22 **Abstract**

23 A fully coupled meteorology-chemistry model (WRF-Chem) has been configured
24 to conduct quasi-global simulation for the 5 years of 2010-2014 and evaluated with
25 multiple observation datasets for first time. The evaluation focuses on the simulation over
26 the trans-Pacific transport region using various reanalysis and observational datasets for
27 meteorological fields and aerosol properties. In general, precipitation and winds are well
28 simulated by the model. The simulation captures the overall spatial and seasonal
29 variability of satellite retrieved aerosol optical depth (AOD) and absorbing AOD (AAOD)
30 over the Pacific that is determined by the outflows of pollutants and dust and the
31 emissions of marine aerosols. The assessment of simulated extinction Angstrom exponent
32 (EAE) indicates that the model generally reproduces the variability of aerosol size
33 distributions as seen by satellites. In addition, the vertical profile of aerosol extinction
34 and its seasonality over the Pacific that are dominated by marine aerosols near the surface
35 and the outflow of pollutants and dust above 4 km are also well simulated. The difference
36 between the simulation and satellite retrievals can be mainly attributed to model biases in
37 estimating marine aerosol emissions as well as the satellite sampling and retrieval
38 uncertainties. Compared with the surface measurements over the western U.S., the model
39 reproduces the observed magnitude and seasonality of dust, sulfate, and nitrate surface
40 concentrations, but significantly underestimates the peak surface concentrations of
41 carbonaceous aerosol likely due to model biases in the spatial and temporal variability of
42 biomass burning emissions and secondary organic aerosol (SOA) production. A
43 sensitivity simulation shows that the trans-Pacific transported dust, sulfate, and nitrate
44 can make significant contribution to surface concentrations over the rural areas of the

45 western U.S., while the peaks of carbonaceous aerosol surface concentrations are
46 dominated by the North American emissions. Both the retrievals and simulation show
47 small interannual variability of aerosol characteristics for 2010-2014 averaged over three
48 Pacific sub-regions. The evaluation in this study demonstrates that the WRF-Chem quasi-
49 global simulation can be used for investigating trans-Pacific transport of aerosols and
50 providing reasonable inflow chemical boundaries for the western U.S. to further
51 understand the impact of transported pollutants on the regional air quality and climate
52 with high-resolution nested regional modeling.

53

54

55 **1 Introduction**

56 Aerosols, including from natural and anthropogenic sources in Europe, North
57 Africa, and East Asia, can be transported across Pacific Ocean thousands of miles
58 downwind to North America and even beyond. Previous studies using ground-based and
59 satellite measurements and numerical models estimated about 7-10 days of travel time for
60 aerosols to traverse the Pacific Ocean (Eguchi et al., 2009). These transported aerosols
61 can play an important role in atmospheric composition (Yu et al., 2008), air quality (Jaffe
62 et al., 1999; VanCuren, 2003; Heald et al., 2006; Chin et al., 2007; Fischer et al., 2009;
63 Yu et al., 2012; Tao et al., 2016), and regional weather and climate (Eguchi et al., 2009;
64 Yu et al., 2012; Creamean et al., 2013; Fan et al., 2014) over the U.S. West Coast. At the
65 surface, Heald et al. (2006) found that Asian anthropogenic aerosol plume increased
66 aerosol concentration in elevated regions of the northwestern U.S. by $0.16 \mu\text{g m}^{-3}$ in
67 spring 2001. Chin et al. (2007) also found that long-range transported dust increased the
68 annual mean fine particle concentrations by $0.5\text{-}0.8 \mu\text{g m}^{-3}$ over the western U.S., with a
69 maximum enhancement in spring. The trans-Pacific transported aerosols can also
70 significantly absorb and scatter solar radiation (Yu et al., 2012; Fast et al., 2014; Tao et
71 al., 2016), and serve as cloud condensation nuclei and ice nuclei that affect winter storms
72 in the western U.S. (Sassen, 2002; Ault et al., 2011; Creamean et al., 2013; Fan et al.,
73 2014). Deposition of the transported aerosols on snowpack in elevated regions (Hadley et
74 al., 2010) may also accelerate snowmelt and influence the regional hydrological cycle
75 and climate over the western U.S. (Qian et al., 2009 and 2015; Painter et al., 2010).
76 Hence it is important to quantify the trans-Pacific transport of aerosols and how they
77 evolve over the long distance.

