

Authors' Response to Reviewer's Comments C2455

Manuscript No.: gmd-2015-147, submitted to GMD

Title: New developments in the representation of Saharan dust sources in the aerosol-climate model ECHAM6-HAM2

Authors: B. Heinold, I. Tegen, K. Schepanski, and J. R. Banks

We would like to thank the reviewer for her/his time and constructive comments, and hope that we have responded satisfactorily to all the points raised.

Anonymous Referee C2455

Received and published: 9 October 2015

In this study, the authors use a satellite-derived mineral dust source area distribution to prescribe preferential dust sources in the climate model ECHAM6-HAM2. The authors report a large increase (15 to 22%) in total mineral dust emissions compared to the previous version of the model. Comparisons to observations show generally modest improvements.

The paper is well-written, and the analysis is straightforward. Figures illustrate the results and discussion well. I however recommend revisions to improve two aspects, as detailed in my comments below. First, to place the paper more clearly in the context of ECHAM development. Second, to improve the comparison between model and observations with a method that is less influenced by different sampling of model and observations. Those improvements should amount to major revisions.

Actually we see the paper in the context of ECHAM-HAM development in its present form, supplemented with an evaluation of the model capability to represent dust-generating winds compared to a regional model. Regarding the different sampling of model output and satellite observations, we think there is a misunderstanding. The difference in sampling is taken into account. Please see our response to the 2nd main comment.

In addition, I encourage the authors to think about postponing the paper until they have run the free-running simulations that they mention in the conclusion (page 7897, lines 17–19). Although the paper could be published after the authors have addressed the comments below, it would be a relatively minor contribution to the literature. Analysing free-running simulations would give more breadth to the discussion. I also doubt that a standalone paper on free-running simulations could be published, as it would really be incremental, so if free-running results are to be discussed, it is now.

We strongly disagree. The value of this publication, which we do not consider to be minor, is not only in the introduction of a new source approach to the ECHAM-HAMMOZ model and its evaluation, but also in the comparison between a global and a regional model, each with the same dust emission scheme. This provides the unique opportunity to investigate the model description of dust emission processes at different scales. Note that the evaluation of the global model results with observations is an important part of this work and so nudged model runs. The results of free-running simulations, of course, would not be published in a standalone paper but in the framework of a scientific study, e.g., on interactions of mineral dust with ice clouds and radiation or a thorough evaluation of the model representation of key meteorological processes driving Saharan dust emission.

Main comments

1. The changes brought by the MSG-derived DSA are essentially neutral. What decision was made in the end? Does ECHAM6-HAM2 now use the MSG DSA distributions, or did the authors keep the previous representation by Tegen et al. (2002)? The conclusion is unclear on this point (page 7897, lines 10–19). From a model development point of view, I am also surprised that revisiting the simplified assumption made for roughness length (Pages 7884 and 7885, lines 1) is not given more priority than changing the DSA dataset. A more realistic roughness length dataset is dismissed on the ground of failed tests in the past (page 7884, line 4), but that is hardly satisfactory. Why not take the opportunity to see whether combining satellite-derived roughness length and DSA datasets yield better results?

The overall changes may be neutral, but there are small but noticeable improvements in the placement of active dust sources across the Sahara and dust optical thickness in the southern Sahara. We believe that ECHAM-HAM users will benefit from the update of the Tegen et al. (2002) scheme, as it “compensate[s] for uncertainties in soil properties and the misrepresentation of dust generating winds”, although this benefit seems to be less than expected at the moment. As we say in the “Code availability” section, the new MSG-based DSA map will be distributed with the ECHAM6-HAMMOZ model. However, the previous representation of potential dust sources remains part of the model, and users can switch between the different versions as they can for previous development steps.

We agree that roughness length is an important parameter in the dust emission process, which should be considered in a more sophisticated way. However, the challenge is to describe the surface roughness at process scale. For example, even high-resolved roughness length data from satellite remote sensing (e.g., Prigent et al., 2012) may be not representative, e.g., for erodible soil beds in mountain foothills that are important dust sources. Another issue would be how to use high-resolved roughness data on coarse model grids. Any kind of averaging would yield values too high to be typical of erodible soil beds. A practicable way would be to compute dust emission fluxes at the resolution level of roughness data in a mosaic approach, which however needs more effort and may be computationally too expensive for a climate model.

2. Page 7891, line 7 and Figure 6: Comparing against satellite retrievals is obviously useful, but their sampling of the dust distribution is very different from that of the model. It is easy to reach misleading conclusions from such comparisons. Applying each instrument’s retrieval mask on an hourly basis would be the best way to do the comparisons properly (especially since the model is nudged), but if that is not possible at this stage, I would at least expect a masking on a monthly basis. In any case, comparisons as they currently are do not tell much about model skill and how it has changed after using the MSG DSA. Note that the same remarks essentially hold true for comparisons against AERONET.

We account for the difference in sampling between satellite retrievals and model by using the model output only at times, when satellite observations are available. In this case, the agreement should not depend on whether hourly or averaged values are compared. Of course it would be desirable to evaluate the model results at higher temporal resolution, maybe on a case-by-case basis. Unfortunately, this is not feasible for a 2-year period. Instead the modeled dust emission events are evaluated in terms of their time of occurrence and related meteorological mechanisms.

Other comments

1. Page 7886, lines 6–7: I understand that getting closer to a multi-model average is reassuring, but that is not necessarily a good thing. Are there observational estimates of total Saharan dust emissions that could be more usefully compared against?

The aim, of course, is not to further develop models for the sake of matching a multi-model average. The range of model simulations is rather considered to indicate uncertainties in the understanding of key mechanisms. This obviously misleading sentence (“The new values better fit the range ...”) is skipped.

Regional and global estimates of dust input into the atmosphere to date cannot be derived from observations, such as satellite imagery. The few available in-situ measurements of dust emission are rare and limited to specific field sites and short time periods. Estimates of dust emissions, therefore, rely on model simulations, which are constrained by continuous ground-based and space-borne remote sensing as well as campaign-based observations of atmospheric dust load.

2. Page 7887, line 1: “a lower emission flux limit”

Corrected.

3. Figure 3: Isn’t comparing MSG DSA against ECHAM-HAM(MSG) a bit circular? I agree that the model can (and does) still get the emission flux wrong, but I do not think that we learn much from that comparison.

We think there is a misunderstanding. As described on page 7884, line 27-29 and emphasized again on page 7885, line 20-24, the spatial distribution of observed DSA frequencies between March 2006 and February 2010 is only used to provide the location and extent of potential dust sources. Specific dust events, however, are not prescribed. The actual activation of a grid cell as dust source and then the magnitude of computed dust emission depend on the modeled surface friction velocities. Therefore, the comparison between model results and actual MSG DSAs in Figure 3 is largely independent and allows to focus on the model representation of meteorological processes driving dust up-lift.

4. Page 7890, line 23: Water vapour is only really a problem for infrared retrievals, not so much for MISR.

Agreed. Now the sentence reads: “Space-borne remote sensing always suffers from the fact that dust information is obscured by clouds. Further potential issues for infrared retrievals like the SEVIRI dust AOT are high columnar contents of atmospheric water vapor and the skin temperature, [...]”.

5. Page 7893, line 22: What does the 65% figure really mean? Looking at Figure 7, I would expect smaller percentages. Is that 65% of emitted mass rather than of total events?

This is the relative contribution of DSAs between 0600 and 1200 UTC, averaged over the 2-year period. We agree, the 65% figure does not match Figure 7. The value was accidentally taken from Tegen et al. (2013). However, most likely due to remapping to T63 resolution, here, we yield an average contribution of 40% and 45% by morning and afternoon dust events, respectively. The main message remains unaffected though.

The text is corrected accordingly:

Page 7893, lines 22: “[...] average contribution of 40% by emission events during morning hours [...]”.

Page 7893, lines 28/29: “Accordingly, more dust emission events are computed between 1200 and 1800 UTC with approximately 45% on average,[...]”.

Technical comments

Abstract

In the aerosol-climate model ECHAM6-HAM2, dust source activation (DSA) observations from Meteosat Second Generation (MSG) satellite are proposed to replace the original source area parameterization over the Sahara Desert. The new setup is tested in nudged simulations for the period 2007 to 2008. The evaluation is based on comparisons to dust emission events inferred from MSG dust index imagery, AERONET sun photometer observations, and satellite retrievals of aerosol optical thickness (AOT).

The model results agree well with AERONET measurements especially in terms of seasonal variability, and a good spatial correlation was found between model results and MSG-SEVIRI dust AOT as well as Multi-angle Imaging Spectro-Radiometer (MISR) AOT. ECHAM6-HAM2 computes a more realistic geographical distribution and up to 20% higher annual Saharan dust emissions, using the MSG-based source map. The representation of dust AOT is partly improved in the southern Sahara and Sahel. In addition, the spatial variability is increased towards a better agreement with observations depending on the season. Thus, using the MSG DSA map can help to circumvent the issue of uncertain soil input parameters.

An important issue remains the need to improve the model representation of moist convection and stable nighttime conditions. Compared to sub-daily DSA information from MSG-SEVIRI and results from a regional model, ECHAM6-HAM2 notably underestimates the important fraction of morning dust events by the breakdown of the nocturnal low-level jet, while a major contribution is from afternoon-to-evening emissions.

