## 20 Abstract

21 A wealth of recent laboratory and field experiments demonstrate that organic aerosol 22 composition evolves with time in the atmosphere, leading to changes in the influence of the 23 organic fraction to cloud condensation nuclei (CCN) spectra. There is a need for tools that can 24 realistically represent the evolution of CCN activity to better predict indirect effects of organic 25 aerosol on clouds and climate. This work describes a model to predict the CCN activity of 26 organic compounds from functional group composition. Following previous methods in the 27 literature, we test the ability of semi-empirical group contribution methods in Köhler theory to 28 predict the effective hygroscopicity parameter, kappa. However, in our approach we also account 29 for liquid-liquid phase boundaries to simulate phase-limited activation behaviour. Model 30 evaluation against a selected database of published laboratory measurements demonstrates that 31 kappa can be predicted within a factor of two. Simulation of homologous series is used to 32 identify the relative effectiveness of different functional groups in increasing the CCN activity of 33 weakly functionalized organic compounds. Hydroxyl, carboxyl, aldehyde, hydroperoxide, 34 carbonyl, and ether moieties promote CCN activity while methylene and nitrate moieties inhibit 35 CCN activity. The model can be incorporated into scale-bridging testbeds such as the Generator 36 of Explicit Chemistry and Kinetics of Organics in the Atmosphere to evaluate the evolution of 37 kappa for a complex mix of organic compounds and to develop suitable parameterizations of 38 CCN evolution for larger scale models.

## 39 Introduction

40 Organic compounds are an important contributor to the atmospheric submicron aerosol 41 (Jimenez et al., 2009). The organic fraction is projected to increase in the future due to the 42 confluence of a decreasing sulfate and nitrate burden and increases in the global secondary 43 organic aerosol burden (Heald et al., 2008). An important unanswered question is how the 44 organic fraction influences the aerosol's ability to serve as cloud condensation nuclei (CCN), and 45 in turn modulates climate via indirect effects of aerosols on clouds and precipitation (Andreae 46 and Rosenfeld, 2008). Realistic prescribed variations in secondary organic aerosol 47 hygroscopicity have demonstrable impacts on CCN number concentration (Mei et al., 2013) and 48 can change the simulated global aerosol indirect forcing (AIF) by  $\sim 1/6$  of the AIF simulated in a 49 control case (Liu and Wang 2010). To obtain a prognostic understanding of the contribution of 50 the organic fraction to indirect aerosol forcing in future climates, models need improved schemes 51 that map simulated organic aerosol composition to hygroscopicity and CCN activity.

52 Several organic aerosol types (e.g. freshly emitted diesel oil particles or first generation 53 oxidation products of sesquiterpenes) consist of mostly hydrophobic hydrocarbon chains with 54 few functional groups attached. Pure hydrocarbons with carbon number less than C<sub>30</sub> are 55 expected to be semi-volatile and in the liquid phase. Over time the compounds evolve by 56 functionalization, fragmentation and oligomerization (Kroll and Seinfeld, 2008, Ziemann and 57 Atkinson, 2012). As functional groups are added to the carbon chain the products usually, but not 58 always, become less volatile (Goldstein et al., 2007), more dense (Kuwata et al., 2012), more 59 viscous (Sastri and Rao, 1992), and more CCN active (Suda et al., 2014).

Laboratory (George and Abbatt, 2010, Poulain et al., 2010, Cappa et al., 2011, Massoli et al., 2010, Lambe et al., 2011, Duplissy et al., 2011, Kuwata et al., 2013, Rickards et al., 2013, Suda et al., 2014) and field studies (Jimenez et al., 2008, Chang et al., 2008, Mei et al., 2013) have demonstrated a robust link between the aerosol oxidation state and the ability of the organic fraction to promote hygroscopic water uptake and CCN activity. Proxies from mass spectrometry such as the fragmentation peak f<sub>44</sub> or the atomic oxygen-to-carbon ratio are often used to model the increase in hygroscopicity. However, these correlations exhibit significant variability between studies and break down when applied at the compound level (Rickards et al., 2013,
Suda et al., 2014).

69 Chemistry models are already capable of simulating the molecular identities of species 70 present in the condensed phase during multi-day evolution of diluting air-parcels (Lee-Taylor et 71 al., 2015). Mapping this speciated aerosol composition to the aerosol hygroscopicity should 72 ultimately permit quantification of changes in CCN number concentration (provided that the size 73 distribution is also simulated) and associated effects on clouds and climate. Thermodynamic 74 models should be able to predict CCN activity. Many thermodynamic models have made use of 75 activity coefficients predicted by the universal functional group activity coefficient (UNIFAC) 76 group contribution method (Fredenslund et al., 1975). Several investigators have compared 77 UNIFAC predictions of organic aerosol water content to experimental data (Saxena and 78 Hildemann, 1997, Ming and Russell, 2001, Peng et al., 2001, Choi and Chan, 2002, Mochida and 79 Kawamura, 2004, Marcolli and Peter, 2005, Moore and Raymond, 2008). Some of these 80 comparisons prompted proposed revisions of specific group interaction parameters, e.g. [OH] 81 and  $[H_2O]$ . Several thermodynamic models that treat complex phase equilibria of multifunctional 82 multicomponent organic mixtures are based on UNIFAC activity coefficients (Ming and Russell, 83 2002, Raatikainen and Laaksonen, 2005, Topping et al., 2005, Amundson et al., 2007, Zuend et 84 al., 2008, Compernolle et al., 2009). The development of these models has been driven by the 85 need to enable predictions over a wide range of conditions and compositions, including the effect 86 of liquid-liquid phase separation on gas-to-particle partitioning (Zuend and Seinfeld, 2012, 87 Toping et al., 2013). The prediction of CCN activity of organic compounds has received less 88 attention. Rissman et al. (2007) used the aerosol diameter dependent equilibrium model 89 (ADDEM, Topping et al., 2005) with an underlying UNIFAC core to predict the relationship 90 between critical supersaturation and dry for several dicarboxylic acid aerosols. To our knowledge 91 no study to date has systematically focused on the prediction of CCN activity from 92 thermodynamic models.

