and Huybrechts, 1996; Gomez et al., 2013), lakes (Passey, 1981; May et al., 1991), seas and oceans (Govers et al., 2009; Luttrell and Sandwell, 2010), extensional tectonics (negative loads) (Wernicke and Axen, 1988), erosion (negative loads) (McMillan et al., 2002), mantle plumes (basal buoyant and therefore negative loads) (D’Acremont et al., 2003), and more.

Theory to describe deflections of the lithosphere under loads has evolved significantly over the past 160 years (Watts, 2001). The development of this theory started with simple approximations of perfect buoyant compensation of loads by a lithosphere with no strength overlying a mantle of known density (Airy, 1855; Pratt, 1855). These approximations allowed surveyors to explain the observed lack of significant gravity anomalies around large mountain belts (cf., Göttl et al., 2009). While this theory, called isostasy, revolutionized the way topography was viewed on the Earth, more realistic solutions for isostatic deflections of the surface of Earth take into account the bending, or flexure, of a lithospheric plate of nonzero but finite strength. This strength may be defined as the “elastic thickness”, the effective thickness of a flawless plate of the equivalent strength, or as the “flexural rigidity” that is characteristic of a plate of a given thickness (see Eq. A10). By bending over distances of several 10’s to 100’s of km, the lithosphere low-pass filters a discontinuous surface loading field into a smoothed solid-Earth response.

Even though the early geological theories of Pratt (1855) and Airy (1855) focused on simple buoyancy, the differential equation basis for solving lithospheric bending already existed at that time. Bernoulli (1789) and Germain (1826, and earlier work) developed the first differential-equation-based theories for plate bending. Lagrange (1828) reviewed the prize that Germain won in 1811 for her work on elastic plate flexure, and, on realizing an error in the lumping of terms due to Germain’s incorporation of an incorrect formula by Euler (1764), corrected it and produced the first complete flexure equation (see reviews by Todhunter and Pearson, 1886; Ventsel et al., 2002). Around the same time, Cauchy (1828) and Poisson (1828) better connected elasticity theory to plate bending problems. These works predated Kirchhoff (1850), who developed “classical” or “Kirchhoff” plate theory that remains in use
today (Ventsel et al., 2002). While many further advances have been made (e.g., Love, 1888; Timoshenko et al., 1959) especially for structural and aeronautical engineering, it is the classical Kirchhoff plate theory that has been used most widely for geological applications (e.g., Van Wees et al., 1994). Comer (1983) tested classical Kirchhoff plate theory, which is a “thin-plate” theory that simplifies the plate geometry and therefore the mathematics required to solve for it, against a “thick-plate” theory of lithospheric flexure. While this thick-plate theory relaxes several approximations, its solutions are very similar to those for thin-plate flexure (Comer, 1983).

In the first half of the twentieth century, Vening Meinesz (1931, 1941, 1950) and Gunn (1943) applied analytical solutions of the plate theory of Kirchhoff (1850) to geological problems. They employed analytical solutions that relate the curvature of the bending moment of a plate of uniform elastic properties to an imposed surface point load, line load, or sinusoidal load. These load solutions could be used to compute flexural response to any arbitrary sum of individual loads in either the spatial or spectral domain, due to the linear nature of the biharmonic flexure equation (Eqs. 1 and 2), and may be combined with a variety of boundary conditions (Watts, 2001).

Computational advances allowed discretized models to replace purely analytical solutions. These models fall into one of several categories. Many take advantage of the linear nature of the flexure equation for constant elastic thickness to superimpose analytical solutions of point loads (in the spatial domain) or sinusoidal loads (in the wavenumber domain) in order to produce the flexural response to an arbitrary load (Comer, 1983; Royden and Karner, 1984). Other models produce numerical solutions to the thin plate flexure equation by solving the local derivatives in plate displacement with numerical (mostly finite difference) methods (e.g., Bodine et al., 1981; Van Wees et al., 1994; Stewart and Watts, 1997; Pelletier, 2004; Govers et al., 2009; Sacek et al., 2009; Wickert, 2012; Braun et al., 2013). This latter category of models allow for variations in the elastic thickness of the plate, a factor of growing importance as variations in elastic thickness through space and time are increasingly recognized, measured, and computed (e.g., Watts and Zhong, 2000; Watts, 2001; Van der Lee, 2002; Flück, 2003; Pérez-Gussinyé and Watts, 2005; Tassara et al., 2007; Pérez-
Gussinyé et al., 2007, 2009; Tesauro et al., 2009; Kirby and Swain, 2009, 2011; Lowry and Pérez-Gussinyé, 2011; Tesauro et al., 2012b, a, 2013; Braun et al., 2013; Kirby, 2014). In spite of these efforts, the community currently lacks a robust, easy-to-use, generalized tool for flexural isostatic solutions that can be used by modelers and data-driven scientists alike.

Here I introduce a broadly implementable open-source package of solutions to flexural isostasy. This package, called gFlex (for GNU flexure), advances and makes more accessible an earlier model, generically called “flexure” (Wickert, 2012). gFlex has been released under the GNU General Public License (GPL) version 3 and is made available to the public at the University of Minnesota Earth-surface GitHub organizational repository, at https://github.com/umn-earth-surface/gFlex, and through the Python Package Index (PyPI). This allows for rapid collaborative editing of the source code and easy automated installation. It is written in Python (e.g., Rossum et al., 2012) for easy interoperability with a range of other programming languages, models, and geographic information systems (GIS) packages, and to take advantage of the numerical packages for Python that allow much more rapid matrix solutions than would be typical with a more basic interpreted language (Jones et al., 2001; Davis, 2004; Oliphant, 2007; van der Walt et al., 2011). See Section 5 for further information on obtaining and running gFlex.

gFlex can solve plate flexure in two major ways (Figure 2). First, it can produce analytical solutions to flexural isostasy generated by superposition of local solutions to point loads in the spatial domain (i.e. as a sum of Green’s functions) (e.g., Royden and Karner, 1984). These use biharmonic equation for plate flexure with uniform elastic properties (Eqs. 1 and 2) (Bodine et al., 1981). Second, it can compute finite difference solutions for both constant and arbitrarily varying lithospheric elastic thickness structures. These solutions follow the work of Van Wees et al. (1994), and hence Braun et al. (2013), except that gFlex does not incorporate terms for end loads but does include a wider range of implementable boundary conditions (Table 1). gFlex can be run as a standalone program with an input file, as a component of the in-development Landlab landscape modeling framework (Hobley et al., 2013; Tucker et al., 2013) and by extension as a component within the Community Surface Dynamics Modeling System (CSDMS) (Syvitski et al., 2011; Overeem et al., 2013), or as a
pair of “add-ons” to GRASS GIS (Neteler et al., 2012). The GRASS GIS implementation is particularly important, as it provides pre-built and standardized command-line and graphical interfaces and the ability to directly pull inputs from and compare solutions against field data in their native coordinate systems.

2 Methods and Model Development

Two solution types for flexural isostasy are provided in gFlex, and these are formulated for both one-dimensional (line load, assumed to extend infinitely in an orientation orthogonal to the line along which the equation is solved) and two-dimensional (point load) cases. The derivation that forms the basis for both of these is provided in Appendix A, and similar approaches to this derivation may be found in the work of Timoshenko et al. (1959) and Turcotte and Schubert (2002). The analytical and finite difference approaches are compared and shown to approximate each other well in Figure 3.