1 **1 Introduction**

2 Soil dust that makes up the largest part of the global aerosol burden represents an important
3 factor in the Earth system. Airborne dust particles can affect the climate directly by aerosol-
4 radiation interactions or indirectly by modifying cloud properties, atmospheric dynamics, and
5 the biogeochemical cycle (Carslaw et al., 2010; Shao et al., 2011). In addition, mineral dust
6 can cause serious air-quality issues with potential effects on human health, transportation, and
7 solar energy production (Griffin, 2007; Breitkreuz et al., 2007). Despite its large potential
8 impact, considerable uncertainties remain in the estimates of the budget and climate effects of
9 mineral dust (e.g. Boucher et al., 2013; Mulcahy et al., 2014). Since the Sahara desert is the
10 most important dust source worldwide, contributing at least 50% to the global dust load
11 (*Huneeus et al., 2011; Ginoux et al., 2012*), it is of particular importance to consider the dust
12 from this region.

13 The impact of mineral dust upon climate and the feedback of changing climate conditions on
14 dust emission and transport have been investigated largely by general circulation modeling. A
15 test of 14 state-of-the-art global models within the Global Aerosol Model Intercomparison
16 (AeroCom) exercise (Schulz et al., 2009) shows that the seasonal cycle and long-range
17 transport of mineral dust is generally well represented in those models. However, large dis-
18 crepancies exist in the modeled estimates of dust emission, which differ by a factor of about 5
19 globally and for North Africa (Textor et al. 2006; Huneeus et al., 2011). The large spread in
20 the model results indicates that dust emission processes are not fully adequately resolved in
21 current global models, which is attributed to uncertainties in the prescribed soil properties
22 (texture, soil moisture) and the representation of meteorological drivers of dust emission
23 (Knippertz and Todd, 2012, and references therein). To assess which of the sources of uncer-
24 tainty has the largest effect on the model results is difficult because of the complexity of in-
25 volved processes and feedbacks within the coupled models. Due to the high sensitivity of dust
26 emission to the upper range of the wind speed distribution, however, the representation of, in
27 particular, subgrid-scale meteorological processes can be more important than differences in
28 the dust emission scheme or soil characteristics (Luo et al., 2003; Menut, 2008). Different
29 meteorological processes have been identified as potential generators for dust emissions.
30 While synoptic scale meteorological patterns are usually well reproduced, simulations of dust
31 emissions due to moist convection (Knippertz et al., 2009; Reinfried et al., 2009; Heinold et
32 al., 2013) or micro-scale dry convective events (e.g., dust devils, Koch and Renno, 2005;
33 Jemmett-Smith et al., 2015) are challenging.

A member of the AeroCom study is the global aerosol-climate model ECHAM5-HAM. The dust emissions from this model (Sahara: 400 Tg yr⁻¹; global: 585 Tg yr⁻¹) range at the lower end of current model estimates (Huneeus et al., 2011), which, however, may be largely related to a small maximum dust particle size compared to other AeroCom members. *The current version ECHAM6-HAM2 provides global emission fluxes of 948 Tg yr⁻¹ and 552 Tg yr⁻¹ from North African dust sources (2007 – 2008 mean from this study). Whereas the considerable increase in global dust emissions is mainly due to improvements for East-Asian dust sources (Cheng et al., 2008; Zhang et al., 2012), the dust parameterization has remained unchanged for the Sahara, and the higher values result from developments of the driving model ECHAM6.* The global model uses the dust emission scheme by Tegen et al. (2002), which is also implemented and has been further refined in the regional-scale Saharan dust model COSMO-MUSCAT (Heinold et al., 2007; 2011). In this work we present simulations of Saharan dust for the years 2007 and 2008 using the current version of ECHAM6-HAM2, which is updated with the recent developments from the regional model. For the evaluation of modeled dust emission events and the distribution of Saharan dust, dust source activation (DSA) observations from the Meteosat Second Generation (MSG) satellite, standard sun photometer measurements *provided through AERONET*, and satellite retrievals of dust aerosol optical thicknesses are used.

2 Methods

2.1 Model description

In this study we use the current version of the aerosol-climate modeling system ECHAM-HAMMOZ (version echam6.1-ham2.2-moz0.9) that was first described by Stier et al. (2005). It consists of the global circulation model ECHAM6 (Stevens et al., 2013) and the aerosol-chemistry and microphysics package HAM2 (Zhang et al., 2012). ECHAM6-HAM2 simulates the global formation, transport, and removal of aerosol particles in the atmosphere, their processing and interactions. Aerosol populations, which can be internally or externally mixed, are described by a superposition of seven log-normal modes. The emissions of desert dust and marine aerosol are computed online, based on the ECHAM6 meteorology. Emissions of anthropogenic species are prescribed. The aerosol removal from atmosphere is due to sedimentation, dry and wet deposition and is parameterized in dependence of particle size, composition, and mixing state.

The modeled aerosol distribution can affect the climate simulations through interactions with radiation and clouds. A look-up table with Mie pre-calculated parameters is used to dynamically determine the particle optical properties considering their actual size, composition, and water content (Stier et al., 2005; Zhang et al., 2012). The description of cloud microphysics in ECHAM6-HAM2 is based on the two-moment scheme of Lohmann et al. (2007), which allows for accounting for the impact of modeled aerosol populations on the number concentration of cloud condensation and ice nuclei. For further details of the model system we refer to Stier et al. (2005) and Zhang et al. (2012).

In the standard version of ECHAM6-HAM2.1, dust emissions are calculated interactively using the scheme of Tegen et al. (2002), including updates for East-Asian dust source regions from Cheng et al. (2008). The dust emission fluxes are computed as a function of the third power of the wind friction velocity, based on the ECHAM6 predicted wind speed and soil moisture. The dust uplift occurs above a certain threshold of friction velocity (U_t^*), which depends on the diameter of erodible soil particles (D_p), the local roughness length of the overall surface (Z_0), and the local roughness length of the erodible ('smooth') surface (z_{0s}). The computation of the size-dependent threshold friction velocity (U_t^*) follows Marticorena and Bergametti (1995), including a drag partition parameterization, which addresses the impact of non-erodible roughness elements on U_t^* by sheltering loose, erodible particles from wind erosion:

$$U_t^*(D_p, Z_0, z_{0s}) = \frac{U_t^*(D_p)}{f_{\text{eff}}(Z_0, z_{0s})}, \quad (1)$$

with

$$f_{\text{eff}}(Z_0, z_{0s}) = 1 - \left[\ln\left(\frac{Z_0}{z_{0s}}\right) / \ln\left(0.35\left(\frac{10}{z_{0s}}\right)^{0.8}\right) \right]. \quad (2)$$

Here, f_{eff} is the efficient friction velocity ratio defined as the ratio of local to total friction. In ECHAM6-HAM2.1, the roughness length Z_0 is set default to the constant value of smooth roughness length z_{0s} of 0.001 cm. Alternatively, the global satellite-based dataset of aerodynamic roughness length from Prigent et al. (2005) can be used in the model (Cheng et al., 2008), which, however, caused overestimation of the dust optical depth over North Africa in previous tests (see Zhang et al., 2012 for details). It is assumed that dust is preferentially emitted in enclosed topographic depressions, such as paleo- and temporal lake beds (see Figure 1a for location), characterized by low surface roughness and large deposits of loose fine soil par-

1 ticles (Prospero et al., 2002). Minor dust emissions can also occur in other sparsely or non-
2 vegetated areas. The dust emission flux is computed for 192 internal size classes within the
3 diameter range $0.2 - 1300 \mu\text{m}$, which are finally divided up into three log-normally distribut-
4 ed size modes. Freshly emitted dust particles are assigned to the insoluble accumulation and
5 coarse modes having a mass median radius (standard deviation) of $0.37 (1.59) \mu\text{m}$ and 1.75
6 $(2.0) \mu\text{m}$, respectively. Due to the short residence time and a minor impact on the radiation
7 *budget* super-coarse dust particles are neglected (Stier et al., 2005 and Cheng et al., 2008).

8 9 **2.2 New satellite-based Saharan dust source approach**

10 In general, the accuracy of dust emission computations depends on a realistic model represen-
11 tation of the dust-generating winds. In addition, limitations are largely related to the uncer-
12 tainties of available erodibility data, i.e., surface roughness and soil texture. Here, satellite-
13 based information on the frequency of Saharan dust emission events as shown in Figure 1b
14 can provide an alternative for the prescription of potential dust sources over North Africa. The
15 information on the frequency of dust source activation (DSA) are based on the MSG SEVIRI
16 (Spinning-Enhanced Visible and InfraRed Imager) infrared (IR) dust index and are available
17 on a regular $1^\circ \times 1^\circ$ grid for the period March 2006 to February 2010 (Schepanski et al., 2007;
18 2012). This information was derived by utilizing the 15-min dust index fields where the high
19 temporal resolution allowed identifying the dust plume origin by analyzing the dust plume
20 movements.

21 Using the MSG-based dataset in a model, dust emissions are only computed for grid cells,
22 where the DSA frequency exceeds 1% over the base period March 2006 to February 2010.
23 The surface roughness Z_0 in those areas is set to the constant low value of the smooth rough-
24 ness length $z_{0s}=0.001 \text{ cm}$, as in the original model, which results in a low threshold for dust
25 mobilization typical for a fully erodible soil bed (see Eqs. 1 and 2). *The threshold value was*
26 *determined by sensitivity runs with the regional dust model system COSMO-MUSCAT*
27 *(Heinold et al., 2007; 2011), which is also equipped with the Tegen et al. (2002) scheme up-*
28 *dated with the MSG source map. The value of 1% corresponds to four active days per year*
29 *and, was first suggested by Schepanski et al. (2007). Since then the MSG-based DSA frequen-*
30 *cy map has been successfully used in the regional model for case studies (Schepanski et al.,*
31 *2009; Heinold et al., 2011) and multi-year Saharan dust simulations (Tegen et al., 2013). Of*
32 *course, as for all satellite remote sensing, dust source detection from space is limited by the*
33 *impact of clouds and high atmospheric moisture (Brindley et al., 2012). This effect, however,*

may average out to some extent over the 5-year period and is also addressed by the low DSA frequency threshold in the model.

