Abstract

This article describes the extension of the spreadsheet-based point energy balance snow model ESCIMO.spread by (i) an advanced approach for precipitation phase detection, (ii) **a method for cold content and liquid water storage consideration** and (iii) a canopy sub-model that allows to quantify the effect of a forest canopy on the meteorological conditions inside the forest as well as the simulation of snow accumulation and ablation inside a forest stand. To provide the data for model application and evaluation, innovative low-cost Snow Monitoring Systems (SnoMoS) have been utilized that allow the collection of important meteorological and snow information **in- and outside the canopy**. The model performance with respect to both, the modification of meteorological conditions as well as the subsequent calculation of the snow cover evolution are evaluated using in- and outside-canopy observations of meteorological variables and snow cover evolution as provided by a pair of SnoMoS for a site in the Black Forest mountain range (south-west Germany). **The validation results for simulated snow water equivalent with Nash-Sutcliffe Model Efficiency values of 0.81 and 0.71 and root mean square errors of 8.26 and 18.07 mm indicate a good overall model performance in- and outside** the forest canopy, respectively. The newly developed version of the model referred to as ESCIMO.spread (v2) is provided free of charge together with one year of sample data including the meteorological data and snow observations used in this study.

1 Introduction

In forested areas significant variations in snow accumulation can result from the processes of forest canopy interception and sublimation of intercepted snow (Marsh, 1999; Pomeroy et al., 1998). Snowfall in forested areas is either intercepted by stems, needles and branches or passes through the canopy directly reaching the underlying forest floor. Due to its large surface area exposed to the surrounding atmosphere, intercepted snow can be subject to high sublimation losses, especially in dry continental climates. Generally,

sublimation losses of previously intercepted snow can be as high as 30 % of snow precipitation, depending on the efficiency of interception, its duration and the atmospheric boundary conditions (Liston and Elder, 2006b; Pomeroy and Gray, 1995; Strasser et al., 2008). Intercepted snow can also be removed from the canopy by direct unloading and dripping of meltwater to the ground (Liston and Elder, 2006b; Pomeroy et al., 2002). Compared to snow in the open, snow in forest canopies is exposed to different meteorological conditions. It is sheltered from wind and incoming shortwave radiation while receiving increased longwave radiation emitted from the surrounding trees (Link and Marks, 1999a, b). Likewise, humidity and temperature underneath a canopy differ from those in the open (Liston and Elder, 2006b). In the boundary layer, forest canopies moreover strongly modify the interactions between snow-covered surfaces and the atmosphere. Even the litter on the forest floor has a significant effect on the radiative properties of the snow cover beneath a canopy (Melloh et al., 2002; Hardy et al., 2001).

The influences of a forest canopy on the snow cover dynamics beneath are very complex. The snow cover duration in the forest depends on various factors. A delay of the spring snow melt under a dense forest canopy compared to open areas due to the reduction of incoming solar radiation was shown by Link and Marks (1999a). On the other hand shorter snowpack duration in the forest was observed by Dickerson-Lange et al. (2015). Strasser et al. (2011) showed in a numerical modelling experiment for a virtual mountain that in snow-rich winters, the shadowing and its protective effect is dominant. In winters with little snow, snow sublimation losses become dominant and, consequently, the snow lasts longer in the open than inside the forest, mainly for northern exposures (in the Northern Hemisphere). Similar patterns were observed by Pohl et al. (2014) in the Black Forest region.

To develop a free and easy to use tool for the simulation of the temporal evolution of the snow cover with explicit consideration of these complex snow-canopy-atmosphere interactions, **the spreadsheet-based point energy balance snow model ESCIMO.spread developed by Strasser and Marke (2010) (in the following referred to as ESCIMO.spread (v1)) has been extended with a canopy sub-model.** Moreover, the model has been improved by integrating an advanced algorithm for precipitation phase detection that applies wet-bulb

temperature as a criterion to distinguish solid and liquid precipitation. Another model improvement is a new parameterization for cold and liquid water content of the snow cover allowing to consider refreezing of **liquid precipitation** or meltwater in the snowpack. Compared to other existing spreadsheet-based snow models (e.g. the glacier and snow melt study model by Brock and Arnold, 2000) ESCIMO.spread (v2) is particularly fast and can easily be modified by simple change of the parameters and formulae with results immediately visualized. **With hourly recordings of temperature, precipitation, wind speed, relative humidity, global as well as longwave radiation the model's demand on meteorological input is covered by those variables most commonly recorded at any state of the art automatic weather station.** While Walter et al. (2005) have presented a spreadsheet energy balance model that requires even less meteorological input data (daily minimum/maximum temperature and precipitation), their approach operates at a daily time step only and does not allow to quantify sub-daily variations in snow cover conditions. Moreover, compared to the canopy model implemented in ESCIMO.spread (v2), the consideration of canopy effects in the Walter et al. (2005) model is reduced to a canopy-induced extinction of solar radiation only. Canopy effects on other meteorological variables or vegetation-snow cover interactions (e.g. the interception of snow in the canopy) are not accounted for. **By providing the option to define trends in precipitation and/or temperature in the models parameter section, ESCIMO.spread allows to calculate sensitivity tests for changes in temperature and precipitation for any site of interest.** As ESCIMO.spread (v2) is in simple table format and does not include any macros it can be applied by all common spreadsheet programs (e.g., Microsoft Excel, Apple Numbers, OpenOffice Calc) on a variety of platforms (Windows, Linux, Mac OS). Due to its simplicity, ESCIMO.spread (v2) is particularly suitable for application in education (e.g., in practically-oriented student courses) and can even be operated with laptop computers, e.g. to visualize and plausify measured meteorological parameters and the simulated snow cover directly in the field.

