Abstract

During the fifth phase of the Coupled Model Intercomparison Project (CMIP5) substantial efforts were carried out on the systematic assessment of the skill of Earth system models. One goal was to check how realistically representative marine biogeochemical tracer distributions could be reproduced by models. Mean-state assessments routinely compared model hindcasts to available modern biogeochemical observations. However, these assessments considered neither the extent of equilibrium in modeled biogeochemical reservoirs nor the sensitivity of model performance to initial conditions or to the spin-up protocols. Here, we explore how the large diversity in spin-up protocols used for marine biogeochemistry in CMIP5 Earth system models (ESM) contribute to model-to-model differences in the simulated fields. We take advantage of a 500 year spin-up simulation of IPSL-CM5A-LR to quantify the influence of the spin-up protocol on model ability to reproduce relevant data fields. Amplification of biases in selected biogeochemical fields (O_2 , NO_3^- , Alk-DIC) is assessed as a function of spin-up duration. We demonstrate that a relationship between spin-up duration and assessment metrics emerges from our model results and is consistent when confronted against a larger ensemble of CMIP5 models. This shows that drift has implications on their performance assessment in addition to possibly aliasing estimates of climate change impact. Our study suggests that differences in spin-up protocols could explain a substantial part of model disparities, constituting a source of model-to-model uncertainty. This requires more attention in future model intercomparison exercises in order to provide realistic ESM results on marine biogeochemistry and carbon cycle feedbacks.

1.2 Initialization of biogeochemical fields and spin-up protocols in CMIP5

Ocean initialization protocols aim at obtaining stable and equilibrated distributions of model state variables, such as temperature or concentrations of dissolved tracers. Most commonly used initialization protocols consist of initializing both physical and biogeochemical variables with either climatologies of the observed fields or constant values before running the model to equilibrium. In theory, equilibrium corresponds to steady-state and, hence, temporal derivatives of tracer fields close to zero. The time needed to equilibrate tracer distributions or, in other words, the integration time needed by the model to converge towards its own attractor (which is different from the true state of the climate system) varies greatly between components of the climate system. It spans from several weeks for the atmosphere (e.g. Phillips et al., 2004) to several centuries for ocean and sea ice components (e.g. Stouffer et al., 2004). The equilibration of ocean biogeochemical tracers across the entire water column amounts to several thousands of years (e.g. Heinze et al., 1999; Wunsch and Heimbach, 2008) and depends on the state of background ocean circulation as well as the diapycnal diffusivity (e.g. Aumont et al., 1998; Bryan, 1984; Gnanadesikan, 2004; Marinov et al., 2008). In practice, these simulations, called “spin-up”, span in general only several hundreds of years at the end of which a quasi-equilibrium state is assumed for the interior ocean tracers.

The present degree of complexity and increasing spatial as well as temporal resolution of marine biogeochemical ESM components often precludes a spin-up to reach adequate equilibration of biogeochemical tracers. This is a consequence of the increasing number of state variables present in most of the current generation of biogeochemical models (e.g., for each tracer a separate advection equation has to be solved via a numerical CPU time demanding algorithm), more complex process descriptions (e.g., including more plankton functional types than before), and increasing spatial as well as temporal resolution. This number has continuously increased from simple biogeochemical models (e.g. HAMOCC3, Maier-Reimer and Hasselmann, 1987) to marine biodiversity models (e.g. Follows et al., 2007). Current generation biogeochemical

models embedded in CMIP5 ESMs contain roughly two to four times more state variables than the physical models (e.g., atmosphere, ocean, sea-ice), which makes their equilibration computationally costly and difficult. The initialization of biogeochemical state variables is further complicated by the scarcity of biogeochemical observations

as compared to observations of physical variables (e.g., temperature, salinity). While three-dimensional observation-based climatologies exist for macro-nutrients, oxygen, dissolved carbon and alkalinity, for other tracers such as dissolved iron, dissolved organic carbon and biomass of the various plankton functional types data are still sparse (in-spite of considerable efforts such as the GEOTRACES program for trace elements, or MAREDAT for biomasses of plankton functional types). The latter are initialized either with constant values (e.g. global average estimates) or with output from a previous model run. An additional difficulty stems from the use of modern climatologies to initialize the ocean state, implicitly assuming a long-term steady state, which does not necessarily represent the preindustrial state of the ocean. These climatologies incorporate the ongoing anthropogenic perturbation of marine biogeochemical fields, be it the uptake of anthropogenic CO₂ or the excess of nutrients inputs and pollutants (e.g. Doney, 2010). Although methods exist to remove the anthropogenic perturbation from observed ocean carbon tracer fields, their use is still debated since they lead to non-unique results (e.g. Tanhua et al., 2007; Yool et al., 2010).

The equilibration of marine biogeochemical tracer distributions is driven not only by the ocean circulation but also by numerous internal biogeochemical processes acting at various time scales. For example, while the transport and degradation of sinking organic matter spans days to perhaps several months, the associated impact on deep water chemistry accumulates over several decades to centuries as zones of differential remineralization are mixed across water masses and follows the ocean circulation (Wunsch and Heimbach, 2008). For models including interactive sediment modules, the sediment equilibration takes even longer ($O(10^4)$ years; e.g. Archer et al., 2009 and Heinze et al., 1999). As a consequence of the interplay between ocean circulation and biogeochemical processes, biogeochemical models require long spin-up times to

**Inconsistent
strategies to spin up
models in CMIP5**

R. Séférian et al.

equilibrate (e.g. Khatiwala et al., 2005; Wunsch and Heimbach, 2008). Modeling studies of paleo-oceanographic passive tracers such as $\delta^{18}\text{O}$ or $\Delta^{14}\text{C}$ (Duplessy et al., 1991), or global ocean passive tracers (Wunsch and Heimbach, 2008), as well as more recently available modern global scale data compilations (e.g. Key et al., 2004; Sarmiento and Gruber, 2006) and GEOTRACES Intermediate Data product 2014 (Version 2; <http://www.bodc.ac.uk/geotrades/data/idp2014/>) provide an estimate of the time required for the ocean biogeochemical reservoir to equilibrate with the climate systems (excluding continental weathering and reaction with marine sediments). It ranges from 1500 to 4000 years depending on the ocean circulation and can reach up to 10 000 years in the deeper domains of the ocean (Wunsch and Heimbach, 2008).

In a context of model-to-model intercomparison, this time range contributes to the model uncertainty. Lessons from the previous OCMIP-2 exercise have demonstrated that some models required $\sim 10\,000$ years to equilibrate to a global sea–air carbon flux of $0.01\,\text{Pg}\,\text{Cyr}^{-1}$.

While it is recognized that long time-scale processes influence the length of spin-up to equilibrium, the spin-up duration is usually defined ad hoc based on external constraints or internal biogeochemical criteria. The computational cost is commonly invoked as external constraint to shorten and limit the spin-up duration. It is directly related to model complexity (e.g. Tjiputra et al., 2013; Vichi et al., 2011; Yool et al., 2013) and spatial resolution (Ito et al., 2010). The internal biogeochemical criteria applied to derive the duration of the spin-up simulations are generally defined by (i) reaching a steady-state, quasi equilibrium of the long-term global-mean CO_2 fluxes between the ocean and the atmosphere (e.g. Dunne et al., 2013; Ilyina et al., 2013; Lindsay et al., 2014; Séférian et al., 2013), (ii) determining the amount of carbon stored into the ocean at preindustrial state (e.g. Dunne et al., 2013; Vichi et al., 2011) or (iii) representing relevant biogeochemical tracer patterns (e.g., oxygen minimum zone in Ito and Deutsch, 2013).