For testing the MSG source map, we use the nudged version of ECHAM6-HAM2.1. The simulations were carried out for the period 2007 to 2008, using (1) the standard setup, with the original preferential source description from Tegen et al. (2002), (referred to as ORIG hereafter) and (2) masking emissions with the satellite-based Saharan DSA frequency map (referred to as MSG). As in the standard setup, a correction factor of 0.86 (Cheng et al., 2008) is applied to the threshold friction velocity for dust emission calculations in both simulations. *This non-physical scaling is common in global models to compensate for the effects of resolution on dust emission processes (e.g., lower surface winds) and therefore to ensure reasonable global total dust production (e.g., Ridley et al., 2013).* The model was run at T63L31 (1.875° grid spacing; 31 vertical model layers) resolution and was nudged to ERA-Interim meteorological re-analysis.

2.3 Observational data for model evaluation

Sun photometer measurements provided by the Aerosol Robotic Network AERONET (Holben et al., 1998) are used for a quantitative model evaluation at specific locations for the years 2007 and 2008. The model results are compared to monthly averages of the observed coarse mode aerosol optical thickness (AOT) at 500 nm wavelength, which is typically dominated by mineral dust and sea salt particles (O'Neill et al., 2003). The averages of modeled dust AOT only comprise the daytime period between 0900 and 1500 UTC since the measurements are limited to sunlight hours. There are only a limited number of continuous AERONET observations on the fringes and only one station in the center of the Sahara. The comparison is presented for the stations Blida, Algeria (36.5°N, 2.9°E) and Saada, Morocco (31.6°N, 8.2°W) situated in the northern part of North Africa, and Tamanrasset, Algeria (22.8°N, 5.5°E) in the central Sahara. In the main direction of Saharan dust transport across the Atlantic Ocean, the coastal site Dakar, Senegal (14.4°N, 17.0°W) is chosen for the evaluation, and the station Agoufou, Mali (15.3°N, 1.5°W) south of the Sahara in the Sahel (see Figure 3a for the geographical location of the AERONET stations). For the period of interest, cloud-screened level 1.5 data is used for the majority of stations, as only at Blida the coarse mode retrieval is provided at quality level 2.0 (cloud-screened and quality-assured). In addition, new satellite retrievals of mineral dust over North Africa for 2008 are used. The model results are compared to the dust optical thickness at 550 nm that is derived from

SEVIRI observations aboard the MSG satellite (Brindley and Russell, 2009; Banks and Brindley, 2013). The dust detections are based on raw data at 15-minutes temporal and about 3 km spatial resolution at nadir and are available hourly from 0600 to 1600 UTC each day on a 0.25° grid.

Furthermore, the 555-nm aerosol optical thickness retrieved from measurements of the Multi-angle Imaging Spectro-Radiometer (MISR) on NASA's TERRA satellite (Kahn et al., 2007; 2009) is used for model evaluation. The MISR data is provided at a spatial resolution of 17.6 km over land and ocean, but at low temporal resolution as result of the orbit pattern of MISR. The comparison to the two data sets allows for taking into account some measure of the uncertainty of satellite dust products. Space-borne remote sensing always suffers from the fact that dust information is obscured by clouds. Further potential issues for infrared retrievals like the SEVIRI dust AOT are high columnar contents of atmospheric water vapor and the skin temperature, particularly over relatively cold surfaces at high altitude or over vegetated areas, where the thermal contrast between surface and dust layer is reduced (Banks et al., 2013; Brindley et al., 2012; Kahn et al., 2010).

The DSA frequency information from MSG-SEVIRI is used in two ways: (1) using the spatial distribution of observed DSA frequencies to provide a mask for dust emissions as described in Section 2.2 to allow regions to be active dust sources as observed by the MSG dust index, but allowing the dust emission fluxes themselves to be simulated using the modeled surface friction velocities; and (2) using the temporal information of dust emission events from the MSG data to evaluate the temporal changes in DSA frequencies that is simulated by the model.

3 Results

3.1 Saharan dust emissions

The standard ECHAM6-HAM2 model computes an annual total of Saharan dust emissions of about 555 Tg yr⁻¹ and 549 Tg yr⁻¹ for the years 2007 and 2008. The modeled estimate, however, is increased by 15% to 22%, respectively, when the MSG-based source description is used. Monthly statistics of the daily dust emissions over North Africa for the modeled period are presented in Figure 2. It is known that the Saharan dust production is maximum from February to May and in the summer months June to September, while a minimum is found from October to January (e.g., Ben Ami et al., 2011). The model results are well in agreement with this seasonal cycle. In the ECHAM6-HAM2 standard run, the median daily dust emission ranges between 0.5 Tg in fall and 2.5 Tg during the active seasons. The increase in dust

productivity is associated with a higher day-to-day variability with maximum daily dust emissions reaching up to 14 Tg. This is particularly the case for the period January to March, which is more characterized by episodic dust events (Knippertz and Todd, 2012).

Using the MSG-based dust source mask, the maximum daily emissions increase significantly compared to the original setup, with values up to 24 Tg. The differences in the median, however, are less important, except for the months July and August. Larger differences in the median between the two model runs also exist in February and April 2008. The higher maximum dust emissions in summer are mainly related to areas in the southern Sahara and Sahel, where more dust sources are activated in the model run with the MSG source mask.

The distribution of Saharan dust emission events simulated by the ECHAM6-HAM2 model is compared to MSG DSA frequencies for the years 2007 and 2008 in Figure 3. For the direct comparison with the ECHAM6-HAM2 results, the MSG data were remapped to model resolution T63. The frequency of modeled dust emissions was derived applying *a lower emission flux limit* of 1.5×10^{-4} kg m⁻² per grid cell in a 3-h time interval. The threshold excludes minor dust events, which would remain undetected, and was chosen to have approximately equal dust emission counts for the Sahara within the 2-year period in both model results and observations. The 2-year total of modeled dust emission counts for the Sahara is 31.312 (31.300) for the model run with the MSG source mask (original setup) and 29.733 for the MSG data. The maps in Figure 3 show averages for months, in which similar meteorological processes control the dust emissions.

From February to May (FMAM), intense Saharan cyclones along the North African coast (Hannachi et al., 2011; Fiedler et al., 2014) cause major dust emissions in the northern Sahara. In the central and southern Sahara and the Sahel, dust events are often related to enhanced northeasterly harmattan winds resulting from intensifications of the subtropical high (Kalu, 1979; Knippertz et al., 2011). In addition, the breakdown of the nocturnal low-level jet (LLJ) is a key driver of Saharan dust emissions throughout the year (e.g., Knippertz, 2008; Schepanski et al., 2009; Fiedler et al., 2013). While synoptic scale features leading to dust emissions are expected to be well reproduced in a global scale model, it is challenging for such a model to reproduce dust emissions by mesoscale features connected to boundary layer or convective processes. In general, the model well reproduces the expected patterns of Saharan dust emissions in both model runs. However, the placement and number of dust events overall looks more realistic when the ECHAM6-HAM2 model is run using the MSG-based source mask (Figures 3a – 3c). There is a more realistic distribution over West Africa, in particular

1 Mauretania. In comparison to the original setup, this run also simulates more events south of
2 the Anti-Atlas range and less extended source activations mainly over Libya.

3 In the summer months June to September (JJAS) (Figures 3d – 3f), African Easterly Waves
4 (AEWs) and the Saharan heat low (SHL) mainly control the dust uplift over West Africa
5 (Knippertz and Todd, 2012). Dust-emitting winds result either directly from intense AEW
6 disturbances and accelerations at the monsoon front or from the increased formation of LLJs
7 and deep moist convection. The cold-pool outflow from mesoscale convective systems (often
8 referred to as haboobs) is the major cause for dust emissions in the southern Sahara and Sahel
9 (Marsham et al., 2013; Heinold et al., 2013). It is evident from the MSG observations that in
10 both runs dust emission events are generally missing in the foothills of the mountains like the
11 Tell Atlas and Saharan Atlas range as well as the Hoggar and Ennedi Mountains. More dust
12 sources are activated in southern Sahara and Sahel in the ECHAM6-HAM2 run with the MSG
13 source mask. Other minor improvements include the more correctly placed dust source near
14 the coast of the Gulf of Sidra in northeastern Libya.

15 The Bodélé depression is the dominant dust source in the Sahara in the winter months Octo-
16 ber to January (ONDJ) (Figures 3g – 3i). Both model runs show a good agreement with ob-
17 servations in this region. Using the MSG source mask, the model results show more but less
18 extended, and therefore more realistic, activation events near the Libyan coast. The wide-
19 spread dust emissions in the northern part of Sudan are still not sufficiently but slightly better
20 represented.