Here we build on this body of work to predict the contribution of a compound with known
chemical structure to the CCN activity of a particle of known size. The proposed model uses the
UNIFAC equations (Fredenslund et al., 1975) with group interaction parameters form Hansen et

96 al., (1991), Raatikainen and Laaksonen (2005) and Compernolle et al. (2009) to model activity 97 coefficients and free energy of mixing. Liquid-liquid phase boundaries are determined using the 98 area method of Eubank et al. (1992). Molecular volume is estimated from elemental composition 99 and adjustments for functional group composition using the approach of Girolami (1994). The 100 relationship between critical supersaturation and dry diameter is then predicted using Köhler 101 theory (Seinfeld and Pandis, 2006). The basic model mechanics are similar to those employed in 102 multicomponent phase equilibrium models (Ming and Russell, 2002, Raatikainen and 103 Laaksonen, 2005, Topping et al., 2005, Amundson et al., 2007, Zuend et al., 2008) but limited in 104 scope to binary compositions and with focus on accurately representing phase and water activity 105 at conditions relevant at the point of CCN activation only. These predictions are validated by 106 manually mapping chemical composition to UNIFAC groupings and comparing modeled CCN 107 activity against observations from a compiled library of recently published CCN data of mostly 108 weakly oxidized hydrocarbons containing a mixture of alcohol, carbonyl, aldehyde, ether, 109 carboxyl, nitrate, and hydroperoxide moieties. The model is used to predict how the addition of 110 one or more functional groups to otherwise similar molecules promotes CCN activity. 111 Envisioned application to multi-component aerosols and contrasts with more complete

112 thermodynamic models are discussed.

## 113 Model Description

#### 114 Köhler theory

115 The saturation ratio over a curved droplet is given by the Köhler equation

116 
$$S = a_w \cdot \exp\left(\frac{4\sigma_{s/a}(T)M_w}{\rho_w RTD}\right),\tag{1}$$

117 where  $a_w$  is the water activity,  $\sigma_{s/a}$  is the surface tension of the solution/air interface, *T* is 118 temperature,  $M_w$  is the molecular weight of water,  $\rho_w$  is the density of pure water, *R* is the 119 universal gas constant, and *D* is the wet drop diameter. Water activity depends on the water 120 content and the amounts and identities of solutes in the nucleus. The principle water content 121 variable used in this work is the mole fraction

122 
$$x_w = \frac{n_w}{n_w + \sum_i n_{s,i}},$$
 (2)

123 where  $x_w$  is the mole fraction of water,  $n_w$  and  $n_{s,i}$  are the number of moles of water and solutes,

and *i* is the number of dry components. The wet drop diameter can be calculated from  $x_w$  if the dry diameter,  $D_d$ , is specified and it is assumed that the particle is spherical and that the volume of water and solute are additive:

127 
$$D = \langle (x_w - 1)^{-1} (x_w - x_w \sum_i (\epsilon_i v_w v_{s,i}^{-1}) - 1) D_d^3 \rangle^{1/3}.$$
 (3)

128 In Eq. (3)  $v_w$  and  $v_{s,i}$  are the molar volume of the water and solutes and  $\varepsilon_i$  are the volume

129 fractions in the dry particle. Eq. (3) is obtained by rearranging Eq. (7) in Petters et al. (2009a).

130 The critical supersaturation required for an aqueous solution droplet to activate into a cloud

131 droplet is found by combining Eqs. (1) and (3) and finding the  $x_w$  (or *D*) that maximizes  $s_c$ 

132 
$$s_{c} = \left\{ max \left[ a_{w} \cdot \exp\left( \frac{4\sigma_{s/a}(T)M_{w}}{\rho_{w}RT\langle (x_{w}-1)^{-1}(x_{w}-x_{w}\sum_{i}(\epsilon_{i}v_{w}v_{s,i}^{-1})-1)D_{d}^{3}\rangle^{1/3}} \right) \right] \right\} \cdot 100\%,$$

$$x_{w} \in [0,1]$$
(4)

where  $s_c$  is the critical supersaturation in %. The variables that control  $s_c$  are  $v_s$ ,  $a_w$ , and  $\sigma_{s/a}$ . In this work it is assumed that surface tension is that of pure water. Discussion on this and other assumptions are provided at the end of this section. First the prediction of  $v_s$  and  $a_w$  for organic compounds with known chemical structure is described.

## 137 Molar Volume

138 Molar volume is calculated from the molecular formula using the method of Girolami (1994).

139 Each element is assigned a relative volume based on its location in the periodic table. The

140 elemental volumes are summed and scaled by a constant factor to compute  $v_s$ . If the oxygen is

bound in the form of alcohol [OH] or carboxyl [C(=O)OH] moieties, the actual  $v_s$  is smaller due

142 to intramolecular bonding. Therefore  $v_s$  is decreased by 10% for each [OH] or [C(=O)OH] group

- 143 but by no more than 30% of the molar volume derived from the elemental composition. Girolami
- 144 (1994) tested this method for 166 liquids and reports agreement with observations  $v_s \sim \pm 10\%$ .
- 145 Barley et al. (2012) reviewed the performance of various methods for predicting molar volume

146 using a test set of 56 multifunctional organic compounds and report similar scatter.

147 *Water activity* 

148 Water activity is related to the mole fraction via

$$149 a_w = \gamma_w x_w, (5)$$

150 where  $\gamma_w$  is the activity coefficient of water. Activity coefficients are estimated using the semi-

151 empirical group contribution method UNIFAC (Fredenslund et al., 1975). The UNIFAC model

- 152 describes a liquid solution that consists of i components. Each component is divided into k
- 153 groups. The activity coefficient of component *i* in solution ( $\gamma_i$ ) has contributions from
- 154 combinatorial ( $\gamma^{C}$ ) and residual parts ( $\gamma^{R}$ )

155 
$$\ln\gamma_i = \ln\gamma_i^C + \ln\gamma_i^R.$$
 (6)

156 The combinatorial part is computed via

157 
$$\ln\gamma_i^C = \ln\frac{\phi_i}{x_i} + \frac{z}{2}q_i \ln\frac{\phi_i}{\phi_i} + l_i - \frac{\phi_i}{x_i}\sum_j x_j l_j$$
(7a)

158 
$$l_i = \frac{z}{2}(r_i - q_i) - (r_i - 1); z = 10$$
 (7b)

159 
$$\theta_i = \frac{q_i x_i}{\sum_j q_j x_j}; \Phi_i = \frac{r_i x_i}{\sum_j r_j x_j}$$
(7c)

160 
$$r_i = \sum_k v_k^{(i)} R_k; q_i = \sum_k v_k^{(i)} Q_k.$$
 (7d)

In Eqs. (7),  $x_i$  is the mole fraction of component *i*,  $\theta_i$  and  $\Phi_i$  are the average surface and segment fraction, *z* is the lattice coordination number,  $v^{(i)}_k$  is the number of groups of type *k* in component *i*,  $R_k$  and  $Q_k$  are the group volume and surface area parameters derived from Bondi (1964), and  $r_i$ and  $q_i$  are the normalized Van-der-Waals volume and surface area. The summation *i* or *j* is over all components in the mixture, including component *i*.