2.1 Superposition of Analytical Solutions

The first solution type takes advantage of the linear nature of the analytical solution for flexure of a plate of constant thickness and elastic properties when subjected to a point or line load. These solutions may be superposed (i.e. summed) in space to compute the full flexural response. The second approach is to solve the equation for lithospheric flexure as a matrix equation by employing a finite difference scheme. This employs a sparse matrix elimination solver (e.g., Davis, 2004). The primary gFlex finite difference solution follows the approach of Van Wees et al. (1994) to permit computations with steep gradients in flexural rigidity (Appendix 2), but it also offers the discretization of Govers et al. (2009).

The analytical solution imposes the assumption that scalar flexural rigidity, $D$, is uniform. This leads to biharmonic expressions for plate bending in one and two dimensions, respectively:

$$ D \frac{d^4 w}{dx^4} + \Delta \rho gw = q $$  

(1)
\[ D \nabla^4 w = D \frac{d^4 w}{dx^4} + D \frac{d^4 w}{dy^4} + 2D \frac{d^4 w}{dx^2 dy^2} + \Delta \rho g w = q \]  

(2)

Here, \( w \) is vertical deflection of the plate, \( q \) is the applied surface load, and \( \Delta \rho = \rho_m - \rho_f \) is the density of the mantle minus the density of the infilling material. This slat term represents the feedback by which flexural subsidence can lead a depression to be filled by material, which leads to additional flexural subsidence. This can occur, for example, in a system that is fully underwater (e.g., an underwater volcano load) or one in which the depression is completely filled with sediments. If this infilling material is not uniform in density and/or spatial extent—for example, due to onlap or offlap of water along a shoreline—then one may solve this feedback instead via iteration, by solving for \( rho_f = \rho_{air} \approx 0 \) and adding water (or another load) to regions that match certain conditions after every cycle of the iteration.

The above equations are linearizable, and therefore can be solved by superposition of analytical solutions. In gFlex, this is done in the spatial domain on both structured grids and as a response to an arbitrarily placed set of point loads. Spectral solutions are possible (Stephenson, 1984; Stephenson and Lambeck, 1985) and efficient using fast Fourier transform algorithms (cf. Welch, 1967), but have not been implemented. The one- and two-dimensional solutions for lithospheric flexure take the form of an exponentially damped sinusoid. In one dimension, this is represented by the following expression:

\[ w_i = q \frac{\alpha_{1D}^3}{8D} e^{\frac{(x-x_i)}{\alpha_{1D}}} \left[ \cos \left( \frac{x-x_i}{\alpha_{1D}} \right) + \sin \left( \frac{x-x_i}{\alpha_{1D}} \right) \right] \]

(3)

Here, the \( i \) subscript indicates that this is the response to a line-load at a single \( x \)-position, \( x_i \). \( \alpha_{1D} \) is the one-dimensional flexural parameter, defined by Vening Meinesz (1931) (following Hertz, 1884):

\[ \alpha_{1D} = \left[ \frac{4D}{(\Delta \rho)g} \right]^{1/4} \]

(4)
The significance of the flexural parameter is that the flexural wavelength, \( \lambda_\alpha \), is related to the flexural parameter as \( \lambda_\alpha = 2\pi \alpha \). The distance from a point load to the first flexural bulge (“forebulge”) that it creates around its local depression, for example, is a flexural half-wavelength, \( \pi \alpha \). This nature of plate bending as an exponentially decaying periodic function can be seen most easily in the one-dimensional analytical (constant \( T_e \)) solution in Eq. 3.

Brotchie and Silvester (1969) derived that the exponentially damped sinusoid due to a point load in two dimensions should be expressed by \( \text{kei} \) (Abramowitz and Stegun, 1972), which is the zeroth-order Kelvin function that satisfies the equation \( \text{ker}(r) + i\text{kei}(r) = K_0(remark heavy emphasis on the importance of the Kelvin function in solving for plate bending in two dimensions.)

\[
\alpha_{2D} = \left[ \frac{D}{(\Delta \rho)g} \right]^{1/4}
\]

(6)

The subscripts \( i, j \) indicate that this is the flexural response to a single point load at the \( x \)- and \( y \)-positions \( x_i \) and \( y_j \). The two-dimensional flexural parameter, \( \alpha_{2D} \), contains \( D \) instead of \( 4D \) in the numerator because it does not need to include implicit loads and deflections along the \( y \)-orientation that are required in the 1-D line load plate bending case.

Lithospheric flexure calculated by superposition of analytical solutions can be represented as a simple sum across all line loads \( q_l \) or point loads \( q_p \):

\[
w = \sum_{q_l} w_i \quad (1D)
\]

(7)

\[
w = \sum_{q_p} w_{i,j} \quad (2D)
\]

(8)
For a given elastic thickness, each flexural response to a line or point load is similar in shape, but different in amplitude. Therefore, I optimize solution speed by pre-calculating the flexural response to a unit load in the center of a template array. This array has twice the linear dimensions of the solution array, and is subsampled and re-scaled to compute the distributed response to each cell in the grid that contains a load. This technique works for all rectilinear grids with uniform x- and y-grid-spacing, though the x- and y-grid-spacing do not have to be equal to one another. A similar optimization is possible for one-dimensional solutions, but these are so rapid that this has not been found to be necessary. Within gFlex, this solution type is termed “SAS”, which stands for “Superposition of Analytical Solutions”.

The analytical solution response to point or line loads can also be computed for a scattered set of loads and a scattered (and not necessarily the same) set of points at which the flexural response is calculated. This solution type is termed “SAS_NG”, which stands for, “superposition of Analytical Solutions: No Grid”. Because it lacks the grid uniformity that permits the a solution template to be used, its computational time is not optimized in this way (Section 2.5).

2.2 Finite Difference Solutions

Finite difference solutions in one and two dimensions employ Eqs. A20 and A21, respectively. For these solutions, $dx$ and $dy$ may differ from one another, but must be constant in space. First, for the one-dimensional solution, the expansion of Eq. A20 is:

$$D \frac{\partial^4 w}{\partial x^4} + 2 \frac{\partial D}{\partial x} \frac{\partial^3 w}{\partial x^3} + \frac{\partial^2 D}{\partial x^2} \frac{\partial^2 w}{\partial x^2} + \Delta \rho gw = q \quad (9)$$
The two-dimensional solution is based on an expansion of Eq. A21 (Van Wees et al., 1994):

$$D \frac{\partial^4 w}{\partial x^4} + D \frac{\partial^4 w}{\partial y^4} + 2D \frac{\partial^4 w}{\partial x^2 \partial y^2} + 2\frac{\partial D}{\partial x} \frac{\partial^3 w}{\partial x^3} + 2\frac{\partial D}{\partial x^2} \frac{\partial^2 w}{\partial x^2} + 2\frac{\partial D}{\partial y} \frac{\partial^3 w}{\partial y^3} + 2\frac{\partial D}{\partial y^2} \frac{\partial^2 w}{\partial y^2}$$

$$+ \nu \frac{\partial^2 D}{\partial y^2} \frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 D}{\partial x^2} \frac{\partial^2 w}{\partial y^2} + 2\frac{\partial D}{\partial x} \frac{\partial^3 w}{\partial x \partial y^2} + 2\frac{\partial D}{\partial y} \frac{\partial^3 w}{\partial x^2 \partial y} + 2(1 - \nu) \frac{\partial^2 D}{\partial x \partial y} \frac{\partial^2 w}{\partial x \partial y} + \Delta \rho gw = q$$

These equations are discretized using a second-order-accurate centered finite difference approximation (Fornberg, 1988, Table 1).