78 Previous studies have used global models to quantify the long-range transport of
79 aerosols to the western U.S. (Fairlie et al., 2007; Heald et al., 2006; Chin et al., 2007;
80 Hadley et al., 2007). However, simulations were performed at relatively coarse
81 resolutions (typically 1-2 degrees) that cannot fully resolve the large geographical
82 variability of aerosols over the western U.S. with complex topography (Zhao et al.,
83 2013a). Coarse resolution simulations also lack the capability to fully resolve aerosol-
84 cloud-precipitation interaction. Some studies have reported regional simulations at
85 relatively high resolutions over the western U.S. (e.g., Zhao et al., 2013a; Fan et al.,
86 2014; Fast et al., 2014). However, most of them either used sparse in-situ observations to
87 provide lateral boundary conditions that are only suitable for idealized or short-term
88 sensitivity studies, or used simulations from global models with inconsistent physics and
89 chemistry schemes to provide lateral boundary conditions, which introduce biases in
90 estimating the contribution and effect of trans-Pacific transported aerosols.

91 To investigate the impact of trans-Pacific transported aerosols on regional air
92 quality and climate of the US West Coast, a multi-scale modeling framework including
93 global simulation at coarse resolutions that captures the large-scale circulation and
94 provide consistent chemical lateral boundaries for nested regional simulation at high
95 resolutions is needed. WRF-Chem, the Weather Research and Forecasting (WRF) model
96 (Skamarock et al., 2008) coupled with a chemistry component (Grell et al., 2005), is such
97 a modeling framework. As a state-of-the-art model, WRF-Chem supports nested
98 simulations, and includes complex aerosol processes and interactions between aerosols
99 and radiation, clouds, and snow albedo (Zhao et al., 2014). The model has been used
100 extensively to study aerosols and their impacts on air quality and climate at regional

101 scales (e.g., Fast et al., 2006, 2009; Gustafson et al., 2007; Qian et al., 2010; Gao et al.,
102 2011, 2014; Shrivastava et al., 2011; Chen et al., 2013, 2014; Zhao et al., 2010, 2011,
103 2012, 2013a; 2014). Zhao et al. (2013b) is the first study to use WRF-Chem for quasi-
104 global (180° W-180° E, 60° S-70° N) simulations at a resolution of 1° × 1° to examine
105 uncertainties in simulating global dust mass balance and radiative forcing.

106 Although the quasi-global WRF-Chem simulation described by Zhao et al. (2013b)
107 has been used to provide realistic chemical lateral boundary conditions for multiple
108 regional modeling studies (e.g., Zhao et al., 2014; Fan et al., 2015), its evaluation has not
109 been documented so far. In this study, the WRF-Chem simulation for 2010-2014 is
110 evaluated extensively using observational data. For lack of in-situ observations over East
111 Asia and Pacific Ocean during the simulation period, evaluation is performed mainly
112 using reanalysis and satellite retrieval (e.g., CALISPO, MODIS, and MISR) datasets,
113 along with some available ground-based observations from AERONET and IMPROVE
114 in the region. We focus on the simulation over the trans-Pacific transport region as a first
115 step to evaluate the simulation for providing consistent lateral chemical boundaries for
116 nested regional simulations used to investigate the impact of transported aerosols on
117 regional air quality and climate. Spatial evolution of aerosols during the trans-Pacific
118 transport as well as their seasonal and annual variability simulated by WRF-Chem will
119 also be characterized.

120 In the following sections, the detailed setup of WRF-Chem will be described in
121 Section 2. In Section 3 ground-based measurements and satellite retrievals will be
122 presented. In Section 4, we evaluate the WRF-Chem simulated spatial distributions and

123 seasonal and annual variability of aerosols across the Pacific with the observations. The
124 conclusion can be found in Section 5.

125

126 **2 Model description**

127 In this study, WRF-Chem (3.5.1), updated by scientists at Pacific Northwest
128 National Laboratory (PNNL), is used and briefly described in Section 2.1. Section 2.2
129 discusses the setup of model simulations for this study. In Section 2.3, the emissions used
130 in the simulations are described, including anthropogenic and biomass burning emissions,
131 and mineral dust and sea-salt emissions.