166 The residual part is computed via

167 
$$\ln\gamma_i^R = \sum_k \nu_k^{(i)} \left[ \ln\Gamma_k - \ln\Gamma_k^{(i)} \right]$$
(8a)

168 
$$\ln\Gamma_{k} = Q_{k} - \left[1 - \ln(\sum_{m} \Theta_{m} \Psi_{mk}) - \sum_{m} \frac{\Theta_{m} \Psi_{km}}{\sum_{n} \Theta_{n} \Psi_{nm}}\right]$$
(8b)

169 
$$\Theta_m = \frac{Q_m X_m}{\sum_n Q_n X_n} \tag{8c}$$

170 
$$X_m = \frac{\sum_i v_m^{(i)} x_i}{\sum_i \sum_k v_k^{(i)} x_i}$$
(8d)

171 
$$\Psi_{mn} = \exp\left(-\frac{a_{mn}}{T}\right)$$
 (8e)

In Eqs (8),  $a_{mn}$  are empirically determined parameters,  $\Psi_{mn}$  is the group interaction parameter of group *m* with *n*,  $X_m$  is the mole fraction of group *m* in the mixture,  $\Theta_m$  is the area fraction of group *m*,  $\Gamma_k$  is the group residual activity coefficient, and  $\Gamma^{(i)}_k$  is the residual activity coefficient of group *k* in a reference solution containing only molecules of type *i*. Eqs. (8) are also used to compute  $\Gamma^{(i)}_k$ . The summation *n* or *m* is over all different groups in the mixture, and the summation *k* is over all groups in component *i*.

180 aldehyde [HC(=O)], ether [CH<sub>n</sub>(O)], carboxyl [C(=O)OH], nitrate [CH<sub>n</sub>ONO<sub>2</sub>], and

hydroperoxide [CH<sub>n</sub>(OOH)]. Interaction parameters  $a_{mn}$  between the main groups that are used in

this work are tabulated in Table S1. Some of the main groups have several subgroups, with each subgroup having unique volume and surface area parameters  $R_k$  and  $Q_k$ . These are summarized

in Table S2.

## 185 Phase Equilibrium

For some  $x_w$  liquid-liquid phase separation can occur. The normalized Gibbs free energy of the mixture, defined as the actual Gibbs free energy divided by the thermal energy, is needed to compute the number of thermodynamically stable phases in the system. For a binary system consisting of water (*w*) and a single solute (*s*), Gibbs energy is calculated from the activity

$$191 \qquad \Delta g^{mix} = \Delta g^{ideal} + \Delta g^{excess} \tag{9a}$$

$$192 \quad \Delta g^{ideal} = x_w \ln x_w + (1 - x_w) \ln x_s \tag{9b}$$

193 
$$\Delta g^{excess} = x_w \ln \gamma_w + (1 - x_w) \ln \gamma_s, \tag{9c}$$

194 where  $\Delta g^{\text{mix}}$  is the normalized change in Gibbs free energy of the mixture,  $\Delta g^{\text{ideal}}$  is the change in 195 ideal Gibbs free energy of the mixture (Raoult's law) and  $\Delta g^{\text{excess}}$  is the excess Gibbs free energy 196 of mixing quantifying the deviation from Raoult's law. In highly non-ideal solutions liquid-liquid 197 phase separation may occur. Two compositions  $x_a$  and  $x_b$  define the water mole fraction of the 198 two co-existing phases. Computationally,  $x_a$  and  $x_b$  can be obtained from  $\Delta g^{\text{mix}}$  using the area 199 method (Eubank et al., 1992). Briefly, the state space is evaluated by computing the following 200 area for all possible combinations  $x_1$  and  $x_{11}$ 

201 
$$A(x_I, x_{II}) = \left| \left[ \Delta g^{mix}(x_{II}) + \Delta g^{mix}(x_I) \right] \left[ \frac{x_{II} - x_I}{2} \right] \right| - \left| \int_{x_I}^{x_{II}} \Delta g^{mix}(x) dx \right|.$$
(10a)

202 Phase boundaries  $x_a$  and  $x_b$  exist if condition

203 
$$A(x_a, x_b) = \max A(x_I, x_{II}); A > 0$$
 (10b)

is satisfied. If multiple phases coexist in phase equilibrium, the Gibbs-Duhem relationship
 dictates that the chemical potential of each component is equal in all phases. Therefore the water
 activity inside the miscibility gap is constant and the values entering Eq. 4 are subject to the
 constraint

208 
$$a_w = \begin{cases} a_w(x_a) = a_w(x_b) & \text{for } x_a \le x_w \le x_b \\ \gamma_w x_w & \text{else} \end{cases}.$$
 (11)

We note that Eubank et al. (1992) algorithm can be extended to *n*-components. Other numerically efficient approaches to find phase equilibrium, including those of *n*-component mixtures, are available in the literature (e.g. Amundson et al., 2005, 2007, Zuend et al., 2010). Comparison for phase boundaries  $(x_a, x_b)$  calculated using standard UNIFAC parameters and the Eubank method used in this model, and standard UNIFAC parameter and the algorithm in the UHAERO model (Amundson et al., 2007) are in good agreement and summarized in the supplementary information.

216 Model Implementation

The model was implemented to run on a personal computer using the commercial MATLAB
environment (MathWorks, Inc.). Alternatively, the code runs under the Octave environment,

- 219 which is available as free software under the GNU General Public License. Correct
- 220 implementation of the UNIFAC model was confirmed by comparing results from test mixtures

against output from existing implementations which is further described in the supplementary

- information. A compound is defined by specifying a count of subgroups comprising the
- molecule. Eqs. (6)-(8) are solved to find  $\gamma_w$  for *n* linearly spaced values within the domain
- 224  $x_w \in [0.0001, 0.9999]$ . Resulting  $\gamma_w$  are parsed through Eqs. (9)-(11) to find the number of stable
- 225 phases and to define  $a_w$  over the entire domain. These  $a_w$  are interpolated onto a higher
- resolution linearly gridded domain (*m* points) to improve the accuracy of the computation of sc
- using Eq. (4). Values for *n* and *m* are selected to balance computational speed and solution
- accuracy. Equations (6)-(8) have linear time complexity. Equations (9)-(11) have quadratic time
- complexity. Thus the two algorithms have order O(n) and  $O(n^2)$ , respectively. For n > 200, the
- overall model time complexity is  $O(n^2)$ . For n > -800 and m = 10000, the resolution is
- sufficiently high so that the computed  $s_c$  becomes independent of the choice of n. All
- computations in this work were carried out for n = 1000 and m = 10000. Total model execution
- times for a single compound on an Intel(R) Core(TM) i7-2600 3.4 GHz microprocessor using a
- single core were 39 s with MATLAB version R2013a (8.1.0.604) 64-bit and 282 s with GNU
- 235 Octave version 3.8.1 configured for 64-bit.
- 236 Hygroscopicity Parameter