Despite its importance, only limited information on spin-up procedures is available through the CMIP5 metadata portal (<http://metaforclimate.eu/trac>). Information on spin-

models in CMIP5**

R. Séférian et al.

up protocols and model initialization is usually not taken into account in model inter-comparison studies (e.g. Andrews et al., 2013; Bopp et al., 2013; Cocco et al., 2013; Frölicher et al., 2015; Gehlen et al., 2014; Keller et al., 2014; Resplandy et al., 2013, 2015; Rodgers et al., 2014; Séférian et al., 2014). This information, if available, can only be found separately in the reference papers of individual models (e.g. Adachi et al., 2013; Arora et al., 2011; Collins et al., 2011; Dunne et al., 2013; Ilyina et al., 2013; Lindsay et al., 2014; Romanou et al., 2013; Séférian et al., 2013; Tjiputra et al., 2013; Vichi et al., 2011; Volodin et al., 2010; Watanabe et al., 2011; Wu et al., 2013). The duration of spin-up simulations of CMIP5 ocean biogeochemical components spans from one hundred years (e.g., CMCC-CESM) to several thousand years (e.g., MPI-ESM-LR, MPI-ESM-MR) (Fig. 1 and Table 1). Model initialization and spin-up procedures are equally variable across the model ensemble (Fig. 1 and Table 1). Four different sources of initialization and five different procedures of model equilibration emerge from the 23 ESMs reviewed for this study.

Biogeochemical state variables were mostly initialized from observations, although from various releases of the same World Ocean Atlas global climatology (WOA1994, WOA2001, WOA2006, WOA2010). A small subset of ESMs relied either on a mix between previous model output and observations or solely on model output from a previous simulation for initialization. Similarly, spin-up procedures fall into two categories. The first one may be called “sequential”: it consists in decomposing the spin-up integration into one long offline simulation ($\sim 200\text{--}10\,000$ years) and one shorter online simulation ($\sim 100\text{--}1000$ years). During the offline simulation, the biogeochemical model is forced by dynamical fields from the climate model or from reanalysis (CanESM2, MRI-ESM, Fig. 1 and Table 1). Some modeling groups have adopted a “direct” strategy, which consists in running solely one online or coupled spin-up simulation (e.g., GFDL-ESM2M, GFDL-ESM2G, NorESM1-ME). Finally, a spin-up “acceleration” procedure is used by CMCC-CESM. This technique consists of enhancing the ocean carbon outgassing to remove anthropogenic carbon from the ocean, a legacy from initialization with modern data (Global Data Analysis Project or GLODAP following Key et al.,

Interactive Discussion	

2004). None of these spin-up procedures, durations and sources of initialization can be considered as “standard”; each of them is unique and subjectively employed by one modeling group.

Objective arguments and hypotheses justifying the choice of one method of spin-up rather than the others have been the focus of previous studies (e.g. Dunne et al., 2013; Heinze and Ilyina, 2015; Tjiputra et al., 2013). Similarly, modeling groups discussed impacts of their particular spin-up procedure on model performance (e.g. Dunne et al., 2013; Lindsay et al., 2014; Séférian et al., 2013; Vichi et al., 2011). However, no study has addressed the potential for the large diversity of spin-up procedures found across 10 the CMIP5 ensemble to translate into model-to-model differences in terms of comparative model performance assessments or model evaluations in terms of future projections.

1.3 Objectives of this study

This study assesses the role of the spin-up protocol in the representation of biogeochemical fields and subsequent model skill assessment, providing a complementary analysis from the studies of Gupta et al. (2012, 2013). It relies on a 500 year long spin-up simulation from a state-of-the-art Earth system model, IPSL-CM5A-LR to investigate the impacts of spin-up strategy on selected biogeochemical tracers and residual model drift across the various ESMs of the CMIP5 ensemble. We demonstrate that the duration of the spin-up has implications for the determination of robust and meaningful skill-score metrics that should improve future intercomparison studies such as CMIP6 20 (Meehl et al., 2014).

Section 2 describes the model, the observations, the model experiments, as well as the methods used for assessing the impacts of spin-up protocols on the representation of biogeochemical fields in IPSL-CM5A-LR, as well as across the ensemble of CMIP5 ESMs. Section 3 presents the analysis developed for the assessment of the impact of spin-up duration on the representation of biogeochemical structures. Implications and recommendations are respectively discussed in Sects. 4 and 5, respectively.

2 Methods

2.1 Model simulations

This study exploits in particular results from one simulation performed with IPSL-CM5A-LR (Dufresne et al., 2013) as representative for other CMIP5 Earth system models. As

- 5 a typical representative of the current generation of ESMs, IPSL-CM5A-LR combines the major components of the climate system (Chap. 9, Table 9.1, IPCC, 2013). The atmosphere is represented by the atmospheric general circulation model LMDZ (Hourdin et al., 2006) with a horizontal resolution of $3.75^\circ \times 1.87^\circ$ and 39 levels. The land surface is simulated with ORCHIDEE (Krinner et al., 2005). The oceanic component
10 is NEMOv3.2 in its ORCA2 global configuration (Madec, 2008). It has a horizontal resolution of about 2° with enhanced resolution at the equator (0.5°) and 31 vertical levels. NEMOv3.2 includes the sea-ice model LIM2 (Fichefet and Maqueda, 1997), and the marine biogeochemistry model PISCES (Aumont and Bopp, 2006). PISCES simulates the biogeochemical cycles of oxygen, carbon and the main nutrients with
15 24 state variables. The model simulates dissolved inorganic carbon and total alkalinity (carbonate alkalinity + borate + water) and the distributions of macronutrients (nitrate and ammonium, phosphate, and silicate) and micronutrient iron. PISCES represents two sizes of phytoplankton (i.e., nanophytoplankton and diatoms) and two zooplankton size-classes: microzooplankton and mesozooplankton. PISCES simulates semi-labile
20 dissolved organic matter, and small and large sinking particles with different sinking speeds (3 m d^{-1} and 50 to 200 m d^{-1} , respectively). While fixed elemental stoichiometric C : N : P-O₂ ratios after Takahashi et al. (1985) are imposed for these three compartments the internal concentrations of iron, silica and calcite are simulated prognostically. The carbon system is represented by dissolved inorganic carbon, alkalinity and
25 calcite. Calcite is prognostically simulated following Maier-Reimer (1993) and Moore et al. (2002). Alkalinity in the model system includes the contribution of carbonate, bicarbonate, borate, protons, and hydroxide ions. Oxygen is prognostically simulated using two different oxygen-to-carbon ratios, one for the oxic remineralization of organic

matter and one for the sub-oxic pathway (Sarmiento and Gruber, 2006). For carbon and oxygen pools, air-sea exchange follows the Wanninkhof (1992) formulation.

The boundary conditions account for nutrient supplies from three different sources: atmospheric dust deposition for iron, phosphorus and silica (Jickells and Spokes, 2001; 5 Moore et al., 2004; Tegen and Fung, 1995), rivers for nutrients, alkalinity and carbon (Ludwig et al., 1996) and sediment mobilization for sedimentary iron (de Baar and de Jong, 2001; Johnson et al., 1999). To ensure conservation of nitrogen in the ocean, annual total nitrogen fixation is adjusted to balance losses from denitrification. For the other macronutrients, alkalinity and organic carbon, the conservation is ensured by 10 tuning the sedimental loss to the total external input from rivers and dust. In PISCES, an adequate treatment of external boundary conditions has been demonstrated to be essential for the accurate simulation of nutrient distributions (Aumont and Bopp, 2006; Aumont et al., 2003). Riverine carbon inputs induce a natural outgassing of carbon of 0.6 Pg C yr⁻¹ which has been shown essential to model the inter-hemispheric gradient 15 of atmospheric CO₂ under preindustrial state (Aumont et al., 2001).