132 **2.1 WRF-Chem**

133 The MOSAIC (Model for Simulation Aerosol Interactions and Chemistry) aerosol
134 module (Zaveri et al., 2008) coupled with the CBM-Z (carbon bond mechanism)
135 photochemical mechanism (Zaveri and Peters, 1999) in WRF-Chem is selected in this
136 study. MOSAIC uses a sectional approach to represent aerosol size distributions with
137 four or eight discrete size bins in the current version of WRF-Chem (Fast et al., 2006).
138 All major aerosol components including sulfate (SO_4^{2-}), nitrate (NO_3^-), ammonium (NH_4^+),
139 black carbon (BC), organic matter (OM), sea-salt, and mineral dust are simulated in the
140 model. The MOSAIC aerosol scheme includes physical and chemical processes of
141 nucleation, condensation, coagulation, aqueous phase chemistry, and water uptake by
142 aerosols. Dry deposition of aerosol mass and number is simulated following the approach
143 of Binkowski and Shankar (1995), which includes both turbulent diffusion and
144 gravitational settling. Wet removal of aerosols by grid-resolved stratiform clouds and
145 precipitation includes in-cloud removal (rainout) and below-cloud removal (washout) by

146 impaction and interception, following Easter et al. (2004) and Chapman et al. (2009).
147 Cloud-ice-borne aerosols are not explicitly treated in the model, but the removal of
148 aerosols by the droplet freezing process is considered. Convective transport and wet
149 removal of aerosols by cumulus clouds follow Zhao et al. (2013b).

150 Aerosol optical properties such as extinction, single scattering albedo (SSA), and
151 asymmetry factor for scattering are computed as a function of wavelength for each model
152 grid box. Aerosols are assumed internally mixed in each bin (i.e., a complex refractive
153 index is calculated by volume averaging for each bin for each chemical constituent of
154 aerosols). The Optical Properties of Aerosols and Clouds (OPAC) data set (Hess et al.,
155 1998) is used for the shortwave (SW) and longwave (LW) refractive indices of aerosols,
156 except that a constant value of $1.53+0.003i$ is used for the SW refractive index of dust
157 following Zhao et al. (2010, 2011). A detailed description of the computation of aerosol
158 optical properties in WRF-Chem can be found in Fast et al. (2006) and Barnard et al.
159 (2010). Aerosol radiative feedback is coupled with the Rapid Radiative Transfer Model
160 (RRTMG) (Mlawer et al., 1997; Iacono et al., 2000) for both SW and LW radiation as
161 implemented by Zhao et al. (2011). The optical properties and direct radiative forcing of
162 individual aerosol species in the atmosphere are diagnosed following the methodology
163 described in Zhao et al. (2013a). Aerosol-cloud interactions were included in the model
164 by Gustafson et al. (2007) for calculating the activation and resuspension between dry
165 aerosols and cloud droplets.

166 **2.2 Numerical experiments**

167 Following Zhao et al. (2013b), we use a quasi-global channel configuration with
168 periodic boundary conditions in the zonal direction and 360×145 grid cells (180° W- 180°

169 E, 67.5° S-77.5° N) to perform simulation at 1° horizontal resolution over the period of
170 2010-2014. This circumvents some technical difficulties in running global WRF-Chem in
171 v3.5.1 for a near global coverage to characterize the trans-Pacific transport of aerosols.
172 The simulation is configured with 35 vertical layers up to 50 hPa. The meteorological
173 initial and lateral meridional boundary conditions are derived from the National Center
174 for Environmental Prediction final analysis (NCEP/FNL) data at 1° horizontal resolution
175 and 6 h temporal intervals. The modeled wind components u and v and atmospheric
176 temperature are nudged towards the NCEP/FNL reanalysis data throughout the domain
177 with a nudging timescale of 6 h in all cases (Stauffer and Seaman, 1990). This provides a
178 more realistic simulation of large-scale circulation, which is important for modeling long-
179 range transport. The chemical initial and meridional boundary conditions are taken from
180 the default profiles in WRF-Chem, which are the same as those used by McKeen et al.
181 (2002) and are based on averages of mid-latitude aircraft profiles from several field
182 studies over the eastern Pacific Ocean. The impact of chemical boundary conditions on
183 the simulated results is negligible (Zhao et al. 2013b). This study uses a set of selected
184 schemes for model physics, including the MYJ (Mellor–Yamada–Janjic) planetary
185 boundary layer scheme, Noah land surface scheme, Morrison 2-moment microphysics
186 scheme, Kain-Fritsch cumulus scheme, and RRTMG longwave and shortwave radiation
187 schemes.