221

Equation (4) is solved to find  $s_c$  for a specified dry diameter, fixed T = 298.15 K and

238  $\sigma_{s/a} = 0.072 \text{ J m}^{-2}$ . The result is expressed in terms of the hygroscopicity parameter  $\kappa$  (Petters and 239 Kreidenweis, 2007) that is defined via

$$s_{c} = \left\{ max \left[ \frac{D^{3} - D_{d}^{3}}{D^{3} - D_{d}^{3}(1 - \kappa)} \exp\left(\frac{4\sigma_{s/a}}{\rho_{w}RTD}\right) \right] - 1 \right\} \cdot 100\%.$$

$$D \in [D_{d}, \infty]$$

$$(12)$$

The hygroscopicity parameter is obtained by iteratively seeking the  $\kappa$  value that satisfies Eq. (12) for a given  $D_d$ ,  $s_c$  pair. Kappa values obtained by fitting a  $D_d$ ,  $s_c$  pair to Eq. (12) with the assumed temperature and surface tension conceptually correspond to "apparent hygroscopicity at standard state" (Christensen and Petters, 2012). All values in this work are apparent  $\kappa$ 's. For simplicity these are denoted as  $\kappa$  without further qualification. Observations against which the model is evaluated are summarized in the supplementary information and will be discussed further in Section 3.

#### 248 *Model Assumptions and Limitations*

249 The model approach presented here is limited to liquid organic compounds. This assumption 250 is implied in both molar volume and UNIFAC activity coefficient calculations. Comparison with 251 observational CCN data where the reference phase state may be crystalline should be interpreted 252 with caution. For example, CCN experiments performed with crystalline dicarboxylic acids 253 demonstrate that for some compounds deliquescence, i.e. a solubility-controlled phase transition, 254 must precede droplet activation (Petters and Kreidenweis, 2008). The UNIFAC approach is 255 unable to accurately predict the solubility of these compounds if they existed in their crystalline 256 solid state. If, however, the compound is in metastable aqueous solution, the UNIFAC prediction 257 is expected to be valid to within the general accuracy of the specific model implementation. 258 Under atmospheric conditions where the organic compounds are embedded in a matrix 259 comprising a multitude of organic compounds, liquid or amorphous solid is the prevailing stable 260 phase (Marcolli et al., 2004). Furthermore, since metastable states with hygroscopically bound water appear to dominate in the atmosphere (Rood et al. 1989, Nguyen et al., 2014) the liquid 261 262 assumption may not be a serious limitation. Nonetheless, it is unclear whether the assumption of 263 a liquid-like reference state is a serious limitation if the organic particles are highly viscous 264 (Vaden et al. 2011, Shiraiwa et al. 2011, Zobrist et al. 2011, Renbaum-Wolff et al. 2013).

265 Other limitations of the UNIFAC method are the problems of accounting for group proximity 266 effects and the inability to distinguish between isomers. Proximity effects occur when polar 267 groups are separated by less than three to four carbon atoms (Topping et al., 2005). Since only 268 the number of groups of type *i* are specified, all isomers are modeled to have identical  $\kappa$  values. 269 Although experiments show that the location of the functional group has a small and systematic 270 effects on the observed  $\kappa$  (Suda et al., 2014), those effects are relatively small and beyond the 271 resolution of the model presented here.

272 The application of Eq. (4) assumes that the surface tension is that of pure water. Many 273 organic compounds found in ambient organic aerosol lower the surface tension at the solution/air 274 interface (Tuckermann and Cammenga, 2004, Tuckerman, 2007). However, several studies have 275 demonstrated via experiment and theory that surfactant partitioning between the bulk solution 276 and the Gibbs surface phase greatly diminishes the effect one would predict by applying 277 macroscopic surface tensions in Köhler theory (Li et al., 1998, Rood and Williams, 2001, 278 Sorjamaa et al., 2004, Prisle et al., 2011). Neglecting to account for reduced surface tension and 279 using water activity to estimate CCN activity results in an underestimate of  $\kappa$  of ~30% for the 280 strong surfactant sodium dodecyl sulfate (Petters and Kreidenweis, 2013). We note that estimates 281 of surface tension reduction for pure organic liquids can be obtained from critical pressure and 282 boiling point (Sastri and Rao, 1994) and the Sprow and Prausnitz (1966) expression coupled with 283 UNIFAC activity coefficients (Topping et al., 2005, Rafati et al., 2011). Combined with 284 predictions of critical properties from functional group data (Joback and Reid, 1987), predicted 285 binary surface tensions could be obtained for each compound. Including surfactant partitioning 286 in Eq. (4) is possible using the expressions in Petters and Kreidernweis (2013) or similar 287 approaches (Sorjamaa et al., 2004, Raatikainen and Laaksonen, 2011). Thorough validation 288 against experimental data, including measurements of surface tension and CCN activity are 289 needed before this approach should be adopted.

## 290 Relationship to other thermodynamic models and application to multicomponent systems

291 The basic model functionality described here can also be obtained by appropriately 292 initializing other multicomponent equilibrium models (Ming and Russell, 2002, Raatikainen and 293 Laaksonen, 2005, Topping et al., 2005, Clegg and Seinfeld, 2006, Amundson et al., 2007, Zuend 294 et al., 2008) with a set of binary water/organic solutions, parsing the output through a phase 295 equilibrium module (if not included in the thermodynamic model itself) and the Köhler model. 296 The predicted CCN activity mostly depends on the underlying set of group interaction 297 parameters. The output should match with the solution presented here if the same interaction 298 parameter matrix is used. The main conceptual distinction between the approach proposed here 299 and the approach employed by the more complex multicomponent models is our focus on

300 predictions for binary organic/water solutions and limitation of the scope to a narrow range of 301 water activities relevant to CCN activation only. Accurate representation of hygroscopic growth 302 at  $a_w < \sim 0.99$  is not required and would be of secondary concern when tuning interaction 303 parameters.