The core simulation of this study is a 500 year long coupled preindustrial run. It uses the same atmospheric, land surface and ocean configurations as IPSL-CM5A-LR (Dufresne et al., 2013) for which the marine biogeochemistry has been extensively evaluated (see e.g. Séférian et al., 2013 for modern-state evaluation). The only difference between the “standard” preindustrial simulation contributed to CMIP5 and the present one is the initial conditions. While the CMIP5 preindustrial simulation starts 20 from an ocean circulation after several thousand years of online physical adjustment, the present simulation starts from an ocean at rest using the January temperature and salinity fields from the World Ocean Atlas (Levitus and Boyer, 1994). Biogeochemical state variables were initialized from data compilations or climatologies as explained 25 in the following section. Atmospheric CO₂ and other greenhouse gases, as well as natural aerosols, were set to their 1850 preindustrial values. The simulation is extensively described in terms of ocean physics by Mignot et al. (2013). Mignot and coworkers show that the strength of the Atlantic meridional overturning circulation and the Antarc-

tic circumpolar current as well as the upper 300 m ocean heat content stabilize after 250 years of simulation.

Although the spin-up protocol used to conduct this 500 year long simulation is not readily comparable to the one used to produce the initial conditions for the CMIP5 preindustrial simulation, its duration is greater than the median length of on-line adjustment computed from the multiple spin-up protocols applied during CMIP5 (~ 395 years, Fig. 1 and Table 1). Besides, the methodology of initializing biogeochemical state variables from data fields is not broadly employed by the various modeling groups that have contributed to CMIP5. Despite the above-mentioned methodological shortcuts, we take this 500 year long preindustrial simulation as a representative example of a spin-up protocol for the diversity of approaches used by CMIP5 models.

2.2 Observations for initialization and evaluation

Two streams of data sets were used in this study. The first stream combines data from the World Ocean Atlas 1994 (WOA94, Levitus and Boyer, 1994 and Levitus et al., 1993) for the initialization of 3-dimensional fields of temperature and salinity, dissolved nitrate, silicate, phosphate and oxygen, and data from GLODAP (Key et al., 2004) for preindustrial dissolved inorganic carbon and total alkalinity. This stream of data was chosen purposely in our experimental setup to be slightly different than the second stream of data, World Ocean Atlas 2013 (WOA2013, Levitus et al., 2013), the evaluation data set.

A second stream of data was used to compare modeled biogeochemical fields. It includes up-to-date observed climatologies of nitrate and oxygen from the WOA2013. This database is based on samples collected since 1965, and incorporates also data from WOA94 onwards. For the concentrations of preindustrial dissolved inorganic carbon and total alkalinity, we still use GLODAP. The second stream of data was selected to be as close as possible to the “standard” evaluation procedure of skill-assessment protocols found in CMIP5 model reference papers (Adachi et al., 2013; Arora et al., 2011; Collins et al., 2011; Dunne et al., 2013; Ilyina et al., 2013; Lindsay et al., 2014;

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

Romanou et al., 2013; Séférian et al., 2013; Tjiputra et al., 2013; Vichi et al., 2011; Volodin et al., 2010; Watanabe et al., 2011; Wu et al., 2013). Differences between these two streams of data are minor and are further detailed below.

2.3 Approach and statistical analysis

- 5 To quantify the impacts of a large diversity of spin-up procedures on the representation of biogeochemical fields in CMIP5, we employ a three-fold approach.
1. The 500 year long spin-up simulation described in Sect. 2.1 is used to determine the influence of the spin-up procedure on the representation of biogeochemical fields in IPSL-CM5A-LR.
 - 10 2. In the next step, relationships between biases in modeled fields, model-data mismatches and the duration of the spin-up simulation are identified across the CMIP5 ensemble. For this step, drifts in biogeochemical fields are determined from the first century of the preindustrial simulation (referred to as piControl) of each CMIP5 ESM.
 - 15 3. Finally, the modern hindcast (referred to as historical) from each available CMIP5 ESM is used to estimate the impact of these drifts in biogeochemical fields on the ability of models to replicate modern observations. For a given model, we choose to use the first member of the “historical” ensemble if several realizations are available.
- 20 For this purpose, several statistical skill score metrics are computed following Rose et al. (2009) and Stow et al. (2009) from model fields interpolated on a regular 1° grid and to fixed depth levels. The skill score metrics are (1) the global averaged concentrations for overall drift, (2) the average error or bias for mismatches between modeled and observed fields, (3) spatial correlation for mismatches between modeled and observed
- 25 large-scale structures, (4) the difference between modeled and observed spatial variability ($\Delta\sigma$) and (5) the root-mean squared error (RMSE) to assess the total cumulative

errors between modeled and observed fields. These statistical metrics are computed across the water column, but for clarity we focus on surface, 150 m (thermocline) and 2000 m (deep) levels. These statistical metrics were chosen among those described in the literature, because they proved to yield the most indicative scores for tracking model errors or improvement along the various intercomparison exercises (IPCC, 2013).

The drift is determined for either concentrations in simulated biogeochemical fields or for skill score metrics (e.g., RMSE or $\Delta\sigma$) using a linear regression fit over a time window of 100 years. This time window of 100 years was chosen as a trade off between longer time window (> 200 years) that smoothes the drift signal and shorter time window (< 80 years) that introduces fluctuations due to internal variability.

The drift is assumed to decrease exponentially during the spin-up simulation and is described by a simple drift model:

$$\text{drift}(t) = \text{drift}(t = 0) \times \exp\left(-\frac{1}{\tau}t\right) \quad (1)$$

where τ is the relaxation time of the respective field at a given depth level. It corresponds to the time required to nullify the drift.

Our analyses focus on the global distribution of nitrate (NO_3^-), dissolved oxygen (O_2) and the difference between total alkalinity and dissolved inorganic carbon (Alk-DIC).

The latter serves as an approximation of carbonate ion concentration following Zeebe and Wolf-Gladrow (2001). We use this approximation of the carbonate ion concentration rather than its concentration, $[\text{CO}_3^{2-}]$, since the latter was poorly assessed in CMIP5 reference papers and was not provided by a majority of ESMs. These three biogeochemical tracers were chosen because (1) most current biogeochemical models simulate Alk, DIC, NO_3^- and O_2 prognostically and (2) they are frequently used in state-of-the-art model performance assessment (e.g. Anav et al., 2013; Bopp et al., 2013; Doney et al., 2009; Friedrichs et al., 2009, 2007; Stow et al., 2009), and (3) DIC and Alk are both used as “master tracers” for the carbonate system in the ocean biogeochemistry models (while $[\text{CO}_3^{2-}]$, e.g., is not explicitly advected as a tracer but

diagnosed from temperature, salinity, DIC, Alk, $[H^+]$, and pCO_2 when needed). Modeled distributions of NO_3^- , O_2 and Alk-DIC reflect the representation of biogeochemical processes related to the biological pump (CO_2 , NO_3^- , O_2), the air-sea gas exchange and ocean ventilation (CO_2 and O_2), as well as carbonate chemistry (Alk-DIC). These biogeochemical processes are of particular relevance for investigating the impact of climate change on marine productivity (e.g. Henson et al., 2010), ocean deoxygenation (e.g. Gruber, 2011; Keeling et al., 2009) and the ocean carbon sink, processes for which future projections with the current generation of ESMs yield large inter-model spreads (e.g. Friedlingstein et al., 2014; Resplandy et al., 2015; Séférian et al., 2014; Tjiputra et al., 2014).

3 Results

3.1 Comparison of observational datasets

Our review of spin-up protocols for CMIP5 ESM shows that several modeling groups have employed different streams of datasets to initialize their biogeochemical models (e.g., WOA1994, WOA2001), while model evaluation relies on the most up-to-date stream of data. Differences between the two data streams used for initializing and assessing, respectively, NO_3^- and O_2 concentrations are analyzed. Table 2 summarizes RMSE and correlation between WOA1994 and WOA2013 for these two biogeochemical fields.