Finite difference solutions in two dimensions may also be generated following the solution and discretization of Govers et al. (2009), which produces solutions for a more limited range of flexural rigidity variations.

The finite difference solution is computed as a linear matrix equation,

$$A W = Q,$$

where $A$ is a sparse matrix of operators from a linear decomposition of Eq. A20 or A21, $W$ is a vector of deflections (typically unknown), and $Q$ is a vector of imposed loads (typically known). It is solved directly by using the sparse LU factorization package UMFPACK (Davis, 2004) or, at the user’s choice, iteratively with one of the many solvers that are available with the SciPy (Scientific Python) package (Jones et al., 2001).

### 2.3 Boundary Conditions

gFlex supports a number of boundary conditions, and these are summarized in Table 1 and schematically drawn in Figure 4. The finite difference (sparse matrix) numerical sol-
olutions can freely define any combination of no-displacement-and-no-slope (0Displace-
ment0Slope), no-bending-moment-and-no-shear (0Moment0Shear), no-slope-and-no-shear
(0Slope0Shear), and mirror boundaries. Periodic boundaries may be mixed with any com-
bination of the aforementioned boundary conditions, with the requirement that they exist on
both sides of the deflection array, as having (for example) deflections at the west end of the
array sensitive to loading and deflections to the east but the east not be sensitive to the west
is nonsensical. Superposition of analytical solutions naturally produce a 0-displacement
boundary at infinite distance from each point load (NoOutsideLoads). This can be seen by
computing the solutions of Eqs. 3 and 5 as $x \to \infty$ and $y \to \infty$. Each of these boundary
conditions can be related to geological processes or locations that one may wish to model
(Figure 5).

The “0Displacement0Slope” (or “clamped”) boundary condition (Figure 4A) may be used
to approximate a “NoOutsideLoads” case for the finite difference solutions (Figure 3). When
placed one flexural wavelength away from a point or line load, the surface displacement
should for a plate of constant elastic thickness be $\sim 0.2\%$ of that at the point of maximum
deflection, which is negligible compared to most sources of geological error. It is conceivably
that a difference in elastic thickness in a continuous plate may exist that is so great that the
thicker plate can be approximated to not bend; a 0Displacement0Slope boundary condition
may also be used to simulate this, though one must debate whether to do this or to compute
the flexural response across a plate with prescribed elastic thickness variability.

The “0Moment0Shear” boundary condition (Figure 4B) means that the edge of the plate
is completely free to flex, like the cantilevered end of diving board. This is appropriate for
places in which the elastic thickness of the lithosphere goes to zero. Such “broken plate”
boundary conditions have been used in analytical solutions to simulate flexure of the litho-
sphere beneath the Hawaiian Volcanoes, where heating significantly weakens the litho-
sphere (Wessel, 1993). This approximates the (0D) single point discontinuity of a hotspot
as a (1D) line boundary condition. A “broken plate” solution has also been used for zones
beneath mountain ranges where sufficient deformation may weaken the lithosphere (Stew-
art and Watts, 1997), and may be best-suited for continental rift zones (Burov et al., 1994),
as these closely approximate a linear discontinuity in an otherwise thick lithosphere. In all three of these cases, the lithosphere should lose strength as it approaches the boundary condition. For this reason, “0Moment0Shear” is implemented only for the finite difference solution.

is also a possible boundary condition in the analytical case, the difficulty in finding a place where the lithosphere suddenly breaks without a gradual thinning and the success of the numerical solution in reproducing analytical solutions (Figure 3) have motivated the decision to not include an analytical 0Moment0Shear boundary condition as part of gFlex v1.0.

The “0Slope0Shear” boundary condition (Figure 4C) may be considered to be a flat clamp on the boundary of the plate that may be freely moved upwards or downwards. While it may require creative thought to uncover a geological process that holds a plate edge flat but allows it to move freely in the vertical, this boundary condition can also be used at an appropriate distance away from the load(s) to approximate a “NoOutsideLoads” boundary for a finite difference solution, though typically the 0Displacement0Slope boundary provides a closer match.

The “Periodic” boundary condition (Figure 4D) wraps one side of the model around to the other side such that they form an infinite loop. To visualize this, one may imagine taking a paper map and taping either the east and west sides together or the north and south sides together, such that the flexure induced by loads on one edge is continuous with load-induced flexure on the opposite edge. Elastic thickness and loads both wrap around this boundary, making it possible to, if one is not careful, create sudden jumps in elastic thickness at the edge of the model. This takes somewhat longer to solve (Figure 6C), but can be useful to compute a flexural response to the load of a long mountain belt by modeling just a limited region perpendicular to the strike of the range crest and allowing this slice to infinitely repeat in the range-crest-parallel orientation; at the limit of a very narrow slice of model space, this approaches the 1D line load solution. If a future model of lithospheric flexure relaxes the current assumption in gFlex that $dx$ and $dy$ may be different but must be constant in space, the periodic boundary condition should enable a finite difference flexural
model to be employed on a closed surface, such as a sphere, enabling full global modeling. This is, to the best knowledge of the author, the first time that a periodic boundary condition has been implemented for lithospheric flexure.

The “Mirror” boundary condition (Figure 4E) reflects the elastic thickness and load structure across a plane of symmetry at the boundary. This may be used to speed a solution where a plane of mirror symmetry may be implied, which is important for large grids or where gFlex is used as part of a coupled set of numerical models (e.g., through CSDMS: Syvitski et al., 2011; Overeem et al., 2013; Peckham et al., 2013). Example usage cases include topographic unloading by erosion of a symmetrical mountain range (Figure 5C, and 5D), isostatic adjustment under a symmetrical ice cap, and emplacement of a volcanic load. The latter two cases often have fully radial symmetry, and therefore may be placed at the corner of the solution array with mirror boundary conditions on both adjacent sides to further limit the needed computational area. This is also to the best knowledge of the author the first application of a mirror boundary condition to modeling of lithospheric flexure, which is surprising considering its potential utility.

The names of the boundary conditions are based on their effects on deflections, $w$, but solutions also require boundary conditions to be placed upon the flexural rigidity, $D$; these are listed in Table 1. For the 0Displacement0Slope, 0Slope0Shear, and 0Moment0Shear deflection boundary conditions, a 0-curvature flexural rigidity boundary condition has been chosen. This allows near-boundary gradients in flexural rigidity to be assumed to continue outside the computational domain. As noted above, Mirror and Periodic boundary conditions are applied to the rigidity field as well. For the analytical solutions, the approximation is an infinite plate of constant elastic thickness.