With its new features of

- sophisticated precipitation phase detection using a wet bulb temperature threshold,
- **snow temperature estimation,**

- cold content and liquid water content calculation with consideration of refreezing of water from melt or liquid precipitation, and meltwater outflow,
- transformation of standard meteorological observations (precipitation, relative humidity, temperature, wind speed, global radiation) from the open into conditions inside a forest canopy,
- calculation of snow interception and subsequent sublimation, melt or dropping of intercepted snow to the ground and
- calculation of the beneath-canopy snow energy and mass balance,

the new version ESCIMO.spread (v2) reaches beyond the capabilities of most other freely available point-scale **spreadsheet-based** snow models and can be expected to set forth the history of ESCIMO.spread as a well-accepted, documented and freely available snow model for application in both science and education. This paper describes the newly implemented algorithms and evaluates the model results against available hydrometeorological observations **in- and outside** the forest canopy at a site in the Black Forest mountain range (south-west Germany, see Fig. 1) with a mostly temperate snow cover in an elevation of 800 m a.s.l. The applied hydrometeorological data have been recorded by a set of low-cost snow monitoring systems (SnoMoS) recently developed by Pohl et al. (2014). The model can be downloaded from www.alpinehydroclimatology.net together with one year of example meteorological recordings and snow observations.

2 The ESCIMO.spread model (v2)

2.1 General description

The new version ESCIMO.spread (v2) builds upon the ESCIMO.spread model as published by Strasser and Marke (2010). It is a 1-D, one-layer process model which calculates snow accumulation and melt for a snow cover assumed to be a single and homogeneous pack. To

do so, it solves the energy and mass balance equations for the snow surface applying simple parameterizations of the relevant processes. The energy balance of the snow surface is calculated for each hourly time step considering short- and longwave radiation, sensible and latent heat fluxes, energy conducted by solid or liquid precipitation as well as sublimation/resublimation and a constant soil heat flux (Strasser and Marke, 2010). Thereby, absorbed and reflected shortwave radiation is calculated from incoming shortwave radiation on the basis of the snow albedo, which is estimated for each hourly time step using an albedo ageing curve approach. Solid precipitation increases the amount of snow water equivalent (SWE) on the land surface, while liquid precipitation is (up to a certain maximum amount depending on actual SWE) added to the liquid water storage of the snowpack. While melt in ESCIMO.spread (v1) has been calculated from the energy balance remainder only if air temperature exceeds 273.16 K, the newly implemented method for snow temperature estimation (see section 2.3) allows to remove this condition in ESCIMO.spread (v2). The model results are visualized in the form of diagrams for the majority of model variables, together with four quantitative measures of goodness of fit.

2.2 Precipitation phase detection

The new version of ESCIMO.spread (v2) includes an improved distinction between liquid and solid precipitation. As air temperature T_a is often an insufficient indicator for the precipitation water phase (Steinacker, 1983), wet-bulb temperature T_w is used in ESCIMO.spread (v2) as a combined measure of air temperature and humidity to distinguish liquid from solid precipitation. Figure 2 shows the relation between air temperature, wet-bulb temperature and relative humidity for different altitudes to account for the dependence of wet-bulb pressure temperature on air pressure. Each of the displayed lines in Fig. 2 could be interpreted as a borderline to separate liquid and solid precipitation assuming a certain threshold wet-bulb temperature. Largest differences between air temperature and wet-bulb temperature occur at low air humidities, clearly pronouncing the added value associated to application of wet-bulb temperature as a criterion for phase detection.

Generally, wet-bulb temperature can be derived by solving the psychrometric equation

$$e_a(T_a) - e_s(T_w) - A \cdot (T_a - T_w) = 0 \quad (1)$$

for T_w (K), where A (Pa K^{-1}) is the psychrometric constant, and $e_a(T_w)$ (Pa) and $e_s(T_w)$ (Pa) the vapor pressure of the air and the saturation vapor pressure at wet-bulb temperature, respectively. As there is no explicit solution to the psychrometric equation (Campbell and Norman, 1998) and iterations are unfavourable in a spreadsheet model, a pragmatic assumption has been made: for a broad range of combinations of air temperature and relative humidity values, lookup tables have been generated outside the spreadsheet model using an iterative solution scheme for Eq. (1). Beside temperature and humidity, wet-bulb temperature also depends on air pressure p_z (Pa) which is required to calculate the psychrometric constant, A , as (Kraus, 2004)

$$A = \frac{p_z \cdot c_p}{0.622 \cdot L_v}, \quad (2)$$

where c_p is the specific heat capacity of air at constant pressure ($1004 \text{ J kg}^{-1} \text{ K}^{-1}$) and L_v (J kg^{-1}) represents the latent heat of vaporization. In ESCIMO.spread (v2) the temperature dependence of the psychrometric constant is neglected since this dependency is by far less important compared to that associated to air pressure at higher altitudes (Kraus, 2004; Campbell and Norman, 1998). **Air pressure, p (Pa), at a given elevation, z (m), can be derived from standard atmospheric pressure, p_0 (Pa), by integration of the hydrostatic equation assuming a linear decrease of temperature with increasing altitude ($\gamma = -0.0065 \text{ K m}^{-1}$)**