Table 2 indicates that differences between the two streams of data are fairly small. The total difference (RMSE) represents a departure between 5 to 10 % from the global average concentrations of WOA2013 across depth levels. It is generally lower in regions where the sampling density has not increased markedly between the two releases. These values can be used as a baseline for model-to-model comparison assuming that errors attributed to the various sources of initialization cannot be larger than 10 %. Considering that some models have used outputs from previous model

Interactive Discussion	

simulations or globally averaged concentrations as initial conditions, we acknowledge that this baseline is not a perfect criterion for benchmarking model performance. There is, however, no ideal solution to address this issue since there is no standardized set of initial conditions in CMIP5 except some recommendations for the decadal prediction exercise in which specific attention was paid to initialization (e.g. Keenlyside et al., 2008; Kim et al., 2012; Matei et al., 2012; Meehl et al., 2013, 2009; Servonnat et al., 2014; Smith et al., 2007; Swingedouw et al., 2013).

3.2 Equilibration state metrics in IPSL-CM5A-LR

The global mean sea surface temperature (SST) is a common metric to quantify the energetic equilibrium of the model. This metric has been widely used in various papers referenced in this study to determine the equilibration of ESM physical components. Figure 2a shows the evolution of this metric during the 500 year long spin-up simulation. The global average SST sharply decreases during the first 250 years of the simulation. In the last 250 years of the simulation, the global averaged SST displays a small residual drift of $\sim -10^{-4}^{\circ}\text{C y}^{-1}$ which falls into the range of the drifts reported for CMIP5 ESMs. The evolution over the last 250 years is comparable to those of other physical equilibration metrics, such as the ocean heat content or the meridional overturning circulation (Mignot et al., 2013).

The temporal evolution of sea-to-air CO₂ fluxes was used in phase 2 of the Ocean Carbon Model Intercomparison Project (OCMIP-2, Orr, 2002) as an equilibration metric for the marine biogeochemistry and was still widely used during CMIP5. Figure 2b presents its evolution in the 500 year long spin-up simulation. The global ocean sea-to-air CO₂ flux is $\sim -0.7 \text{ PgCyr}^{-1}$ over the last decades of the spin-up simulation (negative values indicate ocean CO₂ uptake). The global sea-to-air carbon flux does not fit the range of values estimated from preindustrial natural ocean carbon flux inversions (e.g. Gerber and Joos (2010) or Mikaloff Fletcher et al. (2007), referred to as MF2007 on Fig. 2), which amounts to $0.03 \pm 0.08 \text{ PgCyr}^{-1}$ (to which an open-ocean river-induced carbon outgassing of 0.45 PgCyr^{-1} has to be added on Fig. 2 accord-

Interactive Discussion

ingly to IPCC, 2013 or Le Quéré et al., 2015). This indicates that the ocean carbon cycle has not reached a steady state in the model system following the 500 years of integration.

Figure 2b also shows that the drift in the global sea-to-air carbon flux reduces slowly after the first 50 years of the spin-up simulation. While this drift is about 0.001 PgCyr^{-2} from year 250 to 500, it is much weaker over the last century of the simulation ($5 \times 10^{-4} \text{ PgCyr}^{-2}$). Using an approximate relaxation time of 73 years estimated from the simple drift model (Eq. 1) over years 250–500 and the drift of 0.001 PgCyr^{-2} , we find that the simulated sea-to-air carbon flux would reach a steady state after ~ 500 supplemental years of spin-up. After the additional 500 supplemental years of spin-up, sea-air carbon flux would fall into the range of inverse estimates of MF2007 with accounting for outgassing of river carbon of 0.45 PgCyr^{-1} . This estimate does not account for the non-linearity of the ocean carbon cycle and the associated process uncertainties (Schwinger et al., 2014). This estimation potentially underestimates the time required to equilibrate the ocean carbon cycle and sea-to-air carbon fluxes in the range of inversion estimates. The duration of the spin-up simulation would have to be increased by an additional 500 years to account for the estimated river-induced natural CO_2 outgassing of about 0.45 PgCyr^{-1} (IPCC, 2013). The drift of 0.001 PgCyr^{-2} is, however, much smaller than the oceanic sink for anthropogenic carbon. Even if not fully equilibrated in terms of carbon balance, it is likely that this run would have given consistent estimates of anthropogenic carbon uptake in transient historical hindcasts.

3.3 Temporal evolution of model errors in IPSL-CM5A-LR

Figure 3 shows the temporal evolution of globally averaged concentrations for O₂, NO₃ and Alk-DIC at the surface (panels a, b and c), 150 m (panels d, e and f) and 2000 m (panels g, h, and i). Globally averaged concentrations of O₂, NO₃ and Alk-DIC (solid lines) reach steady state after 100 to 250 years of spin-up at the surface. While modeled nominal values for O₂ concentration converge toward the observed concentration (i.e., 172.3 μmol L⁻¹), that of NO₃ and to a lesser extent Alk-DIC present persistent

deviations from WOA2013 and GLODAP. At the surface, the convergence of the simulated oxygen to observed value is expected since the dominant governing process of thermodynamic saturation (through the air-sea gas exchange) is well understood and modeled. The deviation in surface NO_3 highlights uncertainty related to near surface biological processes and upper ocean physics. Below the surface, concentrations of biogeochemical tracers drift away from the globally averaged concentrations computed from WOA2013 or GLODAP (Fig. 3d–i). At 150 and 2000 m, the drift in global averaged concentrations for these fields, computed over the last 250 years, is still significant with $p < 10^{-4}$ (Table 3). Dashed lines in Fig. 3 indicate the temporal evolution of RMSE, which quantifies the total mismatch between simulated and observed fields. Except for the surface fields, Fig. 3 shows that RMSE globally increases with time for all biogeochemical fields. The linear drift in RMSE over the last 250 years of the spin-up simulation falls within the 2–3 % kyr^{-1} range at the surface. It is much larger at 2000 m (144–280 % kyr^{-1} ; Table 3). This is also the case regionally, because the latitudinal maximum in RMSE (RMSE_{\max}) is similar to the global RMSE. Table 3 also shows that the magnitude of drift in RMSE for O_2 , NO_3 and Alk-DIC differs at a given depth as different processes affect the interior distribution of these biogeochemical fields.

3.4 Evolution of geographical mismatches in IPSL-CM5A-LR

To further explore the evolution of mismatch in biogeochemical distributions, we analyze differences (ε) between simulated and observed fields of O_2 , NO_3 from WOA2013 and Alk-DIC from GLODAP after the initialization and at the end of the spin-up, i.e., the first year and the last year of the core spin-up simulation performed with the IPSL-CM5A-LR model (Figs. 4, 5 and 6).

Figure 4a, c, and e shows that surface concentrations of biogeochemical fields are associated with small biases at initialization. This error represents less than 5 % of the observed surface concentrations for O_2 , NO_3 and Alk-DIC and reflects the weak difference between the data stream employed for initialization and validation. After 500 years of spin-up, deviations between the modeled and observed fields at the surface have in-

Interactive Discussion		

creased locally by up to ~ 40 % (Fig. 4b, d, and f). The largest deviations are found in high-latitude oceans for O₂ and NO₃ and also to some extent in the tropics for NO₃ and Alk-DIC.

Below the surface, distributions of modeled biogeochemical fields compare well to the observations at 150 m at initialization with averaged errors close to zero (Fig. 5a, c, and e). This result was expected since WOA2013 and WOA1994 differ weakly at these depth levels. Subsurface distributions at initialization strongly contrast with the concentrations that resulted from 500 years of spin-up (Fig. 5b, d, and f). After 500 years of spin-up, strong mismatches characterize the distribution of O₂, NO₃ and Alk-DIC fields in the high-latitude oceans and in the tropics. Figure 5 illustrates that pattern of errors are well correlated. It directly translates the assumptions employed in the

biogeochemical model (here the elemental C : N :-O₂ stoichiometry of PISCES). Figure 6 shows that model-data deviations at 2000 m have substantially increased regionally after 500 years of simulation, showing large errors in the Southern Hemisphere oceans. This appears clearly in Fig. 6d and f for NO₃ and Alk-DIC fields, respectively.