188 **2.3 Emissions**

189 Anthropogenic emissions are obtained from the REanalysis of the TROpospheric
190 (RETRO) chemical composition inventories (<http://retro.enes.org/index.shtml>) except
191 over East Asia and the United States. Over the U.S., the National Emission Inventory

192 (NEI) 2005 (WRF-Chem user guide from http://ruc.noaa.gov/wrf/WG11/Users_guide.pdf)
193 is used. Over East Asia, the Asian emission inventory described by Zhang et al. (2009) at
194 $0.5^{\circ} \times 0.5^{\circ}$ horizontal resolution for 2006 is used except that BC, OC, and sulfate
195 emissions over China are from the China emission inventory for 2010 described by Lu et
196 al. (2011) at a $0.1^{\circ} \times 0.1^{\circ}$ horizontal spatial resolution and a monthly temporal resolution
197 for the simulation period. Biomass burning emissions are obtained from the Global Fire
198 Emissions Database, Version 3 (GFEDv3) with monthly temporal resolution (van der
199 Werf et al., 2010) and vertically distributed following the injection heights suggested by
200 Dentener et al. (2006) for the Aerosol Comparison between Observations and Models
201 (AeroCom) project. Sea-salt emission follows Zhao et al. (2013a), which is based on
202 Gong (2003) to include correction of particles with radius less than $0.2 \mu\text{m}$ and Jaegle et
203 al. (2011) to include the sea-salt emission dependence on sea surface temperature.
204 Vertical dust emission fluxes are calculated with the Goddard Chemical Aerosol
205 Radiation Transport (GOCART) dust emission scheme (Ginoux et al., 2001), and the
206 emitted dust particles are distributed into the MOSAIC aerosol size bins following a
207 theoretical expression based on the physics of scale-invariant fragmentation of brittle
208 materials derived by Kok (2011). For MOSAIC 8-bin, dust particles are emitted into
209 eight size bins with mass fractions of $10^{-6}\%$, $10^{-4}\%$, 0.02%, 0.2%, 1.5%, 6%, 26%, and
210 45%, respectively. Although the main purpose of this study is to evaluate the WRF-Chem
211 simulations, a sensitivity simulation, in which dust, fire, and anthropogenic emissions
212 over North America (10°N - 70°N and 170°W - 60°W) are removed, is also conducted to
213 understand the contribution of trans-Pacific transported aerosols to the surface aerosol
214 concentrations over the western U.S.

215

216 **3 Aerosol Observations**

217 **3.1 Satellite Retrievals**

218 **3.1.1 MODIS**

219 The Moderate Resolution Imaging Spectroradiometer (MODIS) instrument
220 onboard the NASA EOS Terra satellite observes Earth in 36 spectral bands from 0.4 to
221 14.4 μm , and provides nearly daily global coverage with local equatorial overpass time of
222 about 10:30 am since 2000 (King et al., 1999). The “dark target” algorithm has been
223 developed to retrieve AOD and size parameters (Angstrom exponent, effective radius,
224 and fine-mode fraction) over waters and vegetated lands (Kaufman et al., 1997; Remer et
225 al., 2005). The “deep blue” algorithm has been implemented to retrieve AOD over bright
226 land initially, which then has also been extended to vegetated land (Hsu et al., 2006,
227 2013). MODIS aerosol products have been widely used to characterize the regional,
228 seasonal, and global distribution of aerosol and its components (Yu et al., 2003, 2009;
229 Chin et al., 2004; Kaufman et al., 2005a), estimate aerosol radiative forcing (Yu et al.,
230 2004; Remer and Kaufman, 2006), and study aerosol-cloud interactions (Kaufman et al.,
231 2005b; Koren et al., 2005; Yu et al., 2007). In this study, MODIS data from the collection
232 5.1 are used. We use the “deep blue” AOD over land and the “dark target” AOD over
233 ocean, both at 550 nm and at $1^\circ \times 1^\circ$ horizontal resolution. Also, we use the “dark target”
234 over-ocean extinction Angstrom exponent (EAE) over the 470-660 nm wavelength range
235 to evaluate model simulations of particle size information (Anderson et al., 2005; Remer
236 et al., 2005; Levy et al., 2013).