304 We envision that the proposed specialized model approach can be used to categorize 305 individual compound into three miscibility regimes, analogous to the solubility regimes defined 306 in Petters and Kreidenweis (2008). Regime I: the compound is CCN inactive and can be 307 effectively modeled as  $\kappa = 0$ . Regime II: the compound is CCN active without any additional phase constraints. In turn  $\kappa$  is mostly determined by molar volume and slightly modulated by 308 309 activity coefficients. Regime III: the compounds' CCN activity is limited due to miscibility 310 constraints. In turn  $\kappa$  is highly sensitive to overall water content and can either have  $\kappa \sim 0$  or 311 express  $\kappa$  according to its molar volume. Once pure component  $\kappa$ 's are predicted and stored in a 312 database, the overall OA  $\kappa$  in mixed particles can be calculated quickly using the volume 313 weighted mixing rule (Petters and Kreidenweis, 2007). This compound-by-compound treatment 314 of multicomponent mixtures assumes that solute-solute interactions are negligible. Salting-in and 315 salting-out of solution effects are not captured. Effective  $\kappa$ -values for compounds falling into the 316 limited miscibility regime may be misrepresented in this treatment. Whether such effects are 317 important will depend on the fraction of compounds in a mixture that fall into the limited 318 miscibility regime and whether the proposed approach of intermediate complexity – modelling 319 binary solutions coupled with a linear mixing rule – ultimately proves sufficiently accurate 320 model the evolution of ambient OA. In the following we use experimental data to demonstrate 321 that the outlined UNIFAC model is suitable to categorize compounds into these three regimes.

#### 322 **Results and Discussion**

Experimental data for validation was compiled from the literature. A detailed summary of the compound names, chemical structures, physicochemical properties, CCN observations, and observed  $\kappa_{app}$ 's is provided in the supplementary information (Tables S3-S7). This set features compounds with mostly linear carbon backbones C4 to C18 and O:C ratio between 0.1 and 1. The data are grouped into model compounds for primary organic aerosol (POA, Table S3), 328 functionalized hydroperoxy ethers (Table S4), hydroxynitrates (Table S5), carboxylic acids 329 (Table S6), and carbohydrates (Table S7). Compounds included in Table S3 are long chain 330 molecules that have hydrophobic tails (> 14 methylene groups) and a single terminal carboxyl or 331 hydroxyl group. Representative example compounds are oleic acid or cetyl alcohol. Compounds 332 in Table S4 are  $C_{14}$  functionalized hydroperoxy ethers that have 10-12 methylene groups, at least 333 one hydroperoxide and ether group, and a second carbonyl, hydroperxide, or carboxyl group. 334 Compounds in Table S5 are functionalized hydroxynitrates featuring C<sub>10</sub> to C<sub>15</sub> carbon 335 backbones with 1-3 hydroxyl and 1-4 nitrate groups. Compounds in Table S6 are C4-C10 336 carboxylic acids that have 1-2 carboxyl and up to one carbonyl group attached to the carbon 337 backbone. Finally, compounds in Table S7 are C<sub>4</sub>-C<sub>18</sub> carbohydrates that have hydroxyl groups 338 approximately equal to the number of carbon atoms. Data in Table S3 are taken from Raymond 339 and Pandis (2002) and Shilling et al., (2007). Data in Tables S4 and S5 are taken from the 340 supplement of Suda et al. (2014). Data in Tables S6 and S7 are from various sources are 341 summarized in the supplement of Petters et al. (2009b), which was updated with new compounds 342 from Christensen and Petters (2012), and data were re-screened for quality. The compounds were 343 selected to provide systematic variation in the number and type of functional groups with 344 otherwise similar structure, i.e. linear or weakly branched alkane backbone with variable carbon 345 chain length.

346 To illustrate model initialization and model output two example compounds from the 347 supplementary information C12 dihydroxynitrate and C13 trihydroxynitrate, are presented in Table 348 1. For some of the compounds density and solubility data are available and those data are 349 included in the supplementary information. Table 1 shows how the molecular structure is 350 decomposed into the subgroups understood by the UNIFAC and Girolami (1994) model 351 framework. Detailed model output for the two example compounds is illustrated in Figure 1. The 352 predicted mole fraction dependence of  $\Delta g_{mix}$  suggests that the C<sub>13</sub> trihydroxynitrate is miscible 353 with water in all proportions while the C<sub>12</sub> dihydroxynitrate is not. The dashed black line 354 connecting  $x_a$  and  $x_b$  encloses the maximum positive area with the  $\Delta g_{mix}$  line and defines the twophase region. Water activity derived from  $\Delta g^{\text{mix}}$  is graphed in the middle panel. It shows that the 355 356 miscibility gap for the  $C_{12}$  dihydroxynitrate occurs at water activity close to unity. Phase gaps at

357 water activity near unity may result in miscibility-controlled cloud droplet activation (Petters et 358 al., 2006), which is analogous to solubility/deliquescence limited cloud droplet activation 359 (Shulman et al., 1998, Hori et al., 2003, Bilde and Svenningsson et al., 2004, Kreidenweis et al., 360 2006, Petters and Kreidenweis, 2008). Köhler curves in the right panel demonstrate miscibility-361 limited activation behavior. For the  $C_{13}$  trihydroxynitrate, the Köhler curve is smooth and 362 exhibits a single maximum corresponding to the model critical supersaturation. For the  $C_{12}$ 363 dihydroxynitrate two maxima appear. The first maximum corresponds to the point of incipient 364 phase separation  $x_a$ . The height of the miscibility barrier depends on the dry diameter. For large 365 dry particles where the Kelvin term does not play a significant role, the supersaturation of point 366  $x_a$  is reduced and the second classical Köhler maximum will control droplet activation. Similar 367 complex Köhler curves have been reported previously (e.g. Bilde and Svenningsson, 2004, 368 Petters and Kreidenweis, 2008). Experiments with pure crystalline sparingly-soluble organic 369 compounds have demonstrated convincingly that the larger maximum indeed controls cloud 370 droplet activation for solubility-limited cases (Hori et al., 2003, Bilde and Svenningsson, 2004, 371 Hings et al., 2008). The  $s_c$  vs.  $D_d$  relationship for phase-controlled activation does not result in 372  $\kappa_{ann}$  that is independent with respect to  $D_d$  (Petters and Kreidenweis, 2008). Therefore for 373 compounds having  $\kappa < \sim 0.06$  where phase separation might play a role, the observed s<sub>c</sub>, D<sub>d</sub> pair 374 is included in the data tables (Table 1, Tables S3-S7) and  $\kappa$  values are computed from the 375 observation and the model (Eq. 12) at the same  $D_d$ . Note that the  $D_d$ -dependent  $\kappa$  only plays a 376 role in a narrow range of miscibilities. Sufficiently soluble and truly insoluble substances are not 377 affected. In summary, Table 1 and Figure 1 demonstrate model input, illustrate model mechanics, 378 and identify model outputs.