The temporal evolution of the total mismatch between modeled and observed fields of O₂, NO₃ and Alk-DIC over the whole water column is presented in Fig. 7 in terms of RMSE (Fig. 7a–c) and the difference in spatial standard deviation between modeled and observed fields, Δσ (Fig. 7d–f). As expected, Fig. 7 illustrates that there is a good match during the first years of simulation for all biogeochemical fields at all depth levels with low RMSE and Δσ. After a few centuries, patterns of error evolve differently across depth for O₂, NO₃ and Alk-DIC.

Patterns of Δσ present different features than those of RMSE and demonstrate that the simulated fields substantially underestimate the spatial variation of observed biogeochemical fields on subsurface depth surfaces except for Alk-DIC. The temporal evolution of both metrics shows that patterns of error have reached a steady state after few decades within the upper hundred meters of the ocean but continue to evolve at greater depths, even after 500 years. Patterns of errors within the thermocline and deep water masses evolve at time scales of few decades and few centuries, respectively in rela-

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

tion with the structure of the large-scale ocean circulation. Mid-depth (~ 1500 – 2500 m) RMSE evolves much slower because this depth corresponds to the depth of the very old radiocarbon age (e.g. Wunsch and Heimbach, 2007, 2008) whose characteristics time scale spans over thousand of years. At the end of the spin-up simulation, two maxima of comparable amplitude are found for RMSE at 150 and 3750 m for O₂ and at 50 and 3800 m for Alk-DIC.

From these two metrics, the simple drift model (Eq. 1) enables us to determine the relaxation time τ required to reach equilibration over the last century of spin-up simulation. The relaxation times for oxygen RMSE are about 4, 13 and 140 years at the surface 150 and 2000 m, respectively. Different values are derived for oxygen $\Delta\sigma$ with 8, 7 and 46 years at surface, 150 and 2000 m, respectively. Values for other biogeochemical fields are quite similar to those for O_2 except for NO_3 at 150 m. This contrasting result between the two skill score metrics expresses the fact that RMSE accounts for the total distance between modeled and observed oxygen distributions, while $\Delta\sigma$ considers solely the difference in spatial structure between model fields and observations. This shows that the time scale for equilibration of spatial structure is not necessarily the same as the drift.

3.5 Drifts in CMIP5 ESMs preindustrial simulations

In this subsection, we extend our analysis to the CMIP5 archive. We focus on oxygen fields in the long preindustrial simulation, piControl, for the 14 available CMIP5 ESMs. While the duration of CMIP5 piControl simulations ranges from 250 to 1000 years, we choose to compute the relative drift in RMSE and $\Delta\sigma$ across depth over the first century of simulation for each ESM (Fig. 8). This drift is used as a surrogate for drift computed from the spin-up of each model since such simulations are not available through the data portal.

Figure 8 represents the relative drift in RMSE (Fig. 8a–c) and $\Delta\sigma$ (Fig. 8d–f) for O₂ concentrations vs. the spin-up duration (log scale) for each CMIP5 ESM. The analysis shows that numerous models are far from equilibrium with a drift in O₂ concentration

Interactive Discussion	

greater than 10 % over the first century of the CMIP5 preindustrial simulation. Drifts in other biogeochemical tracers (NO_3 and Alk-DIC) show similar features (not shown). The magnitude of the drifts in RMSE and $\Delta\sigma$ tends to increase with depth. It spans within 0–35 % range at the surface up to a 0–400 % range at 2000 m. Figure 8 also shows the best-fit linear regression relationship (or exponential in linear scale) between the drift in RMSE (or $\Delta\sigma$) and the spin-up duration (solid lines). This relationship suggests a general decrease of the drift as a function of spin-up duration for all depth levels. This decrease in drift displays low significance. At the surface and 2000 m, the quality of the fits is generally low with correlation ranging between 0.3 and 0.7. The lower correlation coefficients fall outside the 90 % significance threshold (0.36 determined with a student distribution with significance level of 90 % and 14 models as degree of freedom). Correlation coefficient of RMSE at 150 m is even lower than the 66 % significance threshold (0.1), indicating that there is no decrease in drift as a function of spin-up duration. This low significance level must be put into perspective given the large diversity of spin-up protocols and initial conditions (Fig. 1 and Table 1) that can deteriorate the drift-spin up duration relationship in this ensemble of models.

This drift vs. spin up duration relationship established with the 14 CMIP5 ESMs is nonetheless consistent with the results obtained with the IPSL-CM5A-LR model (shown as solid red lines in Fig. 8), for which the relationship was (1) determined from overlapping time slices of 100 years from year 250 to 500 and (2) extrapolated over the 250–1190 spin-up duration range. Consistency is indicated by the sign of the drift vs. spin up duration relationship of the IPSL-CM5A-LR model at the various depth levels, although their magnitudes differ. This difference in magnitude is not surprising if one considers that drift is highly model and protocol dependent. The importance of the spin-up is emphasized by the fact that the regression fit (red line on Fig. 8 determined from the spin-up simulation) and data point (blue point on Fig. 8 determined from the first century of the CMIP5 piControl simulation) derived from IPSL-CM5A-LR results differ at some depth levels. Despite these differences, our analyses show that a relationship between the drift vs. the spin-up duration emerges from an ensemble of models and is

broadly consistent with our theoretical framework of a drift model established from the results of the IPSL-CM5A-LR model.

3.6 Impact of the drift on model skill score assessment metrics across CMIP5 ESMS

- In the following, we investigate the influence of model drift on skill score assessment metrics that are routinely used to benchmark model performance. For this purpose, the normalized distance between the biogeochemical observations and output from historical simulations of individual CMIP5 ESMs is computed following the approach widely employed to evaluate CMIP5 models (Adachi et al., 2013; Arora et al., 2011; Collins et al., 2011; Dunne et al., 2013; Ilyina et al., 2013; Lindsay et al., 2014; Romanou et al., 2013; Séférian et al., 2013; Tjiputra et al., 2013; Vichi et al., 2011; Volodin et al., 2010; Watanabe et al., 2011; Wu et al., 2013). The normalized distance consists of the scaled RMSE of model output averaged from 1985 to 2005.

The left hand side panels of Fig. 9 present the performance of available CMIP5 models in terms of normalized distance to oxygen observations at the surface, 150 and 2000 m, respectively. The normalized distance is used for model ranking. Following Knutti et al. (2013), either the ensemble mean or the ensemble median is used to identify groups of models with similar skill within the CMIP5 ensemble. Figure 9 shows that the ability of models to reproduce oxygen observations varies across depth levels. The RMSE in the simulated O_2 fields in HadGEM2-CC, HadGEM2-ES, MPI-ESM and CESM1-BGC is smaller than the ensemble mean or ensemble median RMSE. For the HadGEM2 models, this result might arise from the fact that these models (1) are closer to the initial state since they have been spun up for a relatively short integration time or (2) display a better representation of the observed ocean. In either case, this would lead to a departure from the initial state that is smaller than for models that have a longer spin-up duration. On the other side of the ranking, IPSL models, CNRM-CM5, CMCC-CESM and NorESM1-ME exhibit RMSE generally higher than the ensemble mean and median RMSE.

Inconsistent strategies to spin up models in CMIP5

[Interactive Discussion](#)

To assess the impact of model drift inherited from the diversity of spin-up strategies (Fig. 1 and Table 1) on model performance metrics, the incremental deviation due to drift in biogeochemical fields is estimated from the simple drift model (Eq. 1). The incremental deviation, ΔRMSE , is computed using the relaxation time τ determined from the piControl simulations of each CMIP5 model (Fig. 8) and a common duration of $T = 3000$ years for all models:

$$\Delta\text{RMSE} = \int_0^T \text{drift}(t=0) \times \exp\left(-\frac{1}{\tau}t\right) dt \quad (2)$$

where ΔRMSE has the same unit as RMSE. The common duration T is used to bring model drift close to zero and hence to make models comparable to each other.