237 **3.1.2 MISR**

238 The Multi-angle Imaging SpectroRadiometer (MISR) instrument onboard the
239 Terra spacecraft crosses the equator at ~10:30 AM local time since 1999. It observes
240 continuously in four narrow spectral bands centered at 446, 558, 672 and 866 nm using
241 nine separate cameras oriented along the orbital track with surface viewing zenith angles
242 ranging from $\pm 70.5^\circ$ (Diner et al., 1998). Aerosol retrievals are performed on 16×16
243 patches of 1.1 km sub-regions, yielding an aerosol product at 17.6×17.6 km spatial
244 resolution, referred to as a “Level 2” product (Martonchik et al., 2002). MISR Level 2
245 aerosol products have been described in Kahn et al (2009). The latest version (Version 22)
246 of MISR aerosol product also provides the fraction of AOD due to “fine” (particle radii
247 $< 0.35 \mu\text{m}$), “medium” (particle radii between 0.35 and $0.7 \mu\text{m}$) and “large” (particle
248 radii $> 0.7 \mu\text{m}$) particles as well as the fraction of AOD due to “spherical” and
249 “nonspherical” particles at the four MISR spectral bands. Here, we compare the MISR
250 AOD at 550 nm from Version 22 of Level 2 with the model results.

251 **3.1.3 OMI**

252 OMI onboard the NASA Aura satellite has a daily global coverage, and crosses
253 the equator at 1:45 PM local time. The nadir horizontal resolution of OMI is $24 \times 13 \text{ km}^2$.
254 In this study the OMAERUV Level 2 Collection 003 V1.4.2 product (Jethva et al., 2014)
255 is used as an independent data set providing SSA that is derived based on the reflectances
256 measured by the OMI instrument at $0.39 \mu\text{m}$. The information on aerosol absorption in
257 OMI measurements comes, to a large extent, from the interaction with Rayleigh
258 scattering in the UV spectral region (Torres et al., 2013). The retrieved parameters are
259 also reported at $0.38 \mu\text{m}$ and $0.50 \mu\text{m}$. Current OMI AOD has positive biases likely due
260 to a combination of factors including cloud contamination, surface albedo effects,

261 radiometric calibrations, and misidentified aerosol type (Ahn et al., 2008). Therefore, in
262 this study, OMI AAOD at 500 nm is reconstructed using the WRF-Chem simulated 500
263 nm AOD and OMI SSA at 500 nm with the formula of $AAOD_{OMI} = AOD_{MODEL} \times (1 -$
264 $SSA_{OMI})$.

265 3.1.4 CALIPSO

266 In this study, we use aerosol extinction profiles retrieved by the Cloud-Aerosol
267 Lidar with Orthogonal Polarization (CALIOP) onboard the Cloud-Aerosol Lidar and
268 Infrared Pathfinder Satellite Observation (CALIPSO) satellite. The CALIPSO satellite
269 was launched into a Sun-synchronous orbit on 28 April 2006. CALIOP is a dual-
270 wavelength polarization lidar and is designed to acquire vertical profiles of attenuated
271 backscatter from a near nadir-viewing geometry during both day and night phase (Winker
272 et al., 2007). In this study, the aerosol extinction profiles at a nominal horizontal
273 resolution of 5 km from the CALIPSO Level 2 profile products are used to evaluate the
274 model. We focus on the CALIOP nighttime observations in cloud-free condition, because
275 nighttime observations have higher accuracy than daytime observations (Winker et al.,
276 2009).

277 The cloud-aerosol discrimination (CAD) score, which is an indicator that
278 measures confidence level of the discrimination between clouds (positive value) and
279 aerosols (negative value), is used to help screen out aerosol profiles that contain cloud
280 signals. We include the aerosol data with CAD score between -20 and -100, the same as
281 Yu et al., (2010, 2015). The other screening is to exclude aerosol layers where the
282 retrieval algorithm has to adjust the initially selected lidar ratio that is based on the type
283 and subtype of the aerosol layer to be analyzed. It should be noted that when the aerosol

284 extinction is not detected by CALIOP, we set its value and also the corresponding model
285 result equal to zero, and then we compare CALIOP extinction profiles with the model
286 and analyze the seasonal variation.