How well do data-derived and model-derived  $\kappa_{app}$  compare? For numerical comparison both  $\kappa$ 's are included in Tables S3-S7. A graphical illustration of these is presented in Figure 2. To improve clarity compounds with predicted and modelled  $\kappa < 0.001$  are clustered in the lower left corner. Such low  $\kappa$ 's correspond to compounds that are effectively CCN inactive. The range between  $\kappa = 10^{-3}$  and  $10^{-5}$  spans a narrow range in the *s*<sub>c</sub>-*D*<sub>d</sub>- $\kappa$  state space that characterizes CCN activity (cf. Figure 1 Petters and Kreidenweis, 2007). Resolving these differences is not 385 particularly meaningful for the organic dominated particles that typically have  $D_d < 300$  nm. 386 Furthermore, the  $\kappa$  of an internally mixed particle is approximately the weighted volume fraction in the mixture. For  $\kappa < 10^{-3}$  the contribution to a mixed particle's  $\kappa$  is insensitive to the exact 387 388 value. Finally, although state-of-the-science size-resolved CCN measurements can resolve 389 differences in  $\kappa < 10^{-3}$ , compound impurities can interfere. A 1% impurity having  $\kappa$  similar to ammonium sulphate would contribute ~0.06 to a measured particle  $\kappa$ . In addition. solvent 390 391 residuals (Huff Hartz et al., 2006, Shilling et al. 2007, Rissman et al. 2007) and control over the 392 dry particle phase state (Raymond and Pandis, 2002, Hori et al., 2003, Broekhuizen et al., 2004, 393 Bilde and Symposition (2004) can disproportionally bias the characterization of low  $\kappa$ 's. 394 Combined these points justify the definition of  $\kappa < 0.001$  as effectively CCN inactive. 395 Compounds in the CCN inactive corner include all compounds from Table S3, the  $C_{14}$  and  $C_{15}$ 396 hydroxnitrate, and the  $C_{14}$ -trinitrate. These compounds all have 11 or more methylene groups and 397 O:C ratios between 0.11 and 0.65. CCN activity of these compounds is satisfactorily predicted by

the model.

399 Nine compounds are predicted to be CCN inactive but have measurements indicating  $0.001 > \kappa_{obs} > \sim 0.03$ . These are graphed below the dashed line and include C<sub>14</sub> di- and tetra-400 401 nitrate, C<sub>13</sub> hydroxynitrate, C<sub>14</sub> and C<sub>15</sub> dihydroxynitrate, the remaining hydroperoxide ethers 402 from Table S4, and cis-pinonic acid. The observed C14 di- and tetra-nitrate are barely larger than 403 the cutoff for CCN inactive. Variation of  $\kappa$  between the C<sub>14</sub> di- and tri- and tetra-nitrate (cf. 404 Figure 2, Suda et al., 2014) implies that the trinitrate has lower  $\kappa$  than the di- and tetra-nitrate, 405 which suggests that some random variability in the data is superimposed on the trend. Similarly, 406 the observations show that the C<sub>14</sub>- and C<sub>15</sub> dihydroxynitrate are slightly more CCN active than 407 the C<sub>13</sub> dihydroxynitrate. Although this is possible such behaviour is not plausible due to the 408 well-established hydrophobic nature of the added  $CH_x$  groups. One possible explanation for the 409 discrepancies is the sensitivity of observed  $\kappa$ 's to trace contamination. Each of the compounds 410 was purified via high performance liquid chromatography (HPLC, Suda et al., 2014) but degree of purification likely varied between compounds. Furthermore, experimental uncertainty for the 411 412 HPLC-CCN method used is slightly larger than for standard methods since it requires application 413 of fast flow scans. Finally, the data are from a single set of experiments. More data are needed414 before attributing the mismatch to either model or measurement error.

415 Another notable outlier is adipic acid. Here, the observed  $\kappa < 0.01$  corresponds to the 416 solubility-limited value that is referenced against its solid crystalline phase state. In contrast, the 417 predicted value  $\kappa=0.14$  is in good agreement with the molar volume prediction ( $\kappa=0.17$ , cf. 418 Figure 4, Christensen and Petters, 2012) and observed  $\kappa$  that adipic acid particles express when 419 solubility limitations are removed (cf. Figure 1, Hings et al., 2008). This scenario was selected to 420 illustrate the inability of the UNIFAC model to treat solid phases. It therefore cannot capture 421 deliquescence and deliquescence/solubility limited activation. In atmospheric OA multiple 422 organic compounds likely form an amorphous supercooled melt (Marcolli et al., 2004) and 423 metastable aqueous solutions are ubiquitous (Rood et al., 1995). Thus the metastable prediction 424 would be valid to account for adipic acid in the context of atmospheric OA.

425 A series of carboxylic acids and carbohydrates cluster near the 1:1 line at  $\kappa > \sim 0.06$ . These 426 compounds are generally highly functionalized having at least 2 carboxyl, hydroxyl, or carbonyl 427 group for every 4 carbon atoms. The O:C ratio always exceeds 0.5 and is close to 1 for many of 428 the compounds. For the predictions, activity coefficients approach unity, compounds are miscible 429 in water in all proportions, and model  $\kappa$ 's closely track the prediction based on estimated molar 430 volume. Overall comparison of predicted vs. observed  $\kappa$  is approximately within a factor of two 431 and this range is similar to predictions that are based on actual molar volume (cf. Figure 2, 432 Petters et al., 2009b).