We employ ΔRMSE to penalize the normalized distance from the observations assuming that this drift-induced deviation in tracer fields can be added to RMSE. This means that the effect of the penalty is to increase the normalized distance giving a consistent measure of the equilibration error.

Right hand side panels of Fig. 9 show the influence of this penalization approach on the model ranking at the various depth levels. They show that several models have been upgraded in the ranking while others have not. The GFDL-ESM2G and MPI-ESM models that have been upgraded at the surface and 2000 m. On the other hand, the rank of HadGEM2 models has been downgraded to the 6 and 7 position due to the large drift in surface oxygen concentrations in comparison to that of the other models. The surface drift might be attributed to drivers in oxygen fluxes (e.g., SST, SSS). At the bottom of the ranking, models with large deviation from the oxygen observations (i.e., CMCC-CESM, IPSL-CM5B-LR, NorESM1-ME, CNRM-CM5) are found. For these models, the computed ΔRMSE and RMSE result in similar ranking, because even a small drift and hence relatively low ΔRMSE cannot compensate for their large RMSE.

4 Implications

4.1 Implications for biogeochemical processes

Our results show that errors in ocean biogeochemical fields amplify and propagate during the spin-up simulation but not at the same rate at all depths. These differences in error evolution are consistent with an increasing contribution of biogeochemical processes in setting the distribution of tracers at depth. Indeed, Mignot et al. (2013) with the same model simulation showed that the large-scale ocean circulation reaches quasi-equilibrium after 250 years of spin-up, but our analyzes indicate that biogeochemical tracers do not (Fig. 1).

Besides, our analysis demonstrates that error propagation and biogeochemical drift are highly model dependent. For example, despite having the same initialization strategy and comparable spin up duration, the GFDL-ESM2G, GFDL-ESM2M, and NorESM1-ME models display considerable difference in drift (Figs. 8 and 9) that mirror large differences in model performance and properties (e.g., resolution, simulated processes).

The identification of the dynamical or biogeochemical processes responsible for these errors is not within the scope of this study and would required additional long simulations with additional tracers targeted for attribution of the various biogeochemical processes and the underlying ocean physics (e.g. Doney, 2004) involved (e.g. using abiotic, passive tracers as suggested in Walin et al., 2014). Some mechanisms can be nonetheless invoked to explain differences or similarities in behavior between biogeochemical fields. For example, the evolution of surface concentrations for O₂ and Alk-DIC is controlled by the solubility of O₂ and CO₂ in seawater and the concentration of these gases in the atmosphere (set to the observed values and kept constant in all experiments performed with IPSL-CM5A-LR discussed here) and the biological soft-tissue and calcium carbonate counter pumps (in relation with the vertical transport of nutrients and alkalinity). Therefore, the equilibration of the O₂ and Alk-DIC surface fields once the physical equilibrium is reached (~ 250 years of spin-up) is expected

(Figs. 3a–c and 7). Nevertheless, spatial errors could increase depending on the physical state of the model (Fig. 4b and f). By contrast, the evolution of NO_3^- concentration is predominantly determined by ocean circulation, biological processes, and to a lesser extent by external supplies from rivers and atmosphere. Below the surface, concentrations of O_2 , NO_3^- , and Alk-DIC evolve in response to the combined effect of ocean circulation and biogeochemical processes. The combination of dynamical and biogeochemical processes on the one hand, and the spin-up strategy on the other hand both shape the modeled distributions of large-scale biogeochemical tracers.

Consequences of the difficulty in achieving the correct equilibration procedure are even larger for biogeochemical features that are defined by regional characteristics in tracer concentrations, such as high nutrient/low chlorophyll regions, oxygen minimum zones and nutrient-to-light colimitation patterns. This point is illustrated by recent studies focusing on future changes in phytoplankton productivity (e.g. Vancoppenolle et al., 2013 and Laufkötter et al., 2015). Vancoppenolle and co-workers report a wide spread of surface mean NO_3^- concentrations (1980–1999) in the Arctic with a range from 1.7 to $8.9 \mu\text{mol L}^{-1}$ across a subset of 11 CMIP5 models. The spread in present day NO_3^- concentrations translates into a large model-to-model uncertainty in future net primary production. Laufkötter and colleagues determined limitation terms of phytoplankton production for a subset of CMIP5 and MAREMIP (Marine Ecosystem Model Intercomparison Project) models. The authors demonstrate that nutrient-to-light colimitation patterns differ in strength, location and type between models and arise from large differences in the simulated nutrient concentrations. Although large differences between models were reported by Vancoppenolle et al. (2013) and Laufkötter et al. (2015) such as the spatial resolution and the complexity of biogeochemical models, differences in nutrient concentrations were identified as the largest source of model-to-model spread in addition to simply model error. The authors of both studies qualitatively invoked differences in spin-up duration to explain this spread. Besides, a recent assessment of interannual to decadal variability of ocean CO_2 and O_2 fluxes in CMIP5 models, suggests that decadal variability can range regionally from 10 to

5 50 % of the total natural variability among a subset of 6 ESMs (Resplandy et al., 2015). In that study, the authors demonstrate that, despite the robustness of driving mechanisms (mostly related to vertical transport of water masses) across the model ensemble, model-to-model spread can be related to differences in modeled carbon and oxygen concentrations. In light of present results, it appears likely that differences in spin-up strategy and sources of initialization contribute to the amplitude of the natural variability of the ocean CO₂ and O₂ fluxes.

4.2 Implications for future projections

The inconsistent strategy to spin-up models in CMIP5 is a significant source of model uncertainty. It needs to be better constrained in order to draw robust conclusions on the impact of climate change on the carbon cycle as well as its climate feedback (e.g. Arora et al., 2013; Friedlingstein et al., 2014; Roy et al., 2011; Schwinger et al., 2014; Séférian et al., 2012) and on marine ecosystems (e.g. Bopp et al., 2013; Boyd et al., 2015; Cheung et al., 2012; Doney et al., 2012; Gattuso et al., 2015; Lehodey et al., 2006). So far, the most frequent approach relies on the use of long preindustrial control simulations to “remove” the drift embedded in the simulated fields over the historical period or future projections (e.g. Bopp et al., 2013; Cocco et al., 2013; Friedlingstein et al., 2014, 2006; Frölicher et al., 2015; Gehlen et al., 2014; Keller et al., 2014; Steinacher et al., 2010; Tjiputra et al., 2014). Although this approach allows to determine relative changes, it does not allow to investigate the underlying reasons of the spread between models in terms of processes, variability and response to climate change. The “drift-correction” approach, much as the one used for this study, assumes that drift-induced errors in the simulated fields can be isolated from the signal of interest. Verification of this fundamental hypothesis would require a specific experimental set-up consisting in the perturbation of model fields (e.g., nutrients or carbon-related fields) to assess by how much the model projections would be modified. So far, several modeling groups have generated ensemble simulation in CMIP5 using a similar approach. However, the perturbations were applied either to physical fields only or to both the physical

Interactive Discussion	

and marine biogeochemical fields. To assess impacts of different spin-up strategies and/or initial conditions on future projections of marine biogeochemical tracer distributions, ensemble simulations in which only biogeochemical fields are perturbed would be needed.

5 4.3 Implications for multi-model skill-score assessments.

While the importance of spin-up protocols is well accepted in the modeling community, the link between spin-up strategy and the ability of a model to reproduce modern observations remains to be addressed.