22 **3.2 Optical thickness of Saharan dust**

23 *In Figure 4, the sun photometer measurements from the AERONET stations Blida, Saada,*
24 *Tamanrasset, Dakar, and Agoufou (see Figure 3a for their geographical location)* show a
25 clear seasonal cycle in the loading of coarse-mode particles, i.e., mineral dust. High AOT val-
26 ues are generally observed in spring and in the summer months June to September (JJAS),
27 whereas dust emission and transport are minimum during winter. In JJAS, the monthly mean
28 AOT reaches values of up to 0.3 at Blida in the northern Sahara (Figure 4a), and maxima up
29 to 0.6 occur at Agoufou in the Sahel (Figure 4d). The seasonal variation and magnitude of
30 dust load are well reproduced by the model results, especially for Blida and Saada (Fig-
31 ure 4a,b). Here, discrepancies mainly occur in early summer, which may be explained by a
32 misrepresentation of moist convective dust events in the model. The absence of dust emis-
33 sions in the northern Sahara from October to January (cf. Figure 3) is an important reason for

the slight underestimation during this period. More noticeable discrepancies between observations and model results are evident at the Sahel stations Dakar and Agoufou (Figure 4c,d) in spring and in particular in late summer. Although the observed coarse mode AOT is dominated by mineral dust, other (usually fine mode) aerosols, like biomass burning smoke and anthropogenic aerosol, may also partly contribute. Biomass burning smoke contributes considerably to the aerosol load in the Sahel region mainly from October to May, which may be the reason for the underestimation in these months. Sea salt and urban aerosol plays an additional important role at Dakar. A good agreement is also found for Tamanrasset in the Hoggar Mountains (Figure 4e). This is surprising, as models usually tend to underestimate wind speeds and dust emissions in mountainous terrain. On the other hand, Saharan dust transport affects the mountain station Tamanrasset, which is located at 1377 m a.s.l.; and the discrepancies during summertime most likely result from missed emission events related to moist convection, which large-scale models often struggle to reproduce.

The results from the two ECHAM6-HAM2 setups are very similar in particular at those locations where the dust emission is strongly controlled by mesoscale features that are not captured by the model with either setup (e.g., for JJAS in the location of Blida where cold-pool outflows from small-scale precipitation events are expected to play an important role for dust emissions). The model run with MSG-based source mask further increases the dust optical thickness during dust events that are already captured by the original model. This leads to some improvements particularly in the central Sahara and Sahel, although the new model tends to overestimate the peaks of maxima (Figures 4c,d,e). Here, a careful re-tuning of the wind stress correction factor (see Section 2) might be required.

Taylor diagrams (Taylor, 2001) are used to concisely evaluate the geographical distribution of modeled dust *against the dust optical thickness from MSG-SEVIRI observations and the TERRA-MISR aerosol optical thickness for the year 2008*. The Taylor diagrams in Figure 5 show spatial statistics for a domain centered over North Africa with the lower left corner at (5°N, 20°W) and the upper right corner at (40°N, 40°E). The satellite dust retrievals are remapped to the model grid spacing of 1.875° for fair comparison with the simulations. Again, averages are calculated over months with similar meteorological conditions causing dust emissions and for the whole year 2008. The associated contour plots are presented in Figure 6. Essentially, they show the enormous discrepancies between the model results and observations, but also the dramatic differences among the satellite retrievals, which indicate the large uncertainties in the field of space-borne aerosol detection over land.

1 Particularly remarkable is the fact that the MSG dust AOT (Figure 6a,e,i) is up to a factor of 2
2 higher than the MISR AOT (Figure 6b,f,j), especially in spring and fall. This may be ex-
3 plained by the low temporal resolution of the MISR product, but more likely by the different
4 sensitivities of the satellite instruments to variations in the meteorological conditions. While
5 performing well during intense dust events, SEVIRI tends to overestimate AOT at low dust
6 loadings and high atmospheric water content. Meanwhile MISR may be more likely to satu-
7 rate at high dust loadings (Banks et al., 2013). The color-coded dots in Figure 6, which show
8 the seasonal mean of coarse mode AOT at AERONET stations already used in Figure 4, indi-
9 cate that the MSG product likely overestimates the AOT of Saharan dust. However, too high
10 values of AOT were also detected by MISR at least in summer, when mineral dust is the pre-
11 dominant aerosol type.

12 Figure 5a suggests a good agreement in the spatial dust distribution between model results
13 and SEVIRI dust optical thicknesses, but with a clear seasonal dependence. For the standard
14 ECHAM6-HAM2, the correlation coefficient reaches up to 0.69 in summer, but drops to 0.36
15 in October to January (0.70 for the whole year). Interestingly, Banks and Brindley (2013) also
16 found higher biases in boreal winter when comparing their dust AOT data to AERONET
17 measurements. Because of the overestimation of the MSG dust product (see Figure 6), there is
18 a large negative bias in modeled dust AOT, which on average ranges from -50% to -80%. The
19 spatial variability is reflected by the standard deviation. Except from the months February to
20 May, the standard setup shows slightly higher variability than the SEVIRI dust retrieval with
21 measured standard deviations between 0.08 (October – January) and 0.16 (June – September).
22 This corresponds well to the strong spatial diversity with deep, local dust plumes related to
23 moist convection over West Africa in summer in contrast to the weaker dust activities in fall
24 or more large-scale driven events from February to May.

25 In the Taylor diagrams improvements by the new MSG-based setup of ECHAM6-HAM2 are
26 indicated by a decrease in the distance to the reference point marked by ‘REF’ on the abscis-
27 sa. Using the MSG dust source mask, the negative biases are partly reduced during all seasons
28 (indicated by a colored symbol background) and the correlation is slightly improved. The spa-
29 tial variability is increased by 16% (October – January) to 32% (February to May) relative to
30 the standard setup, which is in accordance with the findings seen in Figure 2.

31 In addition, the model results are compared to MISR aerosol optical thicknesses in Figure 5b.
32 The level of agreement is similar as in Figure 5a, with the correlation coefficient ranging be-
33 tween 0.56 and 0.74, but showing notably less seasonal variation in the uncertainties. The

mean bias is also highly negative, but approximately 15% smaller than in the comparison with the SEVIRI dust retrieval, which corresponds well to the discrepancy between the two satellite products (Figure 6). The spatial variability of the modeled dust distribution is about three-fourths of what is seen by MISR, except for the period June to September when it fits the observations in the standard model run. Here, the effect of using the MSG-based source mask is to lower the bias by 10% - 45% and to increase the standard deviation towards a better agreement with the observations in spring and fall, as well as for the whole year 2008 (Figure 5b).

3.3 Sub-daily dust emission frequencies

The sub-daily information available from the MSG dust observations can be used to infer the meteorological mechanisms causing dust emissions and to evaluate their model representation. Since mesoscale models are expected to perform better than coarse-resolved climate models, we will first compare the MSG dust index observations to Saharan dust simulations with the regional model system COSMO-MUSCAT. A detailed description and evaluation of the 2-year model run using COSMO-MUSCAT can be found in Tegen et al. (2013). And secondly, we will relate the ECHAM6-HAM2 results to this comparison.

Figure 7 shows monthly totals of DSA frequencies, including time-of-day information on the dust emission onset. The observed DSA frequencies in Figure 7a are dominated by emissions in the morning hours between 0600 and 1200 UTC, which points towards the breakdown of the LLJ as the key driver of Saharan dust emissions, as already mentioned above (Schepanski et al., 2009). To a minor extent also afternoon and nighttime emission events contribute between May and September, except for August 2007, for which DSA from 1800 to 0000 UTC predominate. Dust emissions at this time of day are usually related to the cold outflow from moist convective systems (Schepanski et al., 2009; Knippertz and Todd, 2012). The MSG dust index observations show a strong inter-annual variability with an increase in DSA frequencies from the year 2007 to 2008 of more than 100%, but a less clear variation from season to season (Figure 7a).

Meanwhile COSMO-MUSCAT computes a pronounced seasonal cycle in the monthly frequencies of Saharan dust emission events with a maximum in spring and summer. In the model results, however, notably more DSAs occur in 2007, and the number of DSA increases less dramatically by only 27% from 2007 to 2008 (Figure 7b). The regional model cannot reproduce the high frequency of morning DSAs. Nonetheless, an average contribution of 40%

by emission events during morning hours indicates that the breakdown of the LLJ also plays an important role in the model. The underestimation of morning DSAs may be due to a misrepresentation of the stable nocturnal stratification by the boundary layer scheme, which results in frequent downward mixing of LLJ momentum and too weak jets at nighttime, as well as a delayed and too gradual morning breakdown (Todd et al., 2008; Schepanski et al., 2009; Heinold et al., 2011, Fiedler et al., 2015). Accordingly, *more* dust emission events are computed between 1200 and 1800 UTC *with approximately 45% on average*, followed by a still significant contribution of DSAs between 1800 and 0000 UTC (Figure 7b). As mentioned before, the dust uplift during late afternoon and evening is typically caused by convective cold pools (Knippertz and Todd, 2012). Aged cold pools and intermittent mixing of momentum from LLJs frequently produce dust-generating winds at night (Heinold et al., 2013; Fiedler et al., 2013). The cold outflow from moist convection, however, is not expected to occur in COSMO-MUSCAT, as moist convection is parameterized (Reinfried et al., 2009; Marsham et al., 2013). It is more likely that the dust emissions between noon and afternoon are modeled because of the reasons above and because of the downward mixing of momentum from a strong-wind layer in the free troposphere once the daytime boundary layer is grown sufficiently thick (Fiedler et al., 2015).