433 The series of hydroxynitrates, dihydroxynitrates, and trihydroxynitrates for different carbon 434 chain length also cluster near the 1:1 line. The spread is within approximately a factor of two and 435 similar to that of the carboxylic acids and carbohydrates. These compounds span the entire range 436 from  $\kappa < 0.001$  to  $\kappa \sim 0.1$  and have as few as two hydroxyl and one nitrate group per 13 carbon atoms (C<sub>13</sub> dihydroxynitrate). The model appears to accurately predict the influence of the 437 438 methylene and hydroxyl groups on the transition from immiscible and CCN inactive to 439 sufficiently miscible and CCN active according to the molar volume of the compound. For the 440 C<sub>11</sub>, C<sub>12</sub>, and C<sub>13</sub> dihydroxynitrates the predicted miscibility-limited activation demonstrated in

Figure 1 seems to adequately explain the transition. The accurate model prediction of this sensitive transition regime is encouraging, especially since no adjustment was made to the  $a_{mn}$ group interaction parameters for [OH], [CH<sub>x</sub>], and [H<sub>2</sub>O] groups.

444 In summary, Figure 2 demonstrates four capabilities of the model. First, the model has good 445 skill in correctly classifying effectively CCN inactive compounds ( $\kappa < 0.001$ ). Second, the model 446 captures the molar volume dependent activation of highly functionalized compounds (low 447 molecular weight dicarboxylic acids and polysaccharides). Scatter between predicted and 448 observed  $\kappa$  is approximately within a factor of two and considered acceptable taking into account 449 the considerable diversity in the underlying CCN data. We note that uncertainties in molar 450 volume estimation of  $v_s \sim \pm 10\%$  stemming from the Girolami et al. (1994) method correspond to 451  $\pm 10\%$  error in predicted  $\kappa$  for these compounds, which is significantly less than the observed 452 scatter in the data (Petters et al., 2009). Third, the model predicts that miscibility limitations are 453 the cause for poor CCN activity of weakly functionalized hydrocarbons, and the phase separation 454 information can be used to quantitatively predict the transition between sufficiently miscible and 455 effectively immiscible species. Finally, the model seems to accurately capture the main 456 functional group dependencies observed previously (Suda et al., 2014): a strong promoting effect 457 of hydroxyl, a weak promoting effect for hydroperoxides, a negligible or inhibiting effect of 458 nitrate, and inhibiting effect of methylene groups on CCN activity. How, then, can one quantify 459 the model sensitivity of  $\kappa$  to the addition of functional groups to otherwise similar molecules?

460 Simulation of homologous series can be used to derive these sensitivities. Figure 3 shows 461 modelled  $\kappa$ 's for a series of functionalized *n*-alkanes. The gradual decreasing trend of  $\kappa$  with 462 increasing carbon number is due to the increase in molar volume. A steep decline is observed 463 when a critical carbon number is exceeded. Beyond this point the additional methylene groups 464 reduce the miscibility with water and render the compound effectively CCN inactive. For 465 example, CCN activity for a C<sub>16</sub> trihydroxyalkane is controlled mostly by molar volume while 466 C<sub>18</sub> trihydroxyalkane is effectively CCN inactive. The critical carbon number is C<sub>7</sub>, C<sub>12</sub>, C<sub>16</sub>, C<sub>20</sub>, 467 and C<sub>24</sub> for the mono-, di-, tri-, tetra-, and penta-hydroxyalkanes, respectively. Starting with an *n*-468 alkane, the most dramatic effect of adding functional groups is to render the molecule miscible

- 469 with water. Contrasting the critical carbon number for different homologous series is can be used
- 470 as a measure of a particular groups' ability to transform the molecule such that it is sufficiently
- 471 miscible in water and can express its molar volume  $\kappa$ . The hydroxyalkane series shows that
- 472 approximately one hydroxyl group is needed to compensate for the addition of 4 methylene
- 473 groups (i.e. to maintain miscibility at the composition of the critical carbon number). Expressed
- 474 as a ratio,  $\Delta$ [CH<sub>n</sub>]/ $\Delta$ [OH] ~ -4/1. Similar ratios for the other groups are derived from the shifts in
- 475 the dihydroxyalkane series upon further functionalization:  $\Delta$ [CH<sub>n</sub>]/ $\Delta$ [C(=O)OH] ~ -5/2,
- $476 \qquad \Delta[CH_n]/\Delta[CH_nC(=O)] \sim -2/3, \\ \Delta[CH_n]/\Delta[HC(=O)] \sim -4/2, \\ \Delta[CH_n]/\Delta[CH_n(O)] \sim -2/4, \\ \Delta[CH_n(O)] \sim -2/4, \\ \Delta[CH_$
- 477  $\Delta$ [CH<sub>n</sub>]/ $\Delta$ [CH<sub>n</sub>(OOH)] ~ -2/2, and  $\Delta$ [CH<sub>n</sub>]/ $\Delta$ [CH<sub>n</sub>C(=O)] ~ -2/3, and  $\Delta$ [CH<sub>n</sub>]/ $\Delta$ [CH<sub>n</sub>ONO<sub>2</sub>] ~
- 478 2/3. This leads to a sorting of relative effectiveness of the groups in promoting miscibility,
- 479 hydroxyl (-4) > acid (-2.5) > aldehyde (-2) > hydroperoxide (-1) > carbonyl (-0.66) > ether (-0.5)
- 480 > nitrate (0.66), where the number in parentheses corresponds to the  $\Delta$ [CH<sub>n</sub>]/ $\Delta$ [*n*]. According to
- this model the addition of nitrate groups is in the same direction as methylene groups, i.e. it
- 482 reduces miscibility. This finding is consistent with CCN experiments on alkenes reacted with
- 483 NO<sub>3</sub> radicals (Suda et al., 2014, supplement), and the known low miscibility of organic nitrates
- 484 in water (Boschan et al., 1995). Furthermore sorting of the different functional groups is
- 485 qualitatively consistent with the sensitivity of  $\kappa$  to the addition of functional groups derived from 486 CCN data (Table S5, Suda et al., 2014).

## 487 *Treatment of OA evolution in the atmosphere*

488 The computational speed of the model is relatively slow. The slow speed is due to the need to 489 evaluate the entire range of mole fractions in order to determine the phase boundaries. 490 Improvement in model execution speed is likely possible via algorithm optimization. 491 Furthermore, parallel execution of the code is possible. With a regular workstation it is feasible to perform offline computation of  $\sim 10^6 \kappa$ 's for a large set of compounds produced by the 492 493 Generator of Explicit Chemistry and Kinetics of Organics in the Atmosphere (GECKO-A) or 494 similar models. Once pure component  $\kappa$ 's are predicted, the evolution of the overall OA  $\kappa$  in 495 mixed particles can be calculated quickly using the linear mixing rule (Petters and Kreidenweis, 496 2007), subject to the limitations of this approach discussed in Section 2. One additional

limitation is the need for algorithms that automatically map the computer-generated simplified
molecular-input line-entry system (SMILES) structures (e.g. Table 3, Lee-Taylor et al., 2015) to
UNIFAC groups. Several of these structures are bridged and even manual mapping of those
structures to UNIFAC groupings will necessitate definition of new groups with unknown
volume, surface, and interaction parameters. Separate studies are needed to establish the minimal
number of new groups that would be needed to obtain optimal coverage for the set of compounds
of interest.