287 **3.2 Ground-based observations**

288 **3.2.1 AERONET**

289 The AERosol RObotic NETwork (AERONET) is a globally distributed remote
290 sensing network for aerosol monitoring from ground stations (Holben et al., 1998).
291 AERONET uses the Cimel sun/sky photometer that measures AOD in 16 spectral
292 channels (340-1640 nm). The measurements provide products every 15 minutes during
293 daytime. In addition, an inversion algorithm is used for the retrieval of aerosol size
294 distribution, complex refractive index, single-scattering albedo, and phase function
295 (Dubovik and King, 2000; Dubovik et al., 2002). The spectral AOD from AERONET has
296 an accuracy of ± 0.01 (Eck et al., 1999; Holben et al., 2001). In the analysis presented in
297 this paper, the cloud screened and quality assured level 2.0 products are used. AERONET
298 products do not measure at wavelength $0.55 \mu\text{m}$, so we calculate them through using the
299 Angstrom exponent and the values at two nearest wavelengths $0.5 \mu\text{m}$ and $0.675 \mu\text{m}$. The
300 AERONET sites are located along the trans-Pacific transport pathways, so the products
301 are important for evaluating the model results. Five sites over East Asia, one island site
302 over North Pacific, and four sites over the western U.S. are selected for comparison as
303 shown in Figure 1.

304 **3.2.2 IMPROVE**

305 The Interagency Monitoring for Protected Visual Environments (IMPROVE)
306 network was initiated in 1985 by U.S. federal agencies including EPA, National Park

307 Services, Department of Agriculture-Forest Service, and other land management agencies
308 as a part of the EPA Regional Haze program (Malm et al., 1994). The network monitors
309 the visibility conditions and changes in national parks and wilderness areas on a long-
310 term basis. The detail sample collection and analytical methodology have been given by
311 Hand et al., (2011), and the data can be downloaded from
312 (<http://views.cira.colostate.edu/fed/DataWizard/Default.aspx>). There are 15 sites (Fig. 1)
313 along the west coast selected to compare with the surface aerosols of the model. In this
314 study, the mass concentrations of sulfate, nitrate, EC, OC, and dust in PM_{2.5} (particulate
315 matter with aerodynamic diameter less than 2.5 μm) are used to evaluate the model. The
316 fine dust was calculated following the formula (Malm et al., 1994; Zhao et al., 2013a):

$$317 \quad \text{PM}_{2.5}\text{-Dust} = 2.2[\text{Al}] + 2.49[\text{Si}] + 1.63[\text{Ca}] + 2.42[\text{Fe}] + 1.94[\text{Ti}]$$

318 Where [Al], [Si], [Ca], [Fe], and [Ti] represent the mass concentration of aluminum,
319 silicon, calcium, iron, and titanium, respectively.

320

321 **4 Results**

322 **4.1 Wind fields and precipitation**

323 Winds and precipitation are two crucial meteorological factors playing important
324 roles in aerosol emission, transport, and removal. The seasonal mean wind fields at 850
325 hPa averaged for the period of 2010-2014 from the WRF-Chem simulation are compared
326 with the Modern-Era Retrospective analysis for Research and Applications (MERRA)
327 reanalysis data (Rienecker et al., 2011) (Figure 2). Strong westerly winds occur over the
328 North Pacific throughout the seasons with a peak (up to 12 m/s) in boreal winter (DJF)
329 followed by boreal spring (MAM). In general, the model can well reproduce the spatial

330 pattern of winds across the Pacific and its seasonality. Figure 3 shows the spatial
331 distribution of seasonal mean precipitation from the Global Precipitation Climatology
332 Project (GPCP) observation (Huffman et al., 2001) and WRF-Chem simulation averaged
333 for the period of 2010-2014. Over East Asia, precipitation reaches a maximum during the
334 boreal summer (JJA) followed by MAM. In the North Pacific basin, the largest
335 precipitation occurs in DJF along the storm tracks with the maximum westerlies. Over the
336 U.S. west coast, precipitation peaks during DJF and reaches a minimum in JJA. The
337 simulation reasonably reproduces the spatial and seasonal variation of precipitation, with
338 overestimation in some regions, particularly over the Inter-Tropical Convergence Zone
339 (ITCZ) and western tropical Pacific that are south of the major pathway of trans-Pacific
340 transport.