$$p_z = p_0 \left[\frac{T_a}{T_a - \gamma \cdot z} \right]^{-\frac{g}{\gamma \cdot R}}, \quad (3)$$

where R is the gas constant of dry air ($287 \text{ J kg}^{-1} \text{ K}^{-1}$) and g is gravity (m s^{-2}). To account for the air pressure dependence, the implemented lookup tables have been prepared for several elevation bands with a 500 m interval. Figure 3 shows a comparison of wet-bulb

temperatures calculated using the lookup table approach to those achieved with an iterative solution for different elevations. The differences between both approaches shown for a common snowfall situation are relatively small. Therefore, the lookup table approach allows a sufficiently accurate estimation of wet-bulb temperature in the model. The threshold for wet-bulb temperature as required for precipitation phase detection in ESCIMO.spread (v2) is one of the user-defined input parameters and is here set to 273.16 K. **To avoid sudden changes in precipitation phase when temperatures fall below the defined temperature threshold, in ESCIMO.spread (v2) a temperature range can be defined (e.g. 273.16 +/- 0.5 K) in which liquid precipitation decreases from 100 to 0 % with solid precipitation increasing accordingly. When temperature is exactly at the defined temperature threshold (here 273.16 K) this approach results in 50 % liquid and 50 % solid precipitation.**

2.3 Cold and liquid water content

A physically based method for estimating the snow temperature and deriving the cold content of a single layer snow pack has been implemented in ESCIMO.spread (v2) following an approach presented by Walter et al. (2005). The snow temperature T_s (K) for a given time step is derived using the snow temperature calculated for the previous time step, T_{st-1} (K), and a temperature change dT (K) as

$$T_s = \min \{T_{st-1} + dT, 273.16\}. \quad (4)$$

The temperature change in Eq. 4 is derived as

$$dT = \frac{E_{t-1} \cdot dt + RF_{t-1} \cdot c_i}{(SWE_{t-1} + P_s) \cdot c_s} \quad (5)$$

where E_{t-1} (W m^{-2}) is the energy balance of the previous time step, dt (s) is the time step length, RF_{t-1} (mm) is the liquid water refrozen in the previous time step, c_i is the

melting heat of ice ($3.337 \times 10^5 \text{ J kg}^{-1}$), SWE_{t-1} (mm) is the SWE of the previous time step, P_s (mm) is the solid precipitation in the current time step and c_s is the specific heat of snow ($2100 \text{ J kg}^{-1}\text{K}^{-1}$).

Using this approach, heat losses resulting from a negative energy balance can be used to build up a cold content, which represents the amount of energy required to increase snow temperature to 273.16 K. Snow temperature and cold content can be considered as equivalent and physically consistent representations of the snow pack's energy state as defined by Eq. 6. The cold content first needs to be reduced to zero by positive energy inputs before actual melt can occur. By implementing a concept for liquid water content as proposed by Braun (1984) and Blöschl and Kirnbauer (1991), melting snow is not immediately removed from the snowpack, but a certain amount of liquid water can be retained (and possibly re-freeze again). Combining these approaches for cold content estimation and liquid water content consideration allows to account for the delay between beginning surface melt and drainage of a snow cover.

The cold content C_c (mm) for each model time step is inferred directly from calculated snow temperature in the form of

$$C_c = \frac{(T_s - 273.16) \cdot (SWE_{t-1} + P_s) \cdot c_s}{c_i}. \quad (6)$$

In the case of a negative energy balance, a refreezing of liquid water in the snowpack, RF (mm), is calculated in the form of

$$\text{RF} = \min \{C_{lw_{t-1}}, (-E \cdot dt)/c_i\}, \quad (7)$$

where $C_{lw_{t-1}}$ (mm) is the liquid water content of the previous time step. C_{lw} for a given time step can be derived as

$$C_{lw} = C_{lw_{t-1}} + P_l - \text{RF}, \quad (8)$$

where P_l (mm) is liquid precipitation.

In the case of a positive energy balance, actual melt, M (mm), is calculated considering the change in cold content between the actual and the previous time step as

$$M = \min \{ (E \cdot dt / c_i) - (C_c - C_{ct-1}), (SWE_{t-1} - C_{ct-1}) \}. \quad (9)$$

C_{lw} is then updated in the form of

$$C_{lw} = \min \{ C_{lwt-1} + M, SWE_{t-1} \cdot HC_w \} \quad (10)$$

where $HC_w (-)$ is a water holding capacity that limits liquid water storage and is specified as a fraction of the total snowpack weight. This parameter is to be defined by the user in the model's parameter section and set to $HC_w = 0.1$ as recommended by Blöschl and Kirnbauer (1991) by default.