504

## 505 Summary and Conclusions

506 This paper describes how functional group contribution methods can be used to estimate the 507 CCN activity of pure organic compounds. Group interaction parameters were taken from a mix 508 of sources and used without further tuning. Model fidelity was evaluated against a database of 509 published CCN data. Weakly functionalized alkanes are correctly classified as effectively CCN 510 inactive (defined as  $\kappa < 0.001$ ). Highly functionalized and water-soluble molecules are predicted 511 to activate in accordance with the estimated molar volume and generally predictions agree with 512 observations within a factor of two. Liquid-liquid phase separation is predicted to occur for 513 compounds with few functional groups and phase separation is predicted to control  $\kappa$ . The model 514 adequately reproduces the observation that hydroxyl groups strongly promote CCN activity 515 while nitrate groups inhibit CCN activity. A few outliers in the model evaluation may be 516 explained by the combination of CCN measurement uncertainty, compound purity, uncertainty in 517 dry particle phase state, and insufficiently tuned group interaction parameters. However, more 518 systematic data on weakly functionalized compounds, including repeat studies, are needed before 519 a retuning of parameters is justified. The model makes new predictions about the relative 520 effectiveness of the groups in promoting miscibility. Most notably, it predicts that 521 hydroperoxides have much less of an effect than hydroxyl, which is slightly surprising since one 522 would expect the hydrogen bonding to be similar. The model state space can serve as a rough 523 guide to define test conditions to quantify via experiment the effectiveness of adding one or more 524 functional groups to a carbon backbone.

525 Although this work is limited to a few functional groups, the presented framework is general

- 526 since interaction parameters are available for a wide range of groups. For atmospheric purposes,
- 527 amines, olefins, and aromatic compounds are the most relevant groups that need to be added.
- 528 Few, if any systematic CCN data for these groups are available. However, the success of the
- 529 current model to estimate  $\kappa$  without the need to tune parameters could be taken as indication that
- 530 first order predictions can be obtained until such data become available.

			3	ОН					

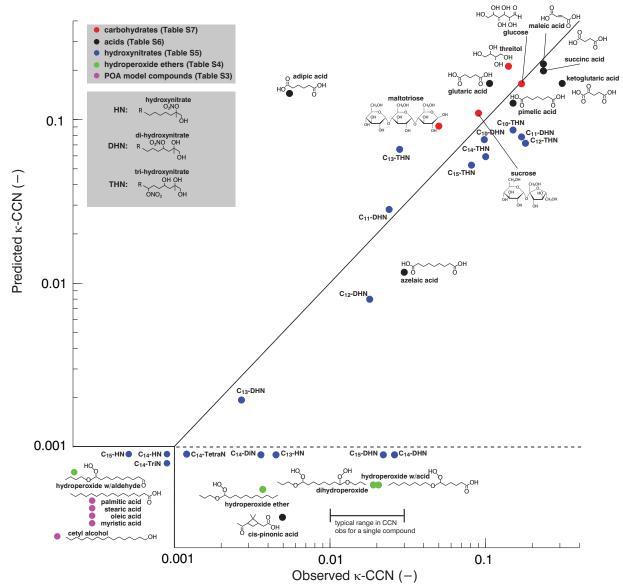

S<sub>C</sub> (%)

**Figure 1.** Modeled  $\Delta g_{mix}$  (left), water activity (middle), and Köhler curves (right) for C<sub>12</sub>

789 dihydroxynitrate and C<sub>13</sub> trihydroxynitrate (see Table 1). Open circles denote the mole fractions

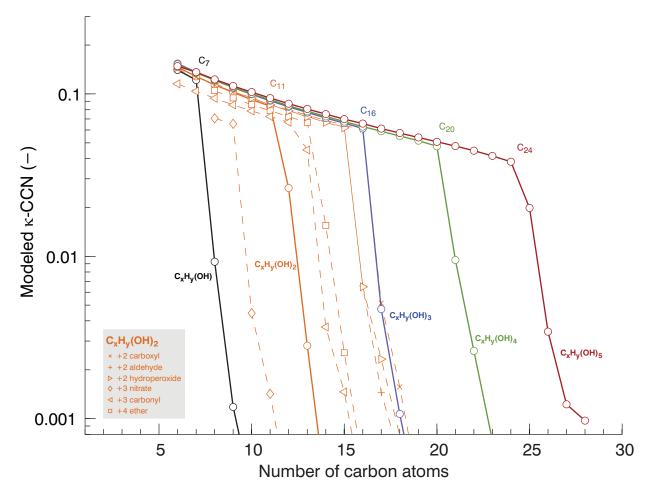

790  $x_a$  and  $x_b$  that correspond to the envelope of compositions where liquid-liquid phase separation is

791 predicted for the C<sub>12</sub> dihydroxynitrate.

793 **Figure 2.** Model predicted vs. experimentally determined  $\kappa$ -values. Values  $\kappa < 0.001$  are 794 classified as CCN inactive and are clustered in the lower left corner of the graph. Colors are used 795 to delineate the grouped source data in the supplementary information (SI). Selected structures 796 from the SI are included in the graph. Cx-HN, Cx-DHN, and Cx-THN denote hydroxynitrate, 797 dihydroxynitrate, and trihydroxynitrate and x denotes the total number of carbon atoms. C14-798 DiN, C14-TriN, C14-TetraN denote the C14 dinitrate, trintrate, and tetranitrate, respectively. Points 799 below the dashed line corresponds to compounds with predicted  $\kappa < 0.001$  and observed  $\kappa >$ 800 0.001. Typical range of observed  $\kappa$  CCN for peroxides is indicated by the horizontal bar.

801

**Figure 3.** Modeled  $\kappa$  values for homologous series of functionalized *n*-alkanes. Solid lines

803 correspond to alkanes with 1-5 non-terminal hydroxyl groups. Orange dashed lines correspond to 804 further functionalized dihydroxyalkanes as described in the legend. Colored carbon numbers (C<sub>7</sub>,

805 C<sub>12</sub>, C<sub>16</sub>, C<sub>20</sub>, and C<sub>24</sub>) correspond to the largest carbon number without miscibility limited

806 activation for the respective hydroxyalkanes series.