Most of the recent CMIP5 skill assessment approaches were based on historical hindcasts that were started from preindustrial runs of varying duration and from various spin-up strategies. Therefore, in typical intercomparison exercises, Earth system models with a short spin-up, and hence modeled distributions still close to initial fields, are confronted with Earth system models with a longer spin-up duration and modeled distributions that have drifted further away from their initial states. Our study highlights that such inconsistencies in spin-up protocols and initial conditions across CMIP5 Earth system models (Fig. 1 and Table 1) could significantly contribute to model-to-model spread in performance metrics. These inconsistencies result in systematic model biases, somewhat in line with Swart and Fyfe (2011), and affect model reliability. The analysis of the first century of CMIP5 piControl simulations demonstrated a significant spread of drift between CMIP5 models (Fig. 8). An approximate exponential relationship between the amplitude of drift and the spin up duration emerges from the ensemble of CMIP5 models, which is consistent with results from IPSL-CM5A-LR. For example, while the global average root-mean square error increased up to 70 % during a 500 year spin-up simulation with IPSL-CM5A-LR, its rate of increase (or drift) decreased with time to a very small rate (0.001 PgCyr^{-1}), suggesting that results should be reliable in the context of transient historical hindcast or future projections. Combining a simple drift model and this relationship, we propose a penalization approach in an effort to assess more objectively the influence of documented model differences on

model-data biases. Figure 9 compares the state-of-the-art approach to assess model performance (left hand side panels) to the drift-penalized approach (right hand side panels). This novel approach penalizes models with larger drift, while not inducing major changes in model ranking. Taking into account drift in modeled fields results in subtle 5 adjustments in ranking, which reflect differences in spin-up and initialization strategies.

The low confidence level of the fit to drift across the multi-model CMIP5 ensemble is a limitation of our approach and the robustness of the fit used to penalize models might be criticized. The low significance level of the fit directly reflects the large diversity of 10 spin-up protocols and initial conditions (Fig. 1 and Table 1). The improved derivation of the penalization factor would require access to output from spin-up simulations for each individual model or, at least, a better quantification of model-model differences in terms of initial conditions. The impact of this penalization approach on model ranking calls 15 for the consideration of spin-up and initialization strategies in the determination of skill assessment metrics (e.g. Friedrichs et al., 2009; Stow et al., 2009) and, by extension, to model weighting (e.g. Steinacher et al., 2010) and model ranking (e.g. Anav et al., 2013).

5 Conclusions and recommendation for future intercomparison exercises

Skill-score metrics are expected to be widely used in the framework of the future CMIP6 (Meehl et al., 2014) with the development of international community benchmarking 20 tools like the ESMValTool (<http://www.pa.op.dlr.de/ESMValTool>, see also Eyring et al., 2015). The assessment of model skill to reproduce observations will focus on the modern period. In order to increase the reliability of these traditional metrics, additional metrics that allow us to determine the equilibrium state of the model like the 25 3-dimensional growth rate or drift of relevant skill score metrics (e.g., RMSE) over the last decades or centuries of the spin-up, should be included in the set of standard assessment tools for CMIP6.

Inconsistent strategies to spin up models in CMIP5

[Interactive Discussion](#)

In an effort to better represent interactions between marine biogeochemistry and climate (Smith et al., 2014), future generations of Earth system models are likely to include more complex ocean biogeochemical models, be it in terms of processes (e.g. Tagliabue and Völker, 2011; Tagliabue et al., 2011) or interactions with other biogeochemical cycles (e.g. Gruber and Galloway, 2008) or increased spatial resolution (e.g. Dufour et al., 2013; Lévy et al., 2012) in order to better represent mesoscale biogeochemical dynamics. These developments will go along with an increase in the diversity and complexity of spin-up protocols applied to Earth system models, especially those including an interactive atmospheric CO₂ or interactive nitrogen cycle (e.g. Dunne et al., 2013; Lindsay et al., 2014). The additional challenge of spinning-up emission-driven simulations with interactive carbon cycle will also require us to extend the assessment of the impact of spin-up protocols to the terrestrial carbon cycle. Processes such as soil carbon accumulation, peat formation as well as shift in biomes such as tropical and boreal ecosystems for dynamic vegetation models require several long time-scales to equilibrate (Brovkin et al., 2010; Koven et al., 2015). In addition, the terrestrial carbon cycle has large uncertainties in terms of carbon sink/source behavior (Anav et al., 2013; Dalmonech et al., 2014; Friedlingstein et al., 2014) which might affect ocean CO₂ uptake (Brovkin et al., 2010).

To evaluate the contribution of variable spin-up and initialization strategies to model performance, these should be documented extensively and the corresponding model output should be archived. Ideally, for future intercomparison exercises like CMIP7, the community should agree on a set of recommendations for initialization, spin-up protocols and duration, following past projects such as OCMIP-2. In parallel, any trade-off between model equilibration and computationally efficient spin-up procedures has to be linked with efforts to reduce model errors due to the physical and biogeochemical parameterizations.

Acknowledgement. This work was supported by the EU FP7 project CARBOCHANGE “Changes in carbon uptake and missions by oceans in a changing climate” which received funding from the European community’s Seventh Framework Programme under grant agree-

ment no. 264879. Supercomputing time was provided by GENCI (Grand Equipement National de Calcul Intensif) at CCRT (Centre de Calcul Recherche et Technologie), allocation 016178. Finally, we are grateful to the ESGF project which make data available for all the community. R. Séférian is grateful Aurélien Ribes for his kind advices on statistics. J. Tjiputra acknowledges ORGANIC project (239965/F20) funded by the Research Council of Norway. C. Heinze and J. Tjiputra are grateful for support through project EVA – Earth system modelling of climate variations in the Anthropocene (229771/E10) funded by the Research Council of Norway, as well as CPU-time and mass storage provided through NOTUR project NN2345K as well as NorStore project NS2345K. K. Lindsay and S. C. Doney acknowledge support from the National Science Foundation.

Inconsistent strategies to spin up models in CMIP5

R. Séférian et al.

Table 1. Summary of spin-up strategy, sources of initial condition, offline/online durations and references used to equilibrate ocean biogeochemistry in CMIP5 ESMs. The so-called direct and sequential strategies inform whether the spin-up of the ocean biogeochemical model is run directly in online/coupled mode or in offline (ocean biogeochemistry only) and online/coupled mode. DIC* refers to the observation-derived estimates of preindustrial dissolved inorganic carbon concentration using the ΔC^* method. w/acc. and forced w/obs. Indicates the strategy using “acceleration” and observed atmospheric forcings during their spin-up, respectively.

Models	spin-up procedure	initial conditions	offline time	online time	total spin-up duration	References

**Inconsistent
strategies to spin up
models in CMIP5**

R. Séférian et al.

Table 2. Differences between the oxygen (O_2 , $\mu\text{mol L}^{-1}$) and nitrate (NO_3 , $\mu\text{mol L}^{-1}$) datasets used for initializing IPSL-CM5A-LR (WOA1994) and the datasets used for assessing its performances (WOA2013).

O_2			NO_3			
Depth	surface	150 m	2000 m	surface	150 m	2000 m
RMSE	7.19	8.75	5.50	2.07	2.90	2.08
R^2	0.98	0.98	0.99	0.96	0.92	0.94

Inconsistent strategies to spin up models in CMIP5

R. Séférian et al.

Table 3. Drift in in % kyr⁻¹ for oxygen (O₂), nitrate (NO₃) and total alkalinity minus DIC (Alk-DIC) at surface, 150 and 2000 m as simulated by the IPSL-CM5A-LR model. The drift has been computed over the last 250 years of the spin-up simulation using a linear regression fit of the globally averaged concentrations, root-mean squared error (RMSE) and latitudinal maximum root-mean squared error (RMSE_{max}) with respect to the values at year 250.