In two-dimensional solutions, boundary conditions meet at corners. Where a boundary condition meets another of the same boundary conditions at the corner, the two generate a continuous boundary condition that includes the corner of the array. This is always the case for the analytical solutions with implicit NoOutsideLoads boundary conditions. Where mirror or periodic boundary conditions meet themselves at corners, these produce doubly reflecting or doubly periodic boundaries; if every boundary is mirror or periodic (nec-
essary in the latter case as Periodic boundary conditions must always exist as pairs on opposite sides), these generate an infinite tessellated plane of loads and elastic thicknesses. Some boundary conditions in gFlex can work harmoniously with others. Periodic and Mirror boundary conditions propagate 0Moment0Shear, 0Slope0Shear, and 0Displacement0Slope boundary conditions that exist orthogonally to them. Where mirror and periodic boundary conditions intersect at a corner, the periodic boundary condition will propagate the mirror boundary to $\pm \infty$. Those boundary conditions that do not reflect or repeat the effects of the other boundary conditions do not share the corners equally: In gFlex, 0Displacement0Slope boundary conditions dictate all corners where they meet other boundary conditions, forcing them to remain fixed at 0; physically, this means that the “clamp” of the 0Displacement0Slope boundary condition continues through the edges of the perpendicular boundaries. 0Moment0Shear boundary conditions were chosen control the corners where they meet 0Slope0Shear boundary conditions, as the 0Moment0Shear boundary condition has been recognized in geological work (e.g., Wessel, 1993; Burov et al., 1994; Stewart and Watts, 1997), while the 0Slope0Shear boundary condition has not.

2.4 Discontinuities and limit as $T_e \to 0$

Two notable issues inherent to the finite difference solutions and the treatment of a continuous plate become apparent as $T_e \to 0$. The first is that a region of $T_e = 0$ must have a width of at least three cells to produce the expected local isostatic equilibrium; this is a result of numerical diffusion in the central difference discretization provided in Equations 9 and 10. The second is that because any region of 0 elastic thickness will enter isostatic equilibrium with its local loads and not be affected by nonlocal effects, if this region lies along the edge, it will ignore all boundary conditions. If a $T_e = 0$ region along a boundary is $\geq 3$ cells wide, it imposes a 0Displacement0Slope boundary condition on the interior cells; smaller regions of $T_e = 0$ will allow some information on the ultimate boundary condition to leak through via numerical diffusion.

These issues are important to note, but unlikely to be important in most use cases of gFlex. First, discontinuous transitions to zones of $T_e = 0$ may also be modeled by segment-
ing the inputs into multiple arrays, running gFlex for each array with a \(0\)\text{Moment0Shear}\) (broken plate) boundary condition applied to the model domain edges representing the discontinuities, and then recombining the outputs into a continuous displacement field. Second, and more importantly, the conditions for broken plate or \(T_e = 0\) solutions to be required are rare on Earth. Elastic thickness of 0 implies that there is no elastic lithosphere, and a broken plate solution implies that there is no shear between adjacent lithospheric blocks. These conditions are most likely to be met in rift zones, though even these have some nonzero thickness of brittle crust. End loads, which are not currently included in gFlex, could be used in combination with a \(0\)\text{Moment0Shear} boundary condition to better-parameterize faults (e.g., Van Wees et al., 1994) and expand the utility of gFlex. However, the typical use case for which gFlex is designed involves glacial-isostatic adjustment, large-scale water loads, sedimentary basin development, large-scale erosional unloading, and other processes that extend across a swath of heterogeneous lithosphere that may contain many faults. In these cases, it has been found to be sufficient to simply characterize a variable field of finite elastic thickness across the domain, where elastic thickness falls around fault zones (e.g., Manriquez et al., 2013).

2.5 Model Benchmarking

A set of tests was performed to measure the speed at which gFlex computes solutions. In these tests, an elastic plate that is 1000 km long (1D and 2D) and 1000 km wide (2D) is subjected to a square load at its center that ranges from 100 km to the full 1000 km on each side. This load places a normal stress of 9702000 Pa on the surface, which is equal to 300 m of mantle material (3300 kg m\(^{-3}\)). In these scenarios, there is no assumed infilling material (\(\rho_f = 0\)). gFlex computed solutions for uniform rectilinear grids of increasing size using gridded and ungridded superposition of analytical solutions (SAS and SAS\_NG, respectively) and finite difference (FD) methods. All boundary conditions (Table 1 and Figure 4) were tested, though not in combination. The finite difference solutions include scenarios with both constant (25 km) and variable (10–40 km) effective elastic thickness, with the latter varying sinusoidally over a wavelength of 500 km such that the plate contains two full \(T_e\)
cycles. In the two-dimensional case, $T_e$ varies in both dimensions to produce a smoothed checkerboard pattern of elastic thickness. Finite difference solutions reported employ the direct solver UMFPACK (Davis, 2004), as it is better-tested in gFlex than the iterative solution methods and is therefore the default solver. Figure 6 displays computation time for all of the benchmarking tests, and Figure 7 is a comparison of the SAS_NG, SAS, and FD solution techniques for the case in which every point at which the solution is calculated also contains a nonzero load. These solution times do not account for file input or output or graphics generation. They do include the initialization time for the solution steps of gFlex, however, so a number of the power-law fits to solution time do not include the times calculated with the smallest arrays.

The factors that determine computation time are solution method and inclusion of periodic boundary conditions. While the SAS_NG method scales the best with increasing grid size, it is so much slower than the other methods that it will not exceed their speed for any standard model runs. The finite difference method is the fastest if every cell contains a load, but can become slower than the analytical methods if only a few loads exist, as these latter methods must make one set of calculations across the grid per load. Standard runtimes are between a fraction of a second and a few minutes on a personal laptop computer (Dell XPS 13 Developer Edition running Ubuntu 14.10) (Figures 6 and 7).

3 Model Interfaces and Coupling

Some users of gFlex may want to run a single calculation, while others may want to produce many solutions as part of a numerical model. Therefore, five different methods to use gFlex have been prepared:

1. Standalone, with input files

2. As part of a Python script

3. Driven by GRASS GIS (Neteler et al., 2012) to simplify integration of geospatially registered data with the lithospheric flexure model
4. As a component for the Community Surface Dynamics Modeling System (CSDMS) framework (Syvitski et al., 2011; Overeem et al., 2013; Peckham et al., 2013), including its tight integration into Landlab, a CSDMS-led Python-based Earth-surface modeling framework that is currently being developed (Hobley et al., 2013; Tucker et al., 2013)

GRASS GIS integration is also possible for model coupling using Python, including efforts that use the Landlab framework.

3.1 Standalone with Input Files

Some users may want to employ gFlex as a single calculation, for example to calculate the flexural response to a set of loads generated by a sedimentary deposit that was measured in the field. The user prepares an input file of model settings, an input ASCII grid of loads, and, should the elastic thickness be nonuniform, an input ASCII grid of lithospheric elastic thicknesses. Outputs from this mode of running gFlex include an ASCII grid of surface deflections and a set of plots of surface deflections and loads.

3.2 As Part of a Python Script

gFlex may also be imported as a Python module to be run either as a standalone simulation or as a component in a multi-model integration effort. This allows it, for example, to be a part of a flexural backstripping toolchain or a model of glacial–isostatic adjustment. Backstripping calculations may be performed by simply removing the sedimentary load (Roberts, 1998), or, in the case of a foreland basin, by inverting for the mountain belt loading history and lithospheric elastic thickness that would be required to produce the basin (Ballato et al., 2016). A programmatic approach is also useful for scenarios in which material infills a depression, but not over the whole domain and/or not with uniform density. While the flexure equations require that \( \rho_f \) be constant, a more flexible way to solve for the effect of infilling material is to compute flexural response with \( \rho_f = \rho_{\text{air}} \approx 0 \), add loads based on some set of rules, and then re-calculate flexure iteratively until convergence is achieved. This can occur
in regions with a complex set of sedimentary deposits (see also Watts et al., 1982; Watts, 2001) and/or to be used for for seawater loading across a shoreline (see also Mitrovica and Milne, 2003).