On the other hand, we should discuss the possibility that the MSG DSA observations and, thus, the model evaluation may be biased towards morning dust emissions. Afternoon to nighttime dust events mostly occur under clouds and thus cannot be detected, while dust emissions between morning and noon tend to occur under clear-sky conditions (Heinold et al., 2013). Further uncertainties in the MSG observations exist due to the sensitivity to atmospheric water vapor, the altitude of the dust layer, and the low contrast in the infrared signal between desert surface and dust at night (Ashpole and Washington, 2012; Brindley et al., 2012). At least for summer, ground-based observations in the central Sahara (Allen et al., 2013; Marsham et al., 2013) and convection-permitting simulations for West Africa (Heinold et al., 2013) show a much larger contribution (30-50%) by convective cold pools in the late afternoon and evening. Taking this into account, the model underestimation of morning dust emission events compared to the MSG observations appears less dramatic. However, a potentially larger contribution by afternoon and evening DSAs in the model would still be due to the wrong meteorological mechanisms, as discussed above.

ECHAM6-HAM2 and COSMO-MUSCAT show very similar results regarding seasonality and inter-annual variability. Again, there is a clear seasonal cycle with a spring and summer

maximum (cf. Figure 2), but the increase in dust source activity in 2008 is less pronounced in the ECHAM6-HAM2 simulations with an increase in the DSA frequencies by less than 20%. In particular, the increase in DSAs in the second half of 2008 is slightly better represented by the regional model. The number of morning dust emission events is significantly reduced compared to COSMO-MUSCAT results, while most dust emission events in ECHAM6-HAM2 occur from 1200 to 1800 UTC. In addition, there is a large contribution of DSAs computed between 1800 and 0000 UTC as well as from 0000 to 0600 UTC (Figure 7c). This indicates that the representation of stable nighttime conditions, which is a prerequisite for nocturnal LLJ formation, is even worse in the global model. Using the MSG-based source mask, we find a minor increase in the number of DSAs from 1200 to 1800 UTC. Moreover, there is a reduction in modeled DSAs in April 2007 by 25% and a 50% increase in August 2008, compared to the original setup (not shown), leading towards a better agreement with the MSG observations.

The comparison shows that the representation of the meteorological drivers of dust emissions is still an important issue in dust modeling on both global and regional scales. COSMO-MUSCAT by design resolves more mesoscale features and is, therefore, better but not yet satisfyingly able to represent the importance of LLJs for dust uplift. Reproducing cold-pool related dust emissions is equally problematic for the regional and global model, because of the parameterization of moist convection (Marsham et al., 2011).

4 Summary

The aerosol-climate model ECHAM6-HAM2 is tested with an alternative description of potential dust sources in the Sahara. A $1^\circ \times 1^\circ$ map of dust source activation frequencies compiled from MSG IR dust index observations over the period 2006 to 2010 is used to replace the original source area parameterization, which assumes the co-location of potential sources and enclosed topographic depressions. The potential of the new, observation-based setup is demonstrated in a case study, running the model in nudged mode for the years 2007 and 2008. The model results are evaluated against maps of DSA events derived from MSG IR dust index imagery, AERONET sun photometer measurements, and satellite AOT retrievals. In addition, sub-daily DSA frequency information from MSG was used to evaluate the model representation of meteorological drivers of Saharan dust emission. Using the MSG-based source map yields a more realistic geographical distribution of Saharan dust emission events. The dust production is increased by about 20% compared to the original

1 model. The higher annual total of Saharan dust emissions agrees well with the estimate from
2 other recent global aerosol-climate models, taking into account the small cut-off size for dust
3 particles in ECHAM6-HAM2. The month-by-month analysis shows that dust production is
4 mainly increased as result of a larger temporal variability while the monthly median is less
5 affected, except for summer months, when more sources in the southern Sahara and Sahel are
6 activated.

7 Generally, there is a good agreement between modeled dust optical thickness and AERONET
8 coarse mode AOT, and only minor differences occur between the two model versions for the
9 northern Sahara. The new setup mainly causes an increase in the dust load during events that
10 are also captured by the standard ECHAM6-HAM2. An improvement in the modeled dust
11 optical thickness is found in the southern Sahara and Sahel region despite an overestimation
12 of summer-time maxima. The latter can be avoided by slightly re-tuning the dust scheme in
13 future studies.

14 When compared to satellite retrievals of dust and aerosol optical thickness from MSG-
15 SEVIRI and MISR, respectively, reasonably high correlations between the model results and
16 observations indicate a good representation of the spatial dust distribution. A likely overesti-
17 mation of AOT by the satellite retrievals complicates the comparison and lets the model re-
18 sults in general appear too low. With the MSG-based source map, the bias is partly reduced in
19 October to January, a period showing large uncertainties, and in spring. The spatial variability
20 is increased towards a somewhat higher level of agreement depended on the season.

21 The evaluation with sub-daily dust information from MSG-SEVIRI shows that the representa-
22 tion of the meteorological drivers of Saharan dust emissions remains a critical issue for
23 ECHAM6-HAM2 as it is for other global models. In comparison to the MSG observations
24 and results from the regional dust model COSMO-MUSCAT, the model dramatically under-
25 estimates the important fraction of dust emissions related to the morning breakdown of the
26 nocturnal low level jet due to poorly reproduced stable nighttime conditions. Instead a major
27 contribution comes from afternoon-to-evening emission events, caused by delayed LLJ
28 breakdowns, downward mixing of momentum from free-troposphere layers during the day,
29 and artificially high mixing at nighttime. Particularly problematic is also the representation of
30 moist convective dust uplift in either regional or global models because of the parameteriza-
31 tion of moist convection.

32 We assume that constraining Saharan dust sources by satellite observations can partly com-
33 pensate for uncertainties in soil properties and the misrepresentation of dust-generating winds.

1 However, the improvements seen in this study are less important than expected from the sim-
2 ulations with the regional dust model COSMO-MUSCAT, in which the MSG source map was
3 successfully tested before. Possibly, the benefit of prescribing potential dust sources by satel-
4 lite-derived DSA frequencies has a more important effect on free-running models, whose
5 wind fields show larger uncertainties (Timmreck and Schulz, 2004). Therefore, additional free
6 climate runs, together with a systematic investigation of dust-generating winds, are needed for
7 a concluding evaluation of the potential of the MSG-based source map in ECHAM6-HAM2.

10 **Code Availability**

11 The ECHAM6-HAMMOZ model is made available to the scientific community under the
12 HAMMOZ Software Licence Agreement. Further details on accessing the source code are
13 given on the HAMMOZ website: [https://redmine.hammoz.ethz.ch/projects/hammoz/wiki/](https://redmine.hammoz.ethz.ch/projects/hammoz/wiki/Distribution)
14 Distribution. ECHAM6-HAMMOZ is provided together with all necessary input data, includ-
15 ing the new MSG-based dust source activation (DSA) map, at grid resolutions between T31
16 and T255.

18 **Acknowledgements**

19 We thank P. Goloub, B. Holben, D. Tanré, B. Mougenot, and E. Cuevas-Agullo for their ef-
20 forts in establishing and maintaining the AERONET sites Agoufou, Blida, Dakar, Saada, and
21 Tamanrasset. The MISR data were obtained from the NASA Langley Research Center At-
22 mospheric Science Data Center. The ECHAM-HAMMOZ model is developed by a consorti-
23 um, which is composed of the ETH Zurich, Max Planck Institute for Meteorology, Jülich Re-
24 search Center, University of Oxford, and Finnish Meteorological Institute, and managed by
25 the Center for Climate Systems Modeling (C2SM) at ETH Zurich. The simulations were per-
26 formed at the German Climate Computing Center (DKRZ), Hamburg/Germany.