	O ₂			NO ₃			Alk-DIC		
metrics	mean	RMSE	RMSE _{max}	mean	RMSE	RMSE _{max}	mean	RMSE	RMSE _{max}
Surf	-0.2	2.6	55.8	-0.1	-0.1	34.2	1.6	-0.1	-0.1
150 m	3.4	39.0	31.5	-15.9	33.4	55.2	6.1	27.9	24.7
2000 m	-30.4	144.3	-40.1	2	51.8	-34.8	-69.6	281.8	47.5

Figure 1. Spin-up protocols of CMIP5 Earth system models. Color shading represents strategies of the various modeling groups. Online and Offline steps refer to runs performed with coupled climate model and with stand-alone ocean biogeochemistry model, respectively. Sources of initial conditions for biogeochemical component for CMIP5 Earth system models are indicated below the barplot.

Inconsistent strategies to spin up models in CMIP5

R. Séférian et al.

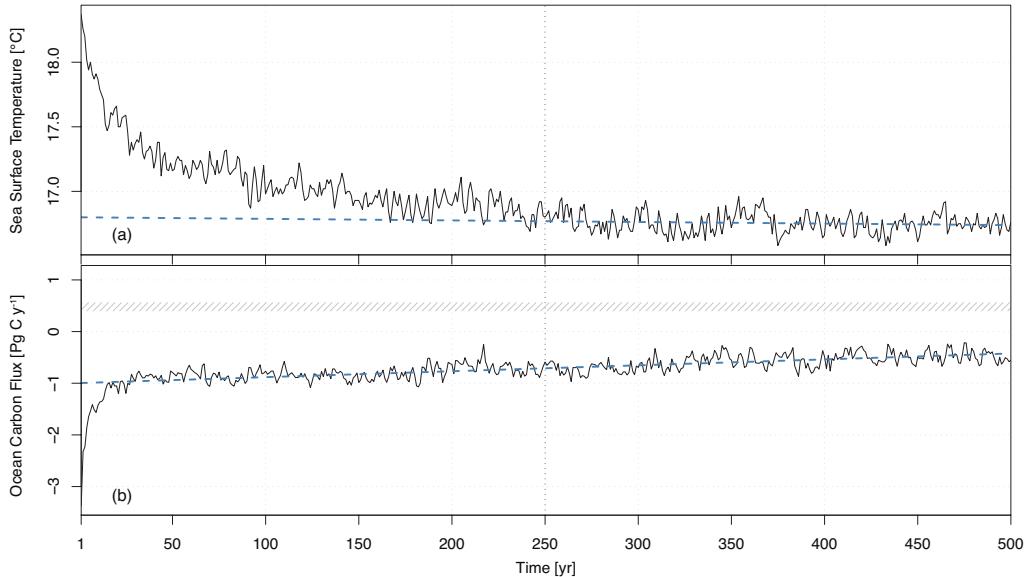

Figure 2. Time series of two climate indices over the 500 year spin-up simulation of IPSL-CM5A-LR. They represent the global averaged sea surface temperature (**a**) and the global mean sea-air carbon flux (**b**). For sea-air carbon flux, negative value indicates uptake of carbon. Steady state equilibrium of physical components as described in Mignot et al. (2013) is reached at ~ 250 years and is indicated with a vertical dashed line. Drifts in sea surface temperature and global carbon flux are indicated with dashed blue lines. They are computed using a linear regression fit over years 250 to 500. Hatching on panel (**b**) represents the range of inverse modeling estimates for preindustrial global carbon flux as described in Mikaloff Fletcher et al. (2007), i.e., $0.03 \pm 0.08 \text{ Pg Cyr}^{-1}$ plus 0.45 Pg Cyr^{-1} corresponding to the riverine-induced natural CO_2 outgassing outside of near-shore regions consistently to Le Quéré et al. (2015).

Figure 3. Time series of globally averaged concentration ($[X]$ in solid lines) and global averaged root mean squared error (RMSE in dashed lines) for dissolved oxygen (O_2), nitrate (NO_3^-) and difference between alkalinity and dissolved inorganic carbon (Alk-DIC) as simulated by IPSL-CM5A-LR. $[X]$ and RMSE are given at surface (**a**, **b** and **c**), 150 m (**d**, **e** and **f**), and 2000 m (**g**, **h** and **i**) for these three biogeochemical fields. Their values are indicated on left-side and right-side y axis, respectively. Hatching represents the $\pm\sigma$ observational uncertainty due to optimal interpolation of in situ concentrations around the observed $[X]$.

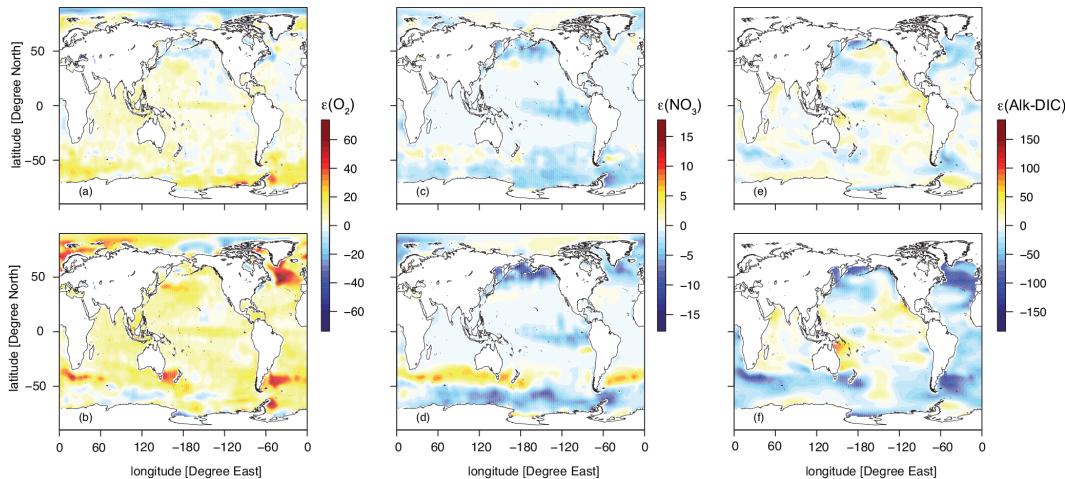

Figure 4. Snap-shots of spatial biases, ε , in surface concentrations ($\mu\text{mol L}^{-1}$) in biogeochemical fields during the 500 year spin-up simulation of IPSL-CM5A-LR. ε in dissolved oxygen (O_2), nitrate (NO_3) and difference between alkalinity and dissolved inorganic carbon (Alk-DIC) is given for the first year (**a**, **c** and **e**, respectively) and for the last year of spin-up simulation (**b**, **d** and **f**, respectively).

Inconsistent strategies to spin up models in CMIP5

R. Séférian et al.

**Inconsistent
strategies to spin up
models in CMIP5**

R. Séférian et al.

Figure 8. Scatterplot of relative drifts in root-mean squared error (RMSE) and difference in spatial standard deviation ($\Delta\sigma$) in O₂ concentration vs. the duration of the spin-up simulation (in logscale) for the available CMIP5 Earth system models. Relative drifts in RMSE and $\Delta\sigma$ are respectively given for surface (**a, d**), 150 m (**b, e**) and 2000 m (**c, f**) for oxygen concentrations. They are estimated from the first century of the piControl simulation for the available CMIP5 models. The best-fit linear regressions between relative drifts in RMSE and $\Delta\sigma$ and spin-up duration are indicated in solid green lines; their 90 % confidence intervals are given by thin dashed envelope. Fits are assumed robust if correlation coefficients are significant at 90 % (i.e., $R > 0.36$). For comparison, similar best-fit linear regressions have been derived from our spin-up simulation with IPSL-CM5A-LR; they are indicated in solid red line. They have been obtained from drifts computed over 100 year-long overlapping time slices of O₂ RMSE from years 250 to 500 at each depth levels and (2) extrapolated over the CMIP5 spin-up duration range (250–10 190 years).