Finally, the outflow (i.e. the excess water that is actually removed from the snowpack), O (mm), can be calculated as

$$O = \max \{ (C_{lwt-1} + P_l + M) - SWE_{t-1} \cdot HC_w, 0 \}. \quad (11)$$

2.4 Modification of meteorological conditions inside the forest canopy

The canopy model newly implemented in ESCIMO.spread (v2) by Liston and Elder (2006b) has already been successfully applied under alpine conditions (see Strasser, 2008 or Strasser et al., 2011). The development of the approach was motivated by the fact that meteorological observations inside forest canopies only sparsely exist necessitating the estimation of inside-canopy conditions from available meteorological observations in the open. The method requires information on leaf area index and canopy height which can either be derived from field measurements or be taken from literature for a wide range of plant species (e.g. from Breuer et al., 2003, or Liston and Elder, 2006b).

Wind speed inside the canopy u_c ($m s^{-1}$) is derived from above-canopy wind speed u ($m s^{-1}$) as (Cionco, 1978)

$$u_c = u \exp(-a \cdot (1 - z/h)), \quad (12)$$

where h (m) is the canopy height and z (m) is the canopy reference level assumed to be $0.6h$ (Liston and Elder, 2006b; Essery et al., 2003).

The canopy flow index, a (–) is calculated as a function of the effective leaf area index, LAI^* ($\text{m}^2 \text{m}^{-2}$), and a scaling factor, β ($= 0.9$) that is introduced by Liston and Elder (2006b) to make LAI^* compatible with the canopy flow index proposed by Cionco (1978):

$$a = \text{LAI}^* \cdot \beta \quad (13)$$

LAI^* includes stems, leaves and branches as described by Chen et al. (1997).

To consider the extinction of solar radiation by the forest canopy, top-of-canopy incoming shortwave radiation, Q_{si} , is reduced following the Beer–Lambert law as

$$Q_{\text{sif}} = Q_{\text{si}} \cdot \tau_v, \quad (14)$$

where Q_{sif} is the incoming shortwave radiation impinging on the snow surface beneath the canopy (Hellström, 2001). τ_v representing the fraction of Q_{si} reaching the land surface is derived as

$$\tau_v = \exp(-k \cdot \text{LAI}^*), \quad (15)$$

with k being a vegetation-dependent extinction coefficient (Liston and Elder, 2006b). Aiming at a best fit to observed radiation inside forest canopies of different species (e.g. spruce, subalpine fir, pine) at a site in the U.S. Department of Agriculture (USDA) Fraser Experimental Forest near Fraser (Colorado, USA), Liston and Elder (2006b) have yielded best overall performance using a k value of 0.71, which is also used for the simulations here.

Incoming longwave radiation inside the canopy is assumed to be composed by a fraction F_g (–) directly reaching the ground through gaps in the forest stand and a fraction F_c (–) emitted by the forest canopy. The canopy-emitted fraction is calculated following Liston and Elder (2006a) as

$$F_c = a + b \cdot \ln(\text{LAI}^*) \quad (16)$$

where $a(-)$ and $b(-)$ are constants with values of 0.55 and 0.29, respectively. A value of F_g can be derived as

$$F_g = 1 - F_c, \quad (17)$$

with both calculated fractions used to estimate inside-canopy incoming longwave radiation Q_{lif} (W m^{-2}) from

$$Q_{\text{lif}} = (F_g \cdot Q_{\text{li}}) + (F_c \cdot \sigma \cdot T_c^4), \quad (18)$$

where Q_{li} (W m^{-2}) represents the top-of-canopy incoming longwave radiation. The latter is provided as input for ESCIMO.spread (v2) and is here estimated as a function of temperature and cloud cover as proposed by Liston and Elder (2006a) due to a lack of observations. σ represents the Stefan Boltzmann constant and T_c (K) the inside-canopy temperature. Assuming a linear dependency on canopy fraction, T_c is derived from top-of-canopy temperature T_a (K) as proposed by Obled (1971):

$$T_c = T_a - F_c \cdot (T_a - (R_c \cdot (T_a - T_{\text{mean}}) + T_{\text{mean}} - \delta T)), \quad (19)$$

where T_{mean} (K) is the mean daily air temperature, $R_c(-)$ is a dimensionless scaling parameter set to 0.8 and δT ($-2\text{K} \leq \delta T \leq +2\text{K}$) is a temperature offset defined to be (Durot, 1999)

$$\delta T = \frac{T_{\text{mean}} - 273.16}{3}. \quad (20)$$

Durot (1999) has further shown that relative humidity inside the canopy, RH_c (%), is often higher compared to the open due to sublimation and evaporation of melted snow. We therefore propose to modify top-of-canopy humidity RH (%) with consideration of the canopy fraction in the form of (Durot, 1999)

$$\text{RH}_c = \max\{\text{RH} \cdot (1 + 0.1 \cdot F_c), 100\}. \quad (21)$$

2.5 Simulating canopy effects on the snow cover

The following describes the newly implemented approaches to describe snow interception through the forest canopy as well as melt-induced unloading of intercepted snow from the canopy.