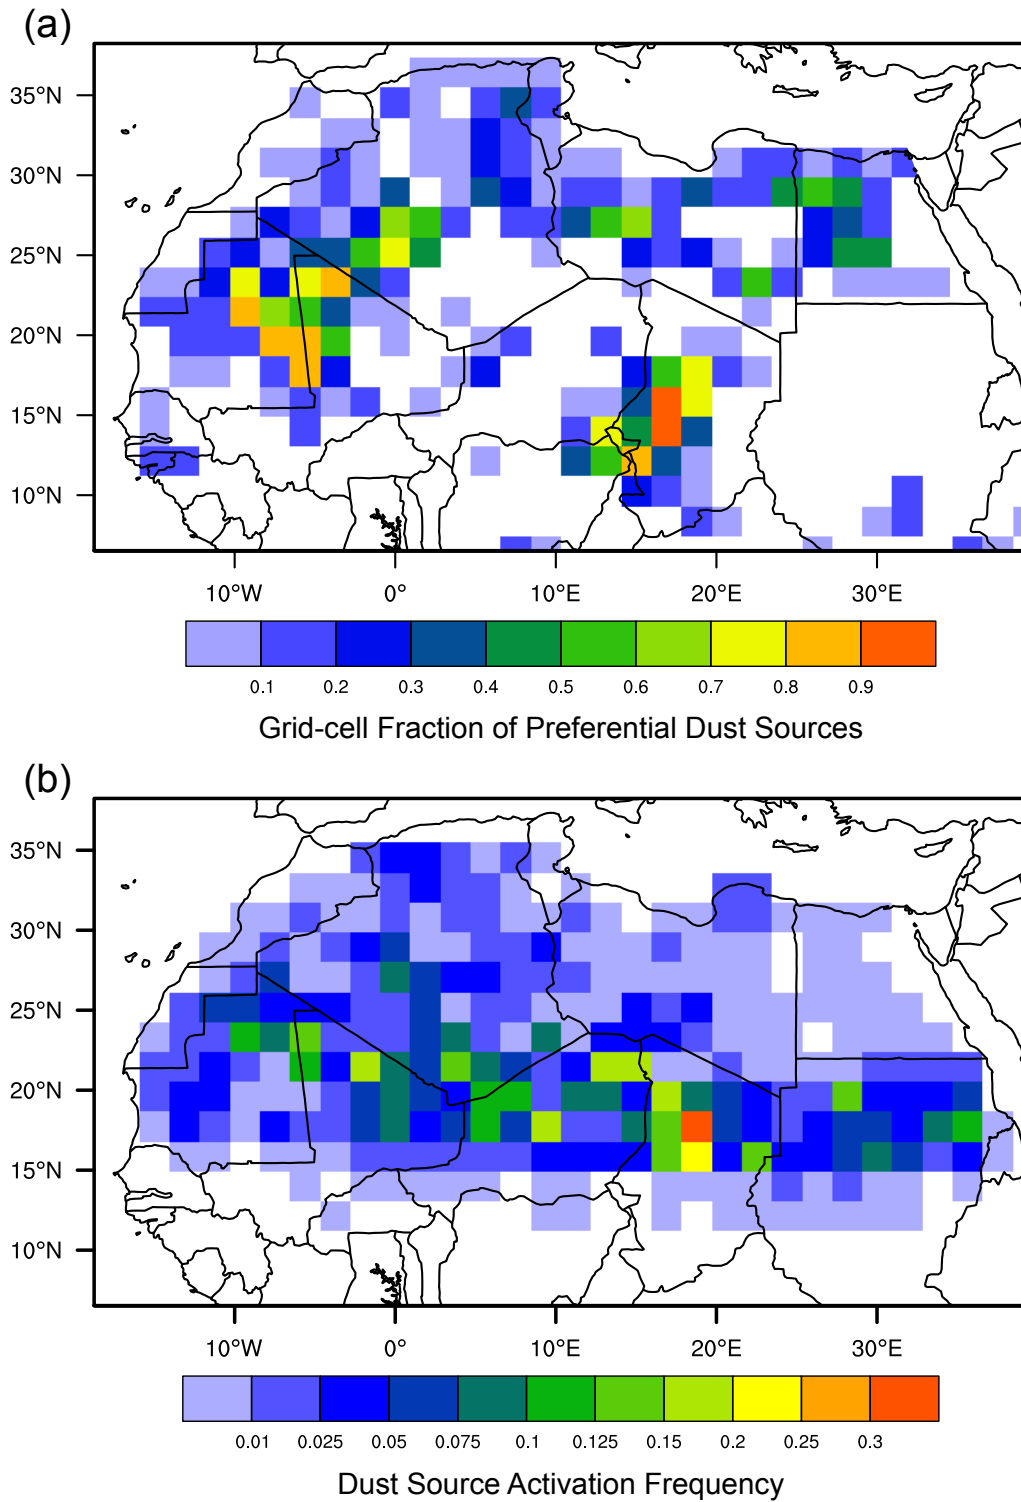

Figure 1: Preferential dust sources in the Sahara Desert on a $1.875^\circ \times 1.875^\circ$ (T63) grid. (a) Grid-cell fraction covered by preferential dust sources calculated from the extent of potential lake areas (Tegen et al., 2002) and (b) dust source activation frequencies derived from the 15-minute MSG-SEVIRI IR dust index for March 2006 to February 2010 (Schepanski et al., 2007; 2012).

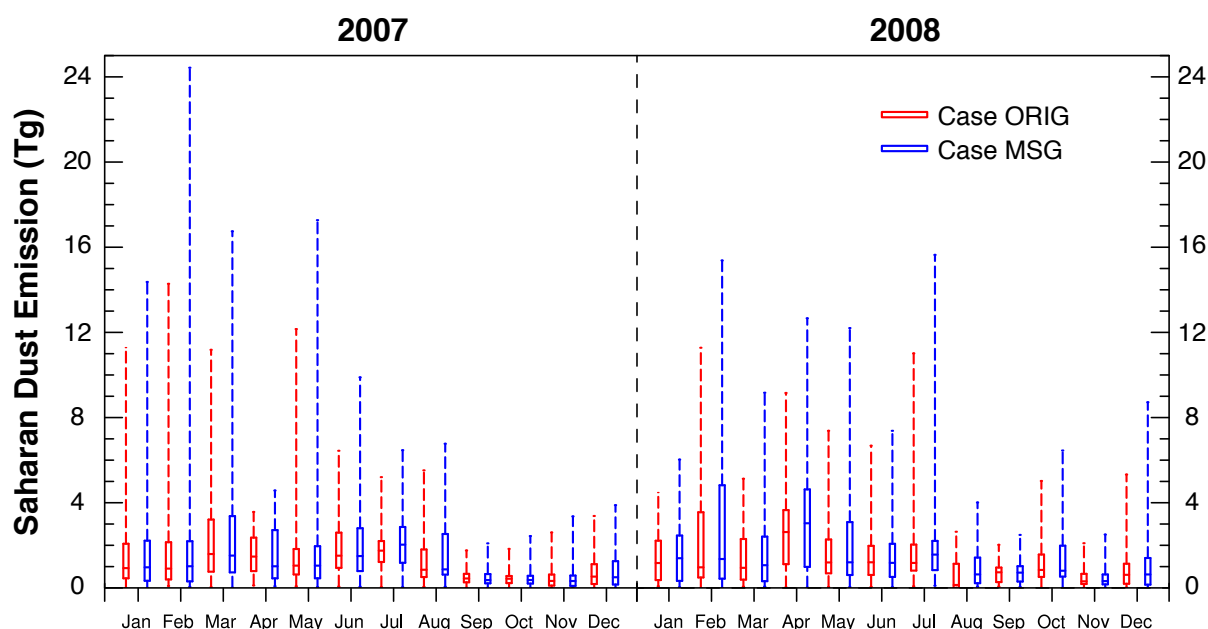

Figure 2: Monthly statistics of daily Saharan dust emissions for 2007 and 2008, computed by the ECHAM-HAM model with the MSG-based source mask (MSG, blue) and the original setup (ORIG, red). The lines of the boxes show the 25th, 50th (median) and 75th percentiles. Dashed lines indicate the range of values between minimum and maximum.