### 3.3 Driven by GRASS GIS

gFlex is also prepared for integration with the open-source geospatial software GRASS GIS (Neteler et al., 2012) as two “add-ons” or “extensions” named “r.flexure” and “v.flexure”, which are raster and vector operations, respectively. As GRASS GIS is a map-based application, r.flexure and v.flexure employ two-dimensional solutions (both analytical and finite difference), though future extension to flexure along chosen one-dimensional profiles would be possible. r.flexure can use the finite difference or SAS solution methods, whereas v.flexure exclusively uses the SAS_NG solution method to take advantage of its ability to produce solutions for an arbitrary scatter of loads points. Advantages of GRASS GIS include:

1. Full integration within a geospatially registered environment, meaning that data can be directly used as model inputs, and that model outputs may be compared against data
2. A documented and standardized command-line interface
3. A pre-built and standardized graphical user interface (GUI)

The graphical user interface is incorporated into the GRASS GIS wxPython GUI (Landa, 2008; Neteler et al., 2012), and this is particularly helpful for researchers who are not as accustomed to command-line interaction with computers to use gFlex with their data. For computer modelers, the GRASS GIS coupling may be used within a broader framework of data–model integration (see, for example, Srinivasan and Arnold, 1994).
3.4 Modeling Frameworks

CSDMS (broadly) and Landlab (in particular) both include methods for integrating modular blocks of code as part of their respective efforts towards the community-wide goal to make modeling of Earth systems less time-intensive and more streamlined (Voinov et al., 2010; Syvitski et al., 2011; Overeem et al., 2013; Peckham et al., 2013; Hobley et al., 2013; Tucker et al., 2013). gFlex is included as a modular component of the the still-in-development Landlab Earth-surface modeling framework (Hobley et al., 2013; Tucker et al., 2013). Landlab integration provides wrapping with the CSDMS Basic Model Interface (BMI) and Component Model Interface (CMI) using the CSDMS Standard Name construction conventions (Peckham et al., 2013). The standard interfaces provided by both of these modeling frameworks will streamline model coupling that uses gFlex and help to prevent duplication of effort in building plate bending models. Furthermore, the inclusion of gFlex in Landlab will allow numerous Earth-surface systems to be modeled more precisely (Figure 1).

4 Application Example: Iceland

As a first example to utilize both the ability of gFlex to generate solutions with variable effective elastic thickness and its incorporation into GRASS GIS, gFlex is used along with a simple and efficient GIS-enabled glacier and ice cap model modified from the work of Colgan et al. (2015, submitted) to model a hypothetical expansion of the Iceland Ice Cap. While the importance of flexural isostasy in ice dynamics modeling has long been well-known (cf. Cuffey and Paterson, 2010), the author knows of no dynamic ice model that runs with a variable elastic thickness lithosphere, making this possibly the first such exercise. Earth’s crust at Iceland has been built by the unique intersection of the Iceland hotspot and the Mid-Atlantic Ridge, which together produce a weak lithosphere with spatially-variable elastic thickness, resulting in short-wavelength variability in solid Earth response to loading. Here I test the two-way coupling between ice dynamics and solid Earth deformation and the
differences in steady-state ice caps that are produced in a modest climate change and ice cap extent scenario.

This coupled ice dynamics and flexural isostatic model of Iceland requires four input components: the elastic thickness structure around Iceland, the modern topography of Iceland, the modern surface temperature field of Iceland, and modern precipitation rates across Iceland. The ice cap model used here (cf. Colgan et al., 2015, submitted) employs a shallow-ice approximation with basal sliding as a linear function of driving stress, which is intentionally much simpler than the modeling approach that Hubbard et al. (2006); Hubbard (2006) used to model the Last Glacial Maximum (LGM) Iceland ice cap. This is because the goal here is to show schematically the importance of including lateral variations in elastic thickness on the reconstructed thickness of an ice cap for a given paleoclimate, with less emphasis on actually reproducing any particular extent of the Iceland Ice Cap.

The elastic thickness structure under Iceland, in this schematic example, is related to the age of the oceanic crust following Calmant et al. (1990), who relates elastic thickness to age of the lithosphere by the simple equation:

$$T_e = (2.70 \pm 0.15) \sqrt{\Delta t}$$

(12)

where $T_e$ is provided in km and the age of the lithosphere, $\Delta t$, is given in millions of years. As continental material also exists within the computational window, the elastic thickness map of Tesauro et al. (2012b, a) is used for all subaerial landmasses. Across the continental shelves, the oceanic-crust-based and Tesauro et al. (2012b, a) maps are blended using spline interpolation within GRASS GIS Neteler et al. (2012). The regional age of oceanic crust is provided by Müller et al. (2008), but their map indicates that even crust at the ridge in Iceland has an age of 6–7 Ma, resulting in a greater computed effective elastic thickness than would be expected based on the presence of the ridge or from heat flow data (e.g., Flóvenz and Saemundsson, 1993). While the structure of Iceland is certainly more complicated than the simpler parts of the ridge due to the effects of the hotspot and its tectonic environs (e.g., Watts and Zhong, 2000; Foulger, 2006), the assumption here is that the lithospheric effective elastic thickness structure due to the ridge is as if young crust
continued along the Mid-Atlantic Ridge through all of Iceland, and the elastic thickness map
(Figure 8I) was modified to approximate this for the sake of this example.

The underlying digital elevation model, GEBCO_08 (British Oceanographic Data Centre (BaODC) and General Bathymetric Chart of the Oceans (GEBCO), 2010), includes the
modern ice caps on Iceland, but these are already flexurally compensated and are small
compared to the of the ice cap modeled here. While their removal would improve recons-
tructed ice discharge, they are ignored due to the schematic nature of this modeling effort.

Modern temperature and precipitation fields are from the Monthly NOAA-CIRES 20th
Century Reanalysis (V2) by Compo et al. (2006, 2011) (for further background on their
methods, see Whitaker and Hamill, 2002). These provide twentieth century mean condi-
tions on a 2°×2°-degree latitude/longitude grid (temperature) or a 94×192 Gaussian grid
(precipitation). These were cast as point data and interpolated using splines in GRASS
GIS (Neteler et al., 2012). Prior to this spline interpolation, temperature was projected to
sea level using the mean cell elevation a lapse rate of 4.7°C km\(^{-1}\), following Anderson et al.
(2014) for ice caps; after interpolation, the resultant temperatures were then interpolated up
to their respective surface elevations using the same 4.7°C km\(^{-1}\) lapse rate. Although not
all of the Icelandic surfaces are covered in ice at present, this rule was prescribed uniformly
for the sake of a schematic model.