Interception of solid precipitation, P_s (mm) at time t is derived introducing a canopy-intercepted load, I (mm), expressed as (Pomeroy et al., 1998)

$$I = I_{t-1} + 0.7 \cdot (I_{\max} - I_{t-1}) \cdot (1 - \exp(-P_s/I_{\max})), \quad (22)$$

where $t - 1$ represents the previous time step and I_{\max} is the maximum interception storage calculated as (Hedstrom and Pomeroy, 1998)

$$I_{\max} = 4.4 \cdot \text{LAI}^*. \quad (23)$$

Sublimation of intercepted snow Q_{CS} (mm) is calculated as described by Liston and Elder (2006b) as

$$Q_{\text{CS}} = C_e \cdot I \cdot \Psi_s \cdot dt, \quad (24)$$

where dt (s) is the time increment (here: 3600 s), Ψ_s (s^{-1}) is the sublimation-loss rate coefficient for an ice sphere and $C_e(-)$ represents the canopy exposure coefficient. Ice spheres are assumed to be characterized by a constant radius of 500 μm as proposed by Liston and Elder (2006b).

The canopy exposure coefficient is calculated as

$$C_e = k_c \cdot (I/I_{\max})^{-0.4}, \quad (25)$$

where $k_c(-)$ is a dimensionless coefficient related to the shape of the intercepted snow deposits (Liston and Elder, 2006b). Sublimation at the canopy scale is hence estimated based

on sublimation from individual ice spheres. Analysing observed (Montesi et al., 2004) and modelled sublimation rates for a 2.7 m-tall subalpine fir tree at the USDA Fraser Experimental Forest, Liston and Elder (2006b) have found that the application of $k_c = 0.010$ seems to best reproduce observed sublimation rates at both, higher and lower elevated tree sites. This value is very close to the value of $k_c = 0.011$ derived by Pomeroy et al. (1998) for Canadian Boreal Forest and is used as k_c value for the calculations with ECIMO.spread (v2) here. This parameter can be easily adapted by changing the respective setting in the parameter section of the model.

The sublimation-loss rate coefficient Ψ_s is calculated from the particle mass m (kg) in the form of

$$\Psi_s = (dm/dt)/m, \quad (26)$$

where the particle mass is given by

$$m = \frac{3}{4} \cdot \pi \cdot \rho_i \cdot r^3, \quad (27)$$

with ρ_i (kg m^{-3}) being ice density and r (m) representing the radius of a spherical ice particle (assumed to be 500 μm as proposed by Liston and Elder, 2006b).

Mass loss from an ice particle is described as a function of intercepted solar radiation, humidity gradients between the ice surface and the surrounding atmosphere, the size of the considered ice particle and a ventilation term, following Thorpe and Mason (1966) and Schmidt (1972):

$$\frac{dm}{dt} = \frac{2 \cdot \pi \left(\frac{\text{RH}}{100} \right) - S_p \cdot \Omega}{h_s \cdot \Omega + \frac{1}{D \cdot \rho_v \cdot S \cdot h}}, \quad (28)$$

where h_s is the latent heat of sublimation ($2.8355 \times 10^6 \text{ J kg}^{-1}$).

The diffusivity of water vapour in the atmosphere, D ($\text{m}^2 \text{ s}^{-1}$) is derived following Thorpe and Mason (1966) as:

$$D = 2.06 \cdot 10^{-5} (T_a/273)^{1.75}. \quad (29)$$

The molecular weight of water M ($18.01 \text{ kg kmole}^{-1}$), the universal gas constant R ($8313 \text{ J kmole}^{-1} \text{ K}^{-1}$), air temperature T_a (K) and the thermal conductivity of the atmosphere λ_t ($0.024 \text{ J m}^{-1} \text{ s}^{-1} \text{ K}^{-1}$) are used to calculate Ω as proposed by Liston and Elder (2006b):

$$\Omega = \frac{1}{\lambda_t \cdot T_a \cdot Nu} \cdot \left(\frac{h_s \cdot M}{R \cdot T_a} - 1 \right). \quad (30)$$

The Nusselt number Nu and Sherwood number Sh are both calculated as:

$$Nu = Sh = 1.79 + 0.606 \cdot Re^{0.5}, \quad (31)$$

where Re ($0.7 < Re < 10$) is the Reynolds number expressed by:

$$Re = \frac{2 \cdot r \cdot u_c}{\nu} \quad (32)$$

with ν representing the kinematic viscosity of air ($1.3 \cdot 10^{-5} \text{ m}^2 \text{ s}^{-1}$) and u_c the ventilation velocity inside the canopy, which is set equal to inside-canopy wind speed as proposed by Liston and Elder (2006b).

Following Fleagle and Businger (1981) the saturation density of water vapor ρ_v (kg m^{-3}) is derived as

$$\rho_v = 0.622 \cdot \frac{e_s}{R_d \cdot T_a} \quad (33)$$

where R_d is the gas constant for dry air ($287 \text{ J K}^{-1} \text{ kg}^{-1}$) and e_s (Pa) is the saturation vapor pressure over ice, estimated following Buck (1981) as:

$$e_s = 611.15 \exp \left(\frac{22.452 \cdot (T_a - 273.16)}{T_a - 0.61} \right). \quad (34)$$

The shortwave radiation absorbed by a snow particle with radius r is defined to be

$$S_p = \pi \cdot r^2 (1 - \alpha_p) \cdot S_i, \quad (35)$$

where α_p is the snow albedo, and S_i (W m^{-2}) is the solar radiation at the earth surface, which in case of ESCIMO.spread (v2) is among the required meteorological input parameters.