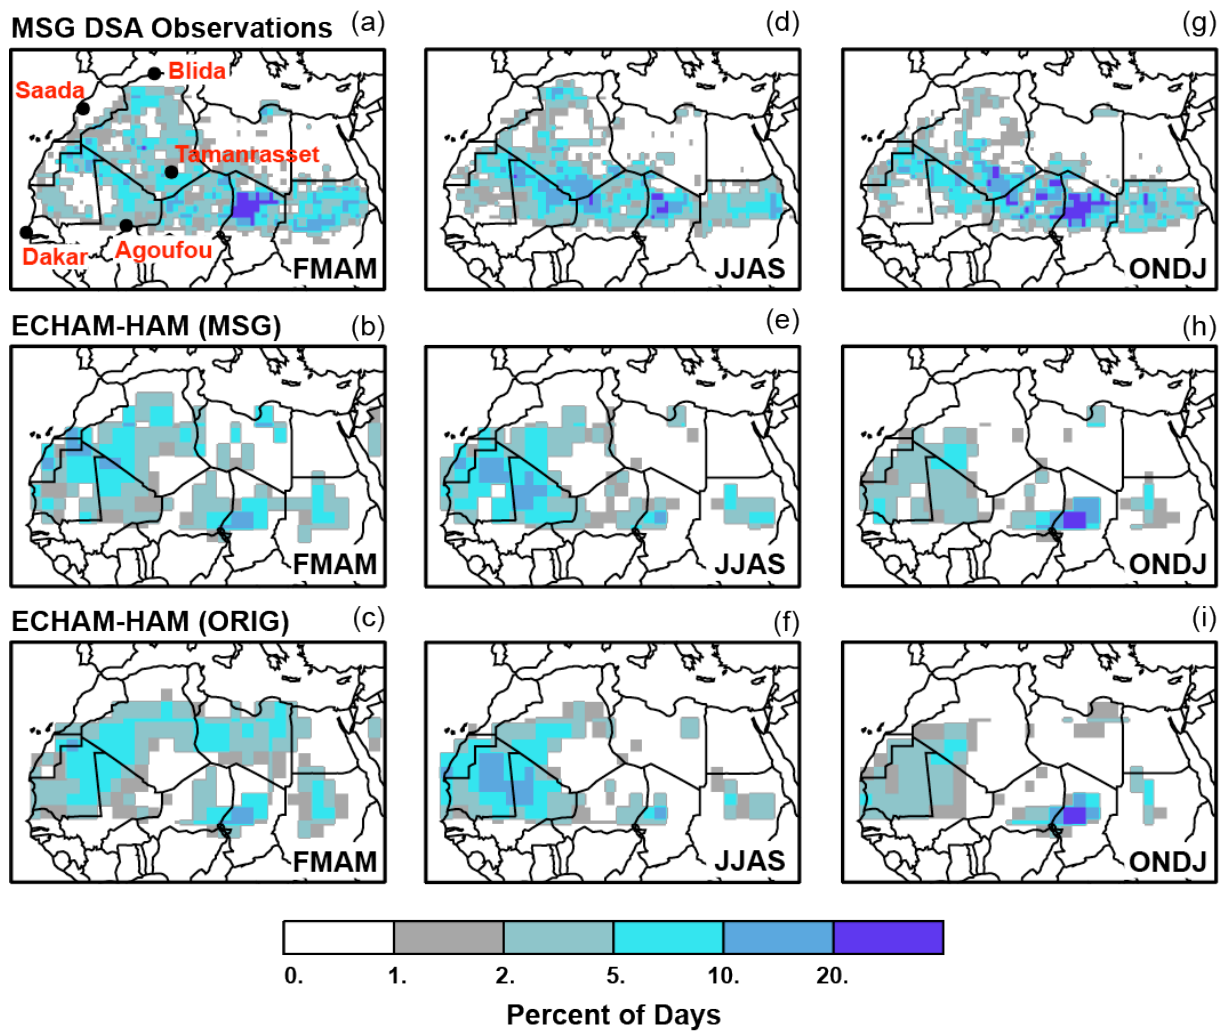

Figure 3: Saharan dust source activations in percent of days as (a, d, g) derived from MSG-SEVIRI dust index imagery and computed by ECHAM-HAM using (b, e, h) the MSG-based source mask and (c, f, i) the original map of preferential dust sources. Shown are average values for the years 2007 and 2008, averaged for the months (a-c) February to May, (d-f) June to September, and (g-i) October to January. Black dots in Figure 3a indicate the location of AERONET stations used for model evaluation.

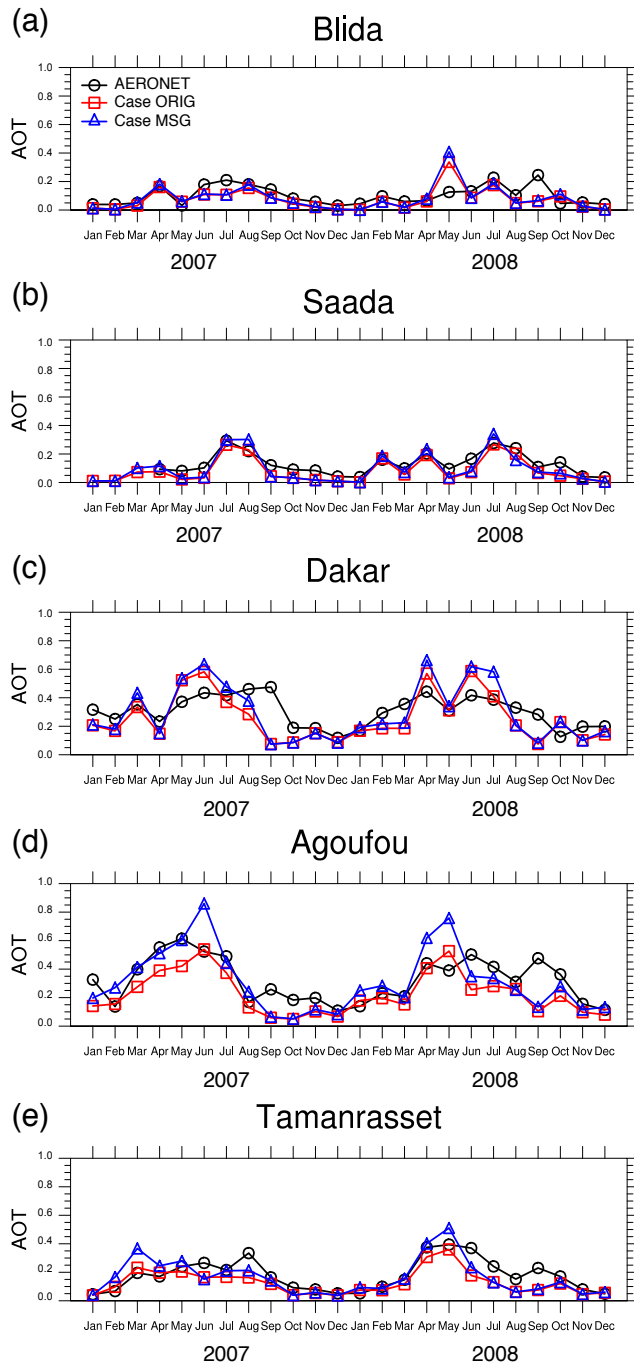

Figure 4: Time series of monthly averages of aerosol optical thickness (AOT) at Blida (36.5°N, 2.9°E), Saada (31.6°N, 8.2°W), Dakar (14.4°N, 17.0°W), Agoufou (15.3°N, 1.5°W), and Tamanrasset (22.8°N, 5.5°E) for the years 2007 and 2008. Compared is the AERONET 500 nm coarse mode data (black line) at quality level 1.5 (2.0 for Blida) and the modeled dust AOT from ECHAM-HAM runs with the MSG-based source mask (blue line) and (red line) with the original map of preferential dust sources.

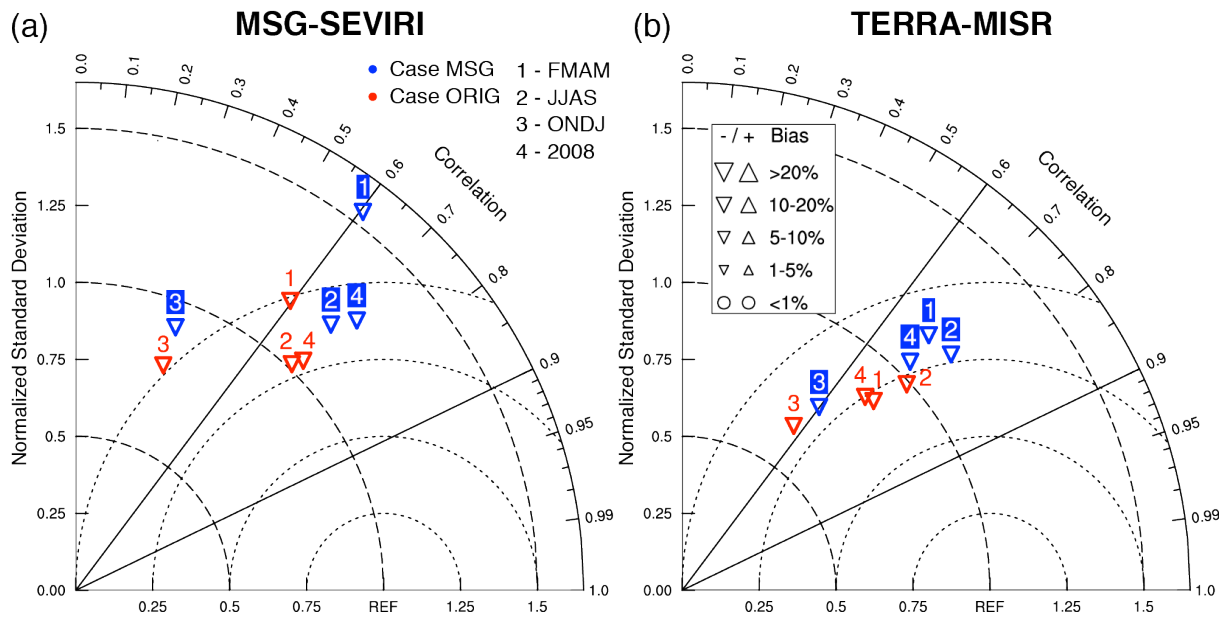

Figure 5: Taylor diagrams comparing the modeled dust optical thickness over North Africa (20°W – 40°E, 5°N – 40°N) from ECHAM-HAM runs using the (blue) MSG source mask and (red) original setup with the dust AOT retrieval from MSG-SEVIRI (left panel) and (right panel) the TERRA-MISR AOT (daytime overpasses). Compared are seasonal averages for the months February – May, June – September, and October – January, and the annual average for the year 2008. The inset in each plot shows the scale for the mean bias.