Three experiments were run: one with no flexure, one with flexure using a constant elas-
tic thickness of 3.7 km (following Hubbard, 2006, and assuming \(E = 65\) GPa), and one in
which the full spatially variable flexure was used. In each of these runs, temperature was re-
duced from its present value by 5°C and ice expanded to cover an area approximately equal
to the currently subaerially exposed continent, approximately consistent with the previous
modeling results of Hubbard et al. (2006) and with a temperature change that is much less
than the LGM drop of 10–13°C that was predicted to cause ice to spread onto the continen-
tal shelves as well (Hubbard et al., 2006). Mass balance was simulated by a positive degree
day melt model. June, July, and August temperatures were used to compute ablation, with
a melt factor of 6 mm d\(^{-1}\) K\(^{-1}\). Precipitation was held constant and all precipitation was
assumed to contribute to positive mass balance. Each scenario was run for 4000 years to
reach full glacial and isostatic equilibrium, with isostatic equilibrium being assumed to occur instantaneously to facilitate more rapid computation of the equilibrium solution.

The results in Figure 8 summarize the experiments. Panels 8C and 8F show the modeled flexural isostatic deformation and panels 8B and 8E show the deviation from the case with no isostasy; each of these pairs is for constant and variable elastic thickness, respectively. 8H shows that with variable elastic thickness (8I), ice thickness variability is concentrated where lithospheric elastic thickness is low.

The example of isostatic response to ice advance in Iceland is just one possibility of a feedback between an Earth-surface (or other geological) process and flexural deformation. Further such scenarios involving, for example, orogenesis and foreland basin formation (in settings such as that studied by Ballato and Strecker, 2014), rifting (Braun et al., 2013), and river delta morphologic evolution (Kim et al., 2006), will improve our understanding of the dynamic interactions between Earth’s surface and subsurface (e.g., Braun et al., 2013).

5 Model Availability

gFlex is available from the University of Minnesota Earth-surface GitHub repository at https://github.com/umn-earth-surface/gFlex. It runs on Linux, Windows, and Mac computers running Python 2.(X≥7).Y. It may be downloaded as an archive that is a snapshot of the state of the code, or “cloned” into an updatable copy of the software on the computer of an end-user. Version 1.0, described in this paper, is stored at https://github.com/umn-earth-surface/gFlex/releases/tag/v1.0a (the alpha version release is for the Discussion Paper, and will be updated to a full release pending reviewer comments). gFlex is also stored on the Python Package Index (PyPI) at https://pypi.python.org/pypi/gFlex for easy automated download and installed with the command-line tool “pip”. gFlex documentation is available in its file “README.md” that is displayed at the main GitHub repository page, and some additional information is presented at the gFlex CSDMS Wiki page at https://github.com/umn-earth-surface/gFlex.
Interfaces to GRASS GIS and Landlab are available from their respective repositories. The GRASS GIS interface works with GRASS GIS 7.X and can be downloaded and installed automatically with the “g.extension” tool within GRASS (Neteler et al., 2012) or be downloaded through the subversion repository at http://trac.osgeo.org/grass/browser/grass-addons/grass7. The Landlab interface is located in the Landlab GitHub repository at https://github.com/landlab/landlab/tree/master/landlab/components/gFlex.

6 Conclusions

gFlex is a new, open-source, easy-to-use model to compute isostatic deflections of Earth’s lithosphere with uniform or nonuniform flexural rigidity due to arbitrarily distributed surface loads. It can be run as a standalone model through a configuration file, a Python module, a component in the Landlab and CSDMS community modeling frameworks, or via one of two GRASS GIS add-ons for a direct link to geospatial data. Its open-source code base may be updated and improved by the community, it may be easily installed using automated tools, and it is poised to be coupled with other models in efforts to understand interactions between multiple components of the Earth system. These attributes all embody my primary aim in creating gFlex: to provide an accessible set of flexural isostatic solutions for work across the geosciences by field scientists and modelers alike.

Appendix A: Derivation: Flexure

Plates and beams resist bending (i.e. flexure) through fiber stresses, which develop during loading-induced deformation. In this appendix, the background of the theory is provided by an abridged one-dimensional derivation, which provides the background to the assumptions made in both the analytical and finite difference one-dimensional and two-dimensional solutions. Components of the theoretical background will also be relevant to the various boundary condition options introduced in the main text.
A derivation of flexural response to a load can be subdivided into two components. The first is the bending moment, which describes the resistance of the plate to bending. The second is the relationship between the bending moment and the imposed load. For simplicity, these derivations will be presented for the one-dimensional case and then generalized to the two-dimensional case. This generalization is non-trivial only for the consideration of material properties in the bending moment derivation.

A1 Bending Moments

The bending moment of a plate describes its resistance to being bent. This comes about because when a plate of nonzero but finite thickness is bent, portions of the plate on the inside of the curve are placed under compression and portions of the plate on the outside of the curve are placed under tension. These fiber stresses ($\sigma_{x'x'}$ in the along-plate coordinate system $x', z'$ depicted in Figure A1) cause each infinitesimal layer of the plate to act like a spring that provides finite strength to the plate through which it resists bending.

Classical (Kirchhoff–Love) plate theory is derived using an approximation of cylindrical bending (cf. Love, 1888). Over short distances, the bent plate is assumed to follow the arc of a circle (Figure A1). Arc length, $s$, is described as the product of the radius of curvature, $r_c$, and the angle over which the arc is defined, $\theta$.

$$s = r_c \theta \quad (A1)$$

In a radial transect through a cylindrically bent plate of finite but nonzero thickness, each level in the plate will have a different radius of curvature. At the midpoint of a single-layer plate (i.e. no changes in material properties with elevation $z$), such as that considered in this treatment of lithospheric flexure, the layer halfway between the top and the bottom of the plate will experience no net extension or shortening. This midpoint layer is therefore taken to be the reference radius of curvature, $r_0$, of a plate that extends from $r = -T_e/2$ to $r = T_e/2$, where $T_e$ is the effective elastic thickness of the plate. To calculate the range of arc lengths, $s$, that exist above and below the reference layer at $r_0$, one can note that Eq. A1 describes a linear relationship between arc length and radius of curvature. Therefore, it
is possible to use the definition of strain and Eq. A1 to define the “fiber strain” in each layer as a function of its distance from the midpoint. To do so, a Cartesian coordinate system \((x', z')\) can be defined to exist along the curve of the bent plate (Figure A1). The normal strain along the \(x'\) orientation, \(\varepsilon_{x'x'}\), is given by:

\[
\varepsilon_{x'x'} = \frac{s + ds}{s} = \frac{r - r_0}{r_0} = \frac{z'}{r_0}
\]  

(A2)

Here, \(ds\) is the difference in arc length in a radial transect across the plate, \(r\) is an arbitrary radius, and \(\theta\) has been dropped because it is constant and therefore cancels out. \(z'\) is defined to be zero at \(r_0\). Sign conventions are unimportant due to the symmetry of the problem above and below the equilibrium layer (Figure A1). To further express this system in terms of Cartesian coordinates that also allow for the cylindrical bending approximation to hold only locally, it becomes useful to reframe the cylindrical curvature expression in Eq. A1 in terms of continuous Cartesian derivatives. To do so, the first step is to take the derivatives with respect to \(x\) of both sides of Eq. A1 while allowing radius of curvature to be an imposed constant, and then approximate \(s\) as a linear segment to apply the distance formula. Note that here the coordinate system is \((x, y)\), parallel and orthogonal, respectively, to the undeformed plate:

\[
\frac{ds}{dx} = r \frac{d\theta}{dx} = \sqrt{1 + \left(\frac{dz}{dx}\right)^2}
\]  