To account for a melt-induced unloading of intercepted snow from the canopy, a melt-unloading rate L_m (kg m^{-2}) is introduced by Liston and Elder (2006b):

$$L_m = 5.8 \cdot 10^{-5} (T_a - 273.16) \cdot dt. \quad (36)$$

We assume an unloading rate of $5 \text{ kg m}^{-2} \text{ day}^{-1} \text{ K}^{-1}$ whenever temperatures are above freezing, with unloading snow adding to snow accumulation at the land surface. The simulated filling and depletion of the interception storage through snow fall, sublimation and melt induced unload is illustrated in Fig. 4 exemplarily for a period in February 2013.

3 Data and test site description

Snow cover simulations in this study are carried out for the forest site Vordersteinwald in the Black Forest mountain range (south-west Germany) (see Fig. 1). This site is eminently suitable for testing of the newly developed version of ESCIMO.spread as it (i) usually experiences alternation of accumulation and melting periods over the winter season, making the simulation of snow conditions particularly demanding and (ii) has been subject to intense snow surveys over the years 2010–present, including simultaneous observation of meteorological and snow conditions in and outside the forest canopy (Pohl et al., 2014).

The forest stand at the study site is mostly conifer with spruce, fir and pine, representing the most common conifer tree species. To quantify the vegetation effect on snow conditions, the applied snow monitoring systems (SnoMoS) were installed pairwise with one SnoMoS located in the open and another set up in close distance inside the forest canopy (see Fig. 5). The data recorded by these low-cost monitoring sensors include hourly values of snow depth, surface temperature, air temperature and humidity, global radiation, wind speed, and barometric pressure.

The continuous monitoring of snow depth with the SnoMoS was accompanied by bi-weekly snow density surveys that allow translation of snow depth into **SWE**. A comprehen-

sive description of the technical specifications and the instrumental setup of the SnoMoS is provided by Pohl et al. (2014). Precipitation recordings for the study site originate from nearby weather station Freudenstadt (DWD, 2015), operated by the German Weather Service (DWD). Precipitation observations have been corrected for differences in terrain elevation between the sites of measurement and model application by applying monthly elevation adjustment factors as proposed by Liston and Elder (2006a). The latter have been taken from Marke (2008) who has investigated altitudinal differences in precipitation for the Upper Danube Watershed. No interpolation using other station data has been carried out due to the closeness of the study site (3 km distance) to station Freudenstadt. Hemispherical images were taken at the forest location and were utilized to derive the effective LAI of the forest stand ($LAI^* = 2.6 \text{ m}^2 \text{ m}^{-2}$). Moreover, a logarithmic function considering snow ageing and new snowfall was used to compute daily snow densities between the surveys. All data used as model input and for model validation are freely provided along with the model.

4 Results

ESCIMO.spread (v2) has been applied to modify outside-canopy meteorological conditions for canopy effects at site Vordersteinwald as well as for a subsequent simulation of the **SWE** evolution for the winter season 2012/2013. Figure 6 shows outside-canopy global radiation modified for canopy effects with the new ESCIMO.spread (v2) algorithms in comparison to inside-canopy observations. As global radiation under mid-latitude prealpine conditions usually provides the largest share of energy for snow melt, an accurate representation of inside-forest global radiation is essential for a realistic reproduction of snow ablation with any energy balance model. The general dimension and temporal variation in global radiation inside the forest canopy seem well reproduced with a certain tendency of the model to underestimate global radiation in the forest. **The latter is also reflected by the scatter plot shown in Fig. 10 opposing simulated and observed global radiation. The satisfactory overall model performance in the modification of global radiation for canopy effects is also confirmed by the high values of the coefficient of determination ($R^2 = 0.66$), the Nash Sut-**

cliffe model efficiency (NSME = 0.64) and the index of agreement (IA = 0.89) as well as by the low root mean square error (RMSE = 8.23 W m⁻²) (see Krause et al., 2005 for a detailed explanation of the efficiency criteria applied). The values of these efficiency criteria are provided in Tab. 1 with the corresponding scatter plots for all meteorological input variables modified for canopy effects shown in Fig. 10. As shown in Fig. 7, the simulated and observed courses of temperature match fairly well until late January, whereas the simulations overestimate daily temperature peaks in spring. The efficiency criteria of R^2 , NSME, IA and RMSE with values of 0.79, 0.82, 0.94 and 1.74 (K), respectively, further underline the good performance of ESCIMO.spread (v2) with respect to the modification of outside-canopy temperature conditions. Compared to global radiation and temperature, the model performance for relative humidity and wind speed with R^2 and IA values in the order of 0.6 and 0.7–0.8 for both criteria, respectively, is distinctly weaker. In case of both variables the NSME with values below 0 indicates that the mean value of the observations would be a better predictor than the model (Krause et al., 2005). The course of relative humidity and wind speed conditions illustrated in Figs. 8 and 9 explains the diametrical picture of model performance described by means of R^2 and IA compared to NSME. While the temporal variation in relative humidity and wind speed is well reflected in the simulations (resulting in good correlation and acceptable values of R^2 and IA), the exact values in the observed time series are seldomly reproduced by the model results, a condition that is considered in the calculation of NSME (Krause et al., 2005). The high temporal and spatial variability in wind speed naturally makes any spatial interpolation or modification for canopy effects particularly challenging. In case of both variables, the simulations tend to exceed observed values of humidity and wind speed in the forest canopy. In case of both variables, higher maximum values can be observed in the simulated time series.