341

342 **4.2 Aerosol optical depth**

343 4.2.1 Spatial and temporal variation

344 Figure 4 shows the spatial distributions of seasonal mean AOD at 550 nm across
345 the Pacific from Asia to North America averaged for 2010-2014 from the retrievals of
346 MODIS and MISR onboard Terra and the corresponding WRF-Chem simulation. In order
347 to reduce the sampling discrepancy between the two retrievals, the daily results from the
348 two satellite retrievals and simulation are sampled and averaged at the same time and
349 location. This way of averaging leads to the blank areas of missing values, which are
350 relatively large in JJA. Satellite retrievals show that AOD is high over the Asian
351 continent and gradually decreases across the Pacific. High AOD coincides with the sub-
352 tropical jet (30°N-50°N, Fig. 2) over the Pacific and results from wind-induced increase

353 in sea-salt loading and the Asian pollutant outflow. Seasonal variation of aerosols across
354 the Pacific is evident, with peak AOD over the western Pacific in MAM and minimum
355 AOD in JJA and SON. Previous studies found that trans-Pacific transport of air pollutants
356 is most efficient in MAM due to active cyclonic activity and that pollutants are lifted to
357 the free troposphere where it can be rapidly transported across the Pacific by strong
358 westerlies (e.g., Forster et al., 2004; Liang et al., 2004; Heald et al., 2006; Yu et al., 2008).
359 The WRF-Chem simulation generally well captures the observed spatial and seasonal
360 variability of AOD across the Pacific. The model underestimates the oceanic AOD to the
361 south of 20°N, which may be due to underestimation of marine emissions and/or
362 overestimation of aerosol wet removal associated with the positive bias in precipitation.
363 The discrepancy may also be due to cloud contamination in the retrievals that leads to an
364 overestimation of AOD in some regions of North Pacific (e.g., Zhang and Reid, 2006).
365 The model also simulates lower AOD over the continent of North America compared
366 with satellite retrievals. The difference between the simulation and retrievals may be due
367 to the uncertainty in satellite retrievals over the continents (e.g., Liu et al., 2004; Levy et
368 al., 2010).

369 Since this study focuses on the trans-Pacific transport and evolution of aerosols,
370 the Pacific is further divided into three sub-regions (Region 1: 20°N-50°N and 120°E-
371 140°E; Region 2: 20°N-50°N and 140°E-140°W; Region 3: 20°N-50°N and 140°W-
372 120°W) representing the West Pacific, the Central Pacific, and the East Pacific shown as
373 the black boxes in Figure 4 for analysis. Figure 5 shows the seasonal mean 550 nm AOD
374 over the three sub-regions from the MISR and MODIS retrievals and the corresponding
375 WRF-Chem simulation at the pass time of MISR and MODIS, respectively, averaged for

376 2010-2014. It shows clearly that AOD peaks in MAM in all the regions across the Pacific.
377 The simulation successfully reproduces the observed seasonal variability. In general, the
378 MODIS and MISR retrievals are consistent and show that AOD reduces from West
379 Pacific to East Pacific, which is also indicated by the simulation. The interannual
380 variability of AOD over the three sub-regions is small for 2010-2014 indicated by the
381 retrievals and simulation (not shown).

382 Available observations from several AERONET sites (Fig. 1) over East Asia, the
383 Pacific, and western US are also compared with the model simulation. Figure 6 shows the
384 comparison of observed and simulated AOD at three representative AERONET sites for
385 2010-2014 over East Asia, an island of Pacific, and the western US coast. The
386 observations and simulation agree well at all three sites, and both reflect the AOD
387 gradient from East Asia to the western U.S. as shown in Figure 4. Observed AOD is the
388 highest with a mean value of 0.31 at the SACOL site over East Asia and reduces to 0.075
389 at the Midway_Island site, and 0.045 at the Frenchman_Flat site. The model reproduces
390 these values at the three sites with correlation coefficients of 0.45, 0.75, and 0.63,
391 respectively. About 90% of simulated AOD is within a factor of 2 of the AERONET
392 measurements.

393 Figure 7 further shows the monthly variation of AOD averaged at the AERONET
394 sites over East Asia, the Pacific island, and the West US (as shown in Fig. 1) from the
395 AERONET observations, MODIS and MISR retrievals, and WRF-Chem simulation. For
396 the simulated AOD, contributions by dust, BC, OC, sulfate, and other aerosols are also
397 shown. Over East Asia, the MISR and AERONET retrievals agree well in monthly
398 variation. The MODIS retrievals generally overestimate AOD. The simulation reproduces

399 the AERONET observed AOD variability. Model results show that anthropogenic
400 aerosols dominate the AOD from summer to winter while dust can significantly
401 contribute to the AOD in spring. Over the island of Pacific (the Midway_Island site),
402 retrievals from AERONET, MODIS, and MISR are consistent with each other and with
403 the simulation on monthly variation of AOD, primarily determined by the sea-salt aerosol,
404 which shows a minimum in summer months. The trans-Pacific transported aerosols (other
405 than sea-salt) also show strong monthly variation with a maximum in April and a
406 minimum in July. Over the western U.S., both retrievals and simulation show the largest
407 AOD occurs in the spring months, which has significant contribution from the dust
408 aerosol transported across the Pacific (to be discussed in section 4.5). MODIS retrieved
409 lower AOD than MISR, and both retrievals are significantly higher than that from the
410 AERONET retrieval in March-October, while the simulation is more consistent with the
411 AERONET retrievals, which suggests that the difference between the MODIS and MISR
412 retrievals and the simulation over the western US shown in Fig. 4 is due to uncertainty in
413 satellite retrievals.