(A3)

One then uses the derivative of the trigonometric identity that \(\theta = \arctan\left(\frac{dz}{dx}\right)\) to write:

\[
\frac{d\theta}{dx} = \frac{\frac{d^2 z}{dx^2}}{1 + \left(\frac{dz}{dx}\right)^2}
\]  

(A4)

Noting that \(\frac{dz}{dx} \ll 1\) for these long-wavelength and low-amplitude deflections of the lithosphere, this term vanishes from the derivation. It is then simple to combine and rearrange Eqs. A3 and A4 to show the intuitive result that smaller radii of curvature produce
greater curvature. Further, by noting that derivatives of vertical position, \( z \), are identical to curvatures of deflection, \( w \), from an initial position \( z_0 \), we can write the following equality:

\[
\frac{1}{r} = \frac{d^2 z}{dx^2} = \frac{d^2 w}{dx^2} \tag{A5}
\]

The next step is to connect these equations for bending into a framework of bending-related stresses and strains. In order to do so, it is first necessary to show the approximate equality between terms depending on \((x, y)\) and those depending on \((x', y')\). This is possible through the small angle approximation, which, combined with \((dz/dx) \ll 1\), means that:

\[
\frac{dw}{dx} \approx \frac{dw}{dx'} \tag{A6}
\]

and therefore, \(dx \approx dx'\).

Eqs. A2 and A5 can be combined for \(r = r_0\).

\[
\varepsilon_{xx} = \varepsilon_{x'x'} = z' \frac{d^2 w}{dx^2} \tag{A7}
\]

The equality between \(dx\) and \(dx'\) makes normal strains in both of these orientations be approximately equivalent, with \(\varepsilon_{xx}\) being the standard way of writing this strain for the remainder of this appendix. Eq. A7 becomes important in the final step to define the bending moment (first step next) in that it relates material strains directly to geometric positions that can be measured and/or modeled.

The bending moment itself, \(M\), is the resistance of the plate to bending. It is defined as the sum through the thickness of the plate of all fiber stresses (\(x\)-oriented normal stresses) \(\sigma_{x'x'}\) times their respective lever arms \(z'\) (cf. Turcotte and Schubert, 2002).

\[
M = \frac{T_e}{2} \int_{-T_e/2}^{T_e/2} \sigma_{xx} z' dz' \tag{A8}
\]
This definition of the bending moment of a plate shows that forces that initiate bending generate torques that oppose the bending. It is possible to rewrite this in terms of strain instead of stress by combining the one-dimensional elastic constitutive relationship (Hooke’s Law) \( \sigma_{xx} = E \varepsilon_{xx} \) with \( 1/(1 - \nu^2) \). \( E \) is Young’s modulus, which is a generalized spring constant that typically ranges between \( 10^{10} \) and \( 10^{11} \) for rock (Turcotte and Schubert, 2002, p. 106), and \( \nu \) is Poisson’s ratio, which describes how much material tends to extend (or shorten) in one direction when shortened (or extended) in another and is commonly taken to be 0.25 for the lithosphere (Turcotte and Schubert, 2002). The latter term involving Poisson’s ratio is the result of the fact that for solutions on the Earth, the one-dimensional solution is assumed to apply for a plane (and loads) that continue indefinitely in the positive and negative \( y \)-directions (i.e. into and out of the page in Figure A1), but strain in this orientation is disallowed. Therefore, these compressive stresses that prevent \( y \)-oriented bulging of the plate act to further inhibit its bending, effectively increasing the flexural rigidity.

\[
M = \frac{E}{1 - \nu^2} \int_{-T_e/2}^{T_e/2} \varepsilon_{xx} z' dz' 
\]  
(A9)

Both \( E \) and \( \nu \) lie outside of the integral because they are assumed constant across \( z' \).

It is possible to solve for the bending moment in one dimension by using Eq. A7 to replace \( \varepsilon_{xx} \) in Eq. A9. As the derivative \((d^2 z/dx^2)\) is orthogonal to the direction of integration, the integral is simple to solve and results in a solution for the bending moment:

\[
M = \frac{ET_e^3}{12(1 - \nu^2)} \frac{d^2 w}{dx^2} 
\]  
(A10)

The terms to the left of the derivative define the scalar flexural rigidity, \( D \):

\[
D = \frac{ET_e^3}{12(1 - \nu^2)} 
\]  
(A11)
As $D$ is very important in controlling flexural response and is a function of $T_e$, $E$, and $\nu$, gFlex contains the additional simplifying assumption that $E$ and $\nu$ are uniform constants. This permits variations in scalar flexural rigidity to map to variations in effective elastic thickness via Eq. A11. It prevents overparameterization in gFlex, and implicitly states the assumption that changes in the effective elastic thickness of the lithosphere, cubed, are more significant than changes in Poisson’s ratio, squared, or Young’s modulus.

To generalize the bending moment to a two-dimensional plate, one must follow Van Wees et al. (1994) in acknowledging that Poisson’s ratio, $\nu$, is applied differently to orientations parallel and perpendicular to those over which the bending occurs (normal moments) and is not important for the shear moments:

$$M_{\kappa} = \begin{bmatrix} M_x \\ M_y \\ M_{xy} \end{bmatrix} = D \begin{bmatrix} \frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial y^2} \\ \nu \frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} \\ (1-\nu) \frac{\partial^2 w}{\partial x \partial y} \end{bmatrix}$$

\[ A12 \]

### A2 Force and Torque Balance

A static lithospheric plate must balance the normal force, $F$, of imposed loads by generating shear forces, $V$ and $V + dV$, due to bending. In Figure A1, the imposed load $q$ is defined as:

$$q = \sum_{x} q(x)$$

\[ A13 \]

This signifies that in the numerical solution, a continuous load field is discretized into individual point loads of length $dx$ and (if a 2D solution is used) width $dy$. Further vertical normal stresses for plate flexure are generated by the the sum of the buoyant restoring force of displaced mantle, $\rho_m g w$, and additional driving forces by any surface loads that fill the flexural depression, $\rho_f g w$. Here I explicitly ignore end loads because they are not part of the numerical solution in gFlex, which was designed with surface loads in mind, though
they are straightforward to include (see Van Wees et al., 1994; Braun et al., 2013). Summed together, these form the additional term $\Delta \rho gw$, where $\Delta \rho = (\rho_m - \rho_f)$. The total shear force balance across a cell is therefore defined as:

\[
\sum F = q + \Delta \rho gw + V - (V + dV) = 0 \quad \text{(A14)}
\]

\[
dV = q + \Delta \rho gw \quad \text{(A15)}
\]

While the load stress, $q$, is directed downwards, its sign convention is flipped such that as observed geologic loads (e.g., sediments, volcanoes) increase in thickness, $q$ increases as well.