The good overall model performance as well as the differences in model performance for the different meteorological variables might at least partly be explainable by the presence/absence of pronounced daily cycles in the hourly values. While systematic daily variations in the temperature and global radiation data can be expected to bias some efficiency criteria towards higher model performance, the lower model performance for wind speed

and relative humidity might partly be due to weaker or missing daily cycles in the analyzed data. To further look into these assumptions, the predictive capabilities of outside-canopy observations for the estimation of inside-canopy conditions are provided in Tab. 2. Comparing the values of the different efficiency criteria calculated for the four meteorological variables to those shown in Tab. 1 reveals that while values of R^2 are equally high for all meteorological variables, the significant increase in NSME values clearly shows the improvements resulting from application of the canopy model, particularly when estimating global radiation inside the forest canopy. Only in case of relative humidity, the outside-canopy measurements seem to slightly better predict inside-canopy conditions. This can be explained by the fact that looking at the SnoMoS data for the winter season 2012/2013, measured humidity outside the canopy is often higher than that observed inside the forest stand, whereas the canopy model in ESCIMO.spread (v2) increases outside-canopy humidity with consideration of the canopy fraction to estimate inside-canopy relative humidity (see Eq. 21).

The simulated snow cover is displayed in Fig. 11 for the open and in Fig. 12 for inside the canopy in comparison to observations at the respective sites. As can be seen from Fig. 11, the newly developed version ESCIMO.spread (v2) much better reproduces the observed snow conditions outside the forest at site Vordersteinwald compared to ESCIMO.spread (v1). This increase in model performance is mostly due to the fact that liquid precipitation in ESCIMO.spread (v1) increases SWE by the total value of observed precipitation, whereas in the new model version liquid precipitation is only added to the SWE up to a maximum value defined by the water holding capacity with the rest leaving the snow pack as outflow (see Eq. 11). While these improvements are less important for simulations at high alpine sites, where the largest share of precipitation in the winter season falls in form of snow (see Strasser and Marke (2010)), at lower elevated sites the comparatively high amounts of liquid precipitation in winter make these model modifications essential. As a result of these further developments, the severe overestimation in simulated SWE observed in the results of ESCIMO.spread (v1) is no longer found in the results of ESCIMO.spread (v2) leading to a significant increase in model performance as confirmed by the values of the different ef-

Discussion Paper | Discussion Paper | Discussion Paper

iciency criteria in Tab. 3. The simulations carried out with ESCIMO.spread (v2) sometimes even show a tendency to underestimate observed snow conditions for the winter season 2012/2013, particularly with respect to the second snow peak at site Vordersteinwald in February 2013. Looking at the results achieved for inside the canopy (see Fig. 12 and Tab. 3), applying the canopy model allows to reasonably reproduce observed snow conditions inside the forest. Compared to the results achieved using observed outside-canopy snow conditions as a predictor for inside-canopy snow conditions (see Tab. 2), application of the proposed canopy model increases NSME values from - 0.49 to 0.81 and reduces RMSE from 23.07 to 8.26 mm.

The fact that the model results inside the canopy are even better than for the outside (see also the scatter plots in Fig. 13), might at least partly be the result of multiple error compensation effects (including errors from precipitation measurement, the transfer of precipitation information from precipitation gauge Freudenstadt to site Vordersteinwald as well as from translating snow depth into SWE). The green line in Fig. 12 shows the simulations achieved using observed meteorological conditions inside the canopy (as provided by the SnoMoS inside the forest). Due to a lack of precipitation recordings inside the forest, the precipitation data used as input for the simulations inside the canopy in this experiment also represent recordings from station Freudenstadt modified for canopy effects. Hence, precipitation inside the canopy as used as input for the snow simulations has to be considered a model result rather than an observation. The same applies to the incoming component of inside canopy longwave radiation, which to a certain fraction represents the simulated top-of-canopy incoming longwave radiation due to a lack of observations outside the forest stand (see Eq. 18 and explanations below). Comparing the results achieved using observed and simulated meteorological conditions inside the forest as model input (see Fig. 12), the meteorological observations allow only slightly better model performance with NSME increasing from 0.81 to 0.82 and RMSE decreasing from 8.26 to 8.02 mm. The results of both model runs show a distinct overestimation of SWE between 15 and 26 December. A closer look at the conditions during this period reveals significant snowfall at temperatures close to 0 °C and air humidity close to saturation. Hence, an explanation for the observed overes-

timation of **SWE** in this period might be a false interpretation of **liquid precipitation as solid precipitation**. While the model acceptably reproduces snow accumulation between 10 and 30 January in the open, a noticeable overestimation of **SWE** can be observed in the results using the modified outside-canopy meteorological conditions. **Moreover, a period of snow accumulation can be observed in the observations and simulations for the open in March, whereas inside the canopy this increase in SWE is merely predicted by the model and not confirmed by the observations.** A comparison of the snow simulations based on observed and simulated meteorological conditions inside the canopy reveals that only little differences exist between both model runs, with the model performance using observed meteorological conditions as model input being slightly better. Taking a closer look at the efficiency criteria in Tab. 3, the model results for both locations seem to well reflect the observed conditions with model performance inside the canopy being even slightly better than in the open.