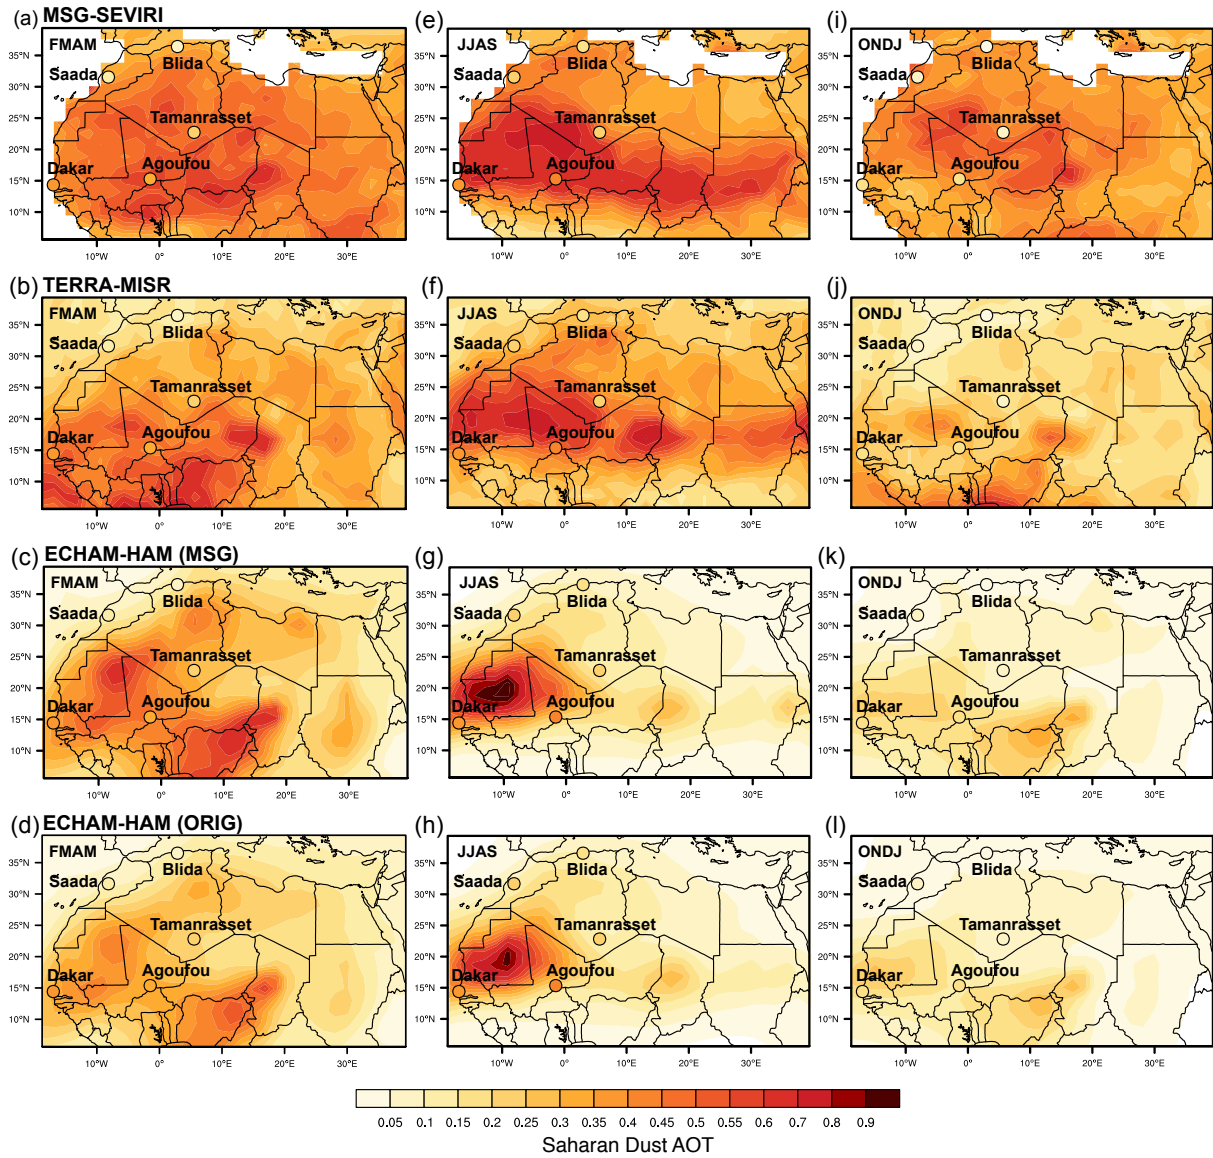

Figure 6: Saharan dust optical thickness for the year 2008, averaged over the months (a-d) February – May, (e-h) June – September, and (i-l) October – January. Compared are (a, e, i) values of dust AOT from MSG-SEVIRI, (b, f, j) the TERRA-MISR AOT, and results from ECHAM-HAM model runs with the (c, g, k) MSG-based and (d, h, l) original setup. Color-coded dots show the corresponding average of the 500-nm coarse mode AOT measured at AERONET stations.

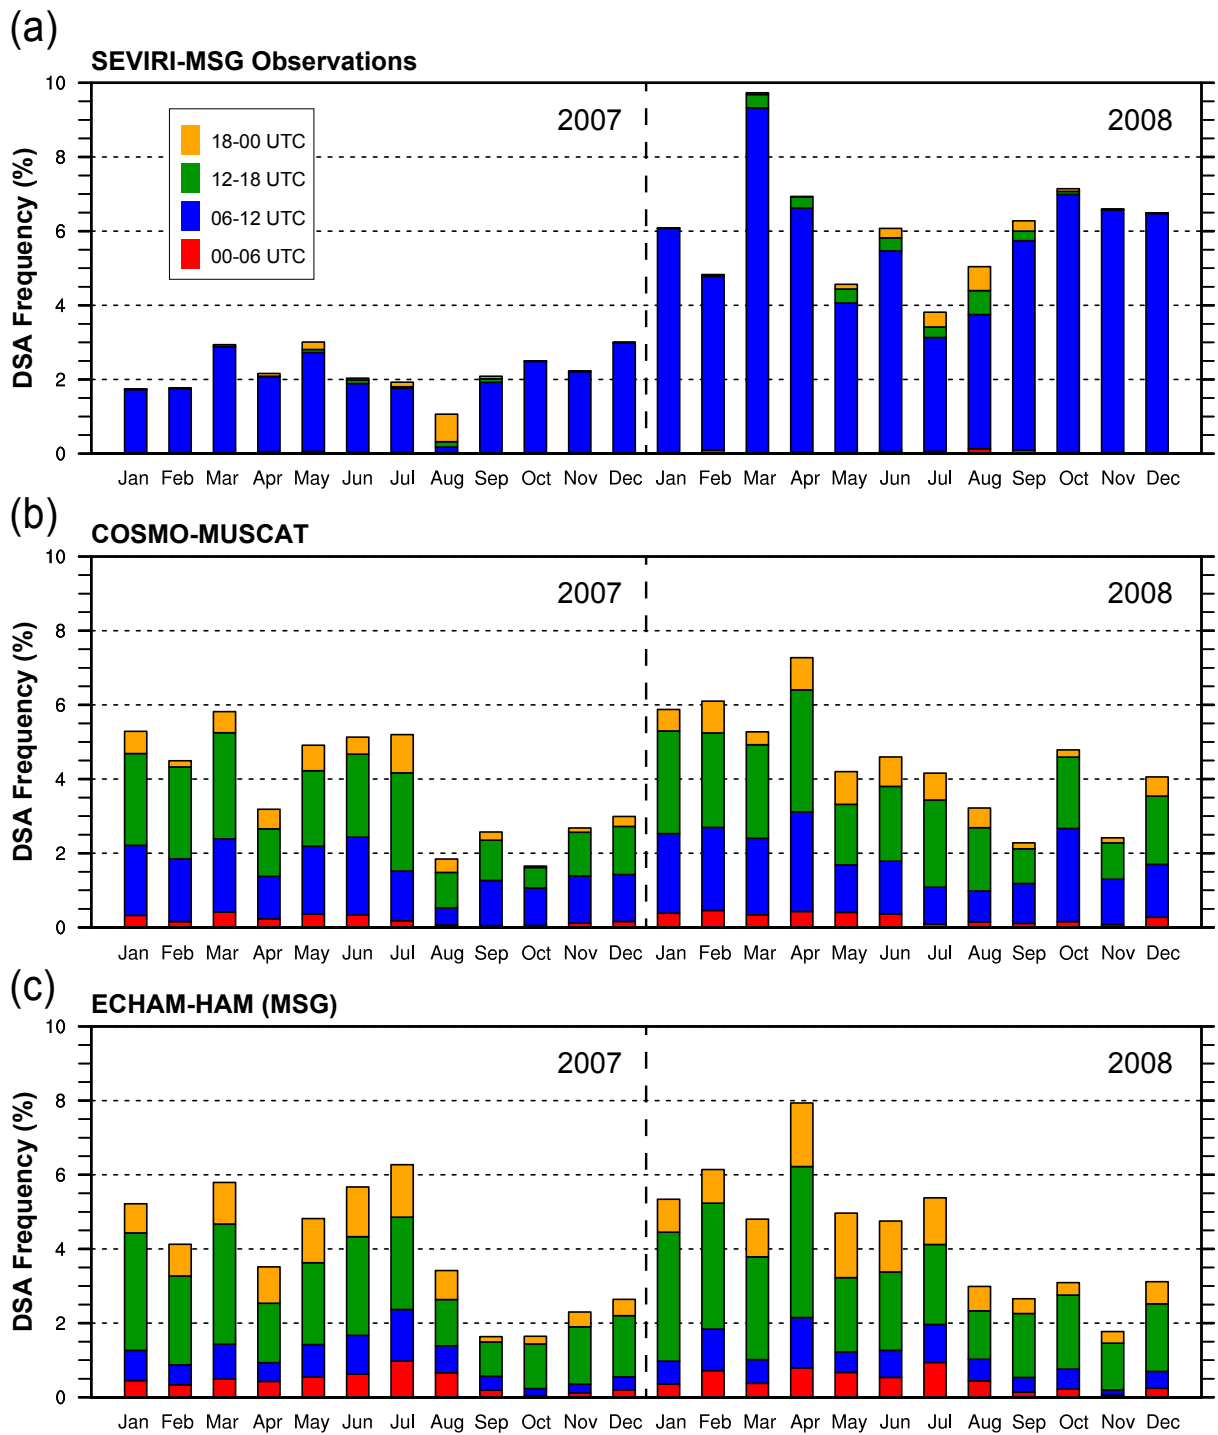

Figure 7: Monthly totals of sub-daily frequencies of Saharan dust source activations for the years 2007 and 2008. The emission events were derived from (a) the MSG infrared dust index and dust computations with (b) the regional dust model COSMO-MUSCAT and (c) the ECHAM-HAM model using the MSG-based source mask.