These shear forces must be balanced in turn by the bending moments in a torque ($\tau$) balance:

\[
\sum \tau = -M + (M + dM) + V \times 0 - (V + dV) \times dx = 0 \quad \text{(A16)}
\]

\[
V + dV \rightarrow 0 \frac{dM}{dx} \quad \text{(A17)}
\]

Eq. A17 states that the shear force ($V$, here $dV$ is vanishingly small in comparison) equals the derivative of the bending moment. The combination of Eqs. A17 and A10 shows that shear force is directly proportional to the third derivative of deflection:

\[
V = \frac{dM}{dx} = D \frac{d^3 w}{dx^3} \quad \text{(A18)}
\]

This observation is key to defining the 0Moment0Shear and 0Slope0Shear boundary conditions (Table 1 and Figure 4).

After noting that $dV \ll V$ and so can be neglected in Eq. A17, Eqs. A15 and A17 can be combined by substituting $V$ in Eq. A15 to relate the bending moment to the imposed loads $q$. When including the restoring force from mantle buoyancy, $\Delta \rho gw$, the resultant equation reads:

\[
\frac{d^2 M}{dx^2} + \Delta \rho gw = q \quad \text{(A19)}
\]
Eq. A19 can be combined with Eqs. A10 and A11 to show in the one-dimensional case that:

\[
\frac{d^2}{dx^2} \left( D \frac{d^2 w}{dx^2} \right) + \Delta \rho gw = q \tag{A20}
\]

In the more general two-dimensional case, one can create an analogous expression by separating the matrix flexural rigidity and curvatures used to create Eq. A12 (Van Wees et al., 1994), resulting in:

\[
\frac{1}{2} \left[ \frac{\partial^2}{\partial x^2} \frac{\partial^2}{\partial y^2} \left( \frac{\partial^2}{\partial x \partial y} + \frac{\partial^2}{\partial y \partial x} \right) \right] \left( D \begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1-\nu}{2} \end{bmatrix} \begin{bmatrix} \frac{\partial^2 w}{\partial x^2} \\ \frac{\partial^2 w}{\partial y^2} \\ \frac{\partial^2 w}{\partial x \partial y} + \frac{\partial^2 w}{\partial y \partial x} \end{bmatrix} \right) + \Delta \rho gw = q \tag{A21}
\]

**Acknowledgements.** ADW greatly appreciates Eric Hutton's insights and help with CSDMS integration and project architecture as well as Daniel Hobley's work to integrate gFlex with Landlab. Václav Petráš' help in incorporating gFlex as an official set of GRASS GIS extensions was very much appreciated. Liam Colgan kindly supplied his glacier model source code, and conversations with Robert S. Anderson, Leif S. Anderson, and Gregory E. Tucker helped to inspire the project. 20th Century Reanalysis V2 data were provided by the NOAA/OAR/ESRL PSD, Boulder, Colorado, USA, from their Web site at http://www.esrl.noaa.gov/psd/. Funding for this project was provided by the US Department of Defense through the National Defense Science & Engineering Graduate Fellowship Program, the US National Science Foundation Graduate Research Fellowship under Grant No. DGE 1144083, an ExxonMobil geoscience grant, and by the Emmy Noether Programme of the Deutsche Forschungsgemeinschaft (DFG) through funds awarded to T. Schildgen under Grant No. SCHI 1241/1-1.

Table 1. Boundary conditions. Names provided here are the same as those used in the model. The first five can be selected for numerical solutions. The final one, NoOutsideLoads, is the outcome of superposition of analytical solutions, which allows the entire space to respond to local loads as if the 0-deflection boundaries were infinitely far away. In this notation, the subscript $b$ indicates the boundary, generically. Where 0 and $n$ are included as subscripts, i.e. for the mirror and periodic boundary conditions, these indicate boundaries at the first and last node of the model domain along a particular axis. Subscript $x$, which is a stand-in for $x$ or $y$, is a variable distance to indicate the symmetry across a mirror boundary. Each of these boundary conditions requires a corresponding boundary condition for flexural rigidity.

Figure 1. Flexural isostasy can be produced in response to a range of geological loads.
Figure 2. Flowchart for gFlex as (1) a standalone model with configuration and input files, (2) a Python module or coupled component in a modeling framework, or (3) a GRASS GIS component.
Figure 3. Numerical (FD) and analytical (SAS) solutions in 1D (A) and 2D (C) and their differences (B and D) in response to a 100-km-(long/in-diameter) central line/circular load. These differences are due primarily to the NoOutsideLoads boundary condition of the analytical solution and the 0Displacement0Slope boundary condition of the numerical solution. This can be seen in panel B where the example with a lower elastic thickness is less-offset due to the greater number of flexural wavelengths between the load and the boundary, and in the greater agreement between the solutions on the longer diagonal boundaries in D. The offset in the middle, visible as a small bump in B and a blue diamond surrounded by red petals in D, is due to the difference between approximating the load as a sum of point impulses (analytical) and as the solution to a rectangularly gridded matrix equation based on the same theory (numerical).
Figure 4. Schematics of boundary condition types allowed in the finite difference solutions to gFlex.
Figure 5. Example runs of gFlex with varying elastic thickness and boundary conditions. A depicts a long north–south mountain belt and foreland basin under uniform elastic thickness. B provides a contrived field of variable elastic thickness. C is similar to A except in that it uses a mirror boundary for a symmetrical mountain belt over a continuous lithospheric plate instead of a broken plate solution, and that the plate has the variable elastic thickness structure given in B. D depicts the flexural interaction of two mountain belts on the same variable-elastic-thickness lithosphere shown in B and has mirror boundary conditions at all edges.
Figure 6. Model benchmarking. A: The ungridded superposition of analytical solutions (SAS\_NG) computation time is proportional to the number of cells with loads present, as the solutions are calculated once for each of these positions. B: The gridded superposition of analytical solutions (SAS) scales to the total number of grid cells times the number of cells with loads, as this is the total number of computations that must be made. C: Finite difference solutions are computed with sparse matrices with dimensions equal proportional to the grid dimensions, squared, and therefore scale with the number of total grid cells. All of the solution time relationships are close to linear except for the two-dimensional finite difference solutions, due to the added complexity of their finite difference stencil. Many fits are to a subset of the data to avoid those solutions that are so rapid that the amount of time required for the non-solver portions of the code becomes significant. All marker symbols are semi-transparent, meaning that darker symbols than those that appear in the legend imply additional data points underneath.
Figure 7. Comparison between solution methods where every cell in the domain contains a load. The ungridded superposition of analytical solutions (SAS_NG) scales best but in these tests is the slowest. It can, however, be faster when fewer cells contain loads. Some fits are to a subset of the data to avoid those solutions that are so rapid that the amount of time required for the non-solver portions of the code becomes significant. All marker symbols are semi-transparent, meaning that darker symbols than those that appear in the legend imply additional data points underneath.
Figure 8. This coupled model run for a hypothetical extent of the Iceland ice cap shows the influence of a variable elastic thickness structure (I). The areal extent of the three ice caps is nearly identical (A, D, G) in this small-scale and largely topographically controlled example. Flexural isostasy with a constant 3.7-km elastic thickness (C) (following Hubbard, 2006) reduces ice cap extent and causes some interior ice thickening when compared to the case without flexure (B) as the ice cap conforms to the bowl-shaped depression that it creates. Deformation in the case with variable elastic thickness (F) focuses along the ridge and extends farther on the southwestern side that has greater elastic thickness, and modifies the topography of western Iceland (low elastic thickness) to produce spatially variable ice thickness changes (E, H).
Figure A1. Schematic of the bending of a buoyant plate under a load that is long in the $y$-orientation.