5 Conclusions

A new version of the spreadsheet-based point energy balance snow model ESCIMO.spread has been presented (ESCIMO.spread (v2)) that allows an improved precipitation phase detection, **estimation of snow temperature**, consideration of cold and liquid water content in the snow cover, estimation of inside canopy meteorological conditions from meteorological observations in the open and the simulation of snow accumulation and ablation inside a forest canopy. It thereby does not require meteorological observations in the canopy but instead derives inside-canopy meteorological conditions from available observations in the open requiring only LAI and canopy height as plant-specific input parameters. The derived meteorological conditions inside the canopy are not only applicable as input for snow cover simulations but can be expected to be of interest for a variety of scientific disciplines, e.g. forest ecology or pedology. To provide the data required for model application and evaluation, a pair of SnoMoS has been utilized as an innovative technology that allows the collection of important meteorological variables at low financial costs. **Comparison of simulated inside-canopy meteorological conditions to observations at a site in the Black Forest region**

(Germany) reveals good overall model performance, particularly with respect to global radiation (NSME = 0.64, RMSE = 8.23 W m^{-2}) and temperature (NSME = 0.79, RMSE = 1.74 K) representing the most important meteorological variables for the estimation of snow melt. In case of relative humidity and wind speed the model efficiency with NSME values of -1.10 and -0.29 and an RMSE of 6.31 % and 0.59 m/s for the two variables, respectively, was noticeably lower. This lower model performance might at least partly be the result of weaker or missing daily cycles in the hourly data as well as potential biases in the measurements of the applied low cost monitoring systems, which are described in detail by Pohl et al. (2014). A satisfactory model performance unfolds when comparing the simulated snow cover evolution in- and outside the canopy to snow observations provided by the SnoMoS. NSME here reaches values of 0.81 and 0.71 with an RMSE of 8.26 and 18.07 mm for simulated SWE in- and outside the canopy, respectively. While snow cover evolution is well reproduced for both, out- and inside the forest canopy, model performance is slightly higher for inside-canopy conditions, even though the empirical model parameters have not yet been adjusted to (pre)alpine forest species. This might at least partly be explainable by multiple error compensation effects (including errors from precipitation measurement, the transfer of precipitation information from precipitation gauge Freudenstadt to site Vordersteinwald and the translation from snow depth to SWE). Making use of the full potential of simultaneous observation of snow and meteorological conditions as provided by the SnoMoS, an effort is currently undertaken to develop parameters for the applied canopy model that are tailored to the specific conditions in (pre)alpine forests. Moreover, despite its physically-based character and advanced model features, ESCIMO.spread (v2) still oversimplifies some important processes of the snow-vegetation interaction. In the current version the model only considers unloading of intercepted snow as a result of melting. While the fact that wind also induces unloading of intercepted snow is well known, the combined dependence on plant characteristics (e.g. plant structure and plant element flexibility) and meteorological conditions (e.g. snow temperature, wind speed and direction) makes this a complex process hard to consider in numerical models (Liston and Elder, 2006b). The modification of short-wave and longwave radiation assumes a plant specific extinction coefficient and a constant

canopy fraction, respectively. While these assumptions can be expected to reasonably reproduce the general observed **patterns** in local radiation, they are not capable to accurately capture the actual radiation conditions whenever canopy densities strongly vary or sun is shining through open areas in the trees as a result of changing solar zenith angles.

Code availability

ESCIMO.spread (v2) can be downloaded free of charge at www.alpinehydroclimatology.net together with one year of sample data including the meteorological and snow observations used in this study. The model has been tested on OpenOffice 4.1.1. as well as on different versions of Microsoft Excel for Windows and Mac.

Table 1. Performance of ESCIMO.spread (v2) in the modification of outside-canopy global radiation, temperature, relative humidity and wind speed for canopy effects.

Variable	NSME	R^2	IA	RMSE
Global radiation	0.64	0.66	0.89	8.23 (W/m^2)
Air temperature	0.79	0.82	0.94	1.74 (K)
Relative humidity	-1.10	0.61	0.74	6.31 (%)
Wind speed	-0.29	0.60	0.80	0.59 (m/s)

Table 2. Predictive capabilities of outside-canopy observations for inside-canopy conditions.

Variable	NSME	R^2	IA	RMSE
Global radiation	-28.24	0.66	0.39	73.79 (W/m^2)
Air temperature	0.74	0.85	0.95	1.92 (K)
Relative humidity	-0.81	0.65	0.76	5.84 (%)
Wind speed	-13.66	0.60	0.48	2.01 (m/s)
SWE	-0.49	0.87	0.82	23.07 (mm)

Table 3. Performance of ESCIMO.spread (v1) and ESCIMO.spread (v2) at site Vordersteinwald for the winter 2012/2013. As ESCIMO.spread (v1) does not include formulations of inside-canopy processes, model performance for inside-canopy conditions is only available for ESCIMO.spread (v2). The simulations inside the canopy are based on modified outside-canopy meteorological conditions.

Variable	NSME	R^2	IA	RMSE
SWE (v1) outside canopy	-15.20	0.34	0.37	134.28 (<i>mm</i>)
SWE (v2) outside canopy	0.71	0.81	0.90	18.07 (<i>mm</i>)
SWE (v2) inside canopy	0.81	0.83	0.95	8.26 (<i>mm</i>)