414

415 4.2.2 Wavelength dependence

416 The wavelength dependence of AOD that can be represented by the extinction
417 Angstrom exponent (EAE) is an indicator of aerosol particle size (Angstrom, 1929;
418 Schuster et al., 2006). In general, relatively small values of EAE indicate that aerosol size
419 distributions are dominated by coarse aerosols typically associated with dust and sea-salt,
420 while relatively large values of EAE indicate fine aerosols usually contributed by
421 anthropogenic pollution and biomass burning. Figure 8 shows the seasonal mean EAE

422 averaged for 2010-2014 from the MODIS retrievals and the WRF-Chem simulation over
423 the three sub-regions. The retrievals show clearly that the EAE values peak in JJA and
424 reach a minimum in DJF in all three sub-regions. This seasonality reflects the fact that
425 photochemistry is most active in JJA to produce fine aerosol particles such as sulfate. In
426 general, the simulation successfully reproduces the observed EAE seasonality. The
427 retrievals and simulation also show that the values of EAE are greater in the West Pacific
428 than in the Central and East Pacific. This pattern may reflect the dominance of the Asian
429 pollutant outflow on the aerosol size distributions over the West Pacific, while the
430 relatively large-size particles of sea-salt dominates in the other two regions. Again, the
431 annual variability of EAE over the three sub-regions is small (not shown).

432

433 **4.3 Aerosol absorption optical depth**

434 Light absorbing aerosols such as BC and dust play an important role in the
435 atmosphere to absorb radiation and change the heating profiles in the atmosphere.
436 Aerosol absorption optical depth (AAOD) is an important parameter for evaluating the
437 model performance in simulating light absorbing aerosols. Figure 9 shows the seasonal
438 mean AAOD at 500 nm averaged for 2010-2014 and over the three sub-regions from the
439 OMI retrievals and the WRF-Chem simulation. Both retrievals and simulation show
440 small interannual variability (not shown). Both the retrievals and simulation show that
441 AAOD peaks in MAM followed by JJA over the three sub-regions, which may be due to
442 the stronger outflow of dust and anthropogenic pollutants in the two seasons. The
443 simulated AAOD over West Pacific agrees reasonably well with the OMI retrieval in DJF
444 but is higher in the other three seasons. Over Central Pacific, the simulation generally

445 reproduces the retrieved AAOD, except overestimating (underestimating) the retrieved
446 values in JJA (DJF). Over East Pacific, the simulated AAOD is consistent with the
447 retrieved values with some overestimation in JJA. The retrievals and simulation show
448 large variability of AAOD, and they generally agree within the 10th and 90th percentiles
449 of each other. AAOD is larger over West Pacific than Central and East Pacific, which is
450 consistent with the AOD pattern.

451 The AERONET retrieval products (version 2) also provide AAOD values but
452 only at the sites and time when the total AOD exceeds a threshold value of 0.4 at 440 nm
453 because the AERONET inversion algorithms require a high signal-to-noise ratio to
454 retrieve some optical products such as AAOD. The total AOD values over Central Pacific
455 and the western US are less than this threshold value most of the time, and only AAOD
456 values retrieved at the East Asian sites are available and reliable. Figure 10 shows the
457 monthly variation of AAOD averaged at the AERONET sites over East Asia (Fig. 1)
458 from the AERONET observations, OMI retrievals, and WRF-Chem simulation. The
459 AERONET retrievals show the monthly variation of AAOD over East Asia with
460 relatively lower values in JJA probably due to wet removal of aerosols by precipitation
461 and mixing with clean marine air during the East Asian summer monsoon (Zhao et al.,
462 2010). The simulation generally captures the observed monthly variability, but
463 overestimate AAOD in the warm months such as August and September. The model
464 shows that AAOD over East Asia is dominated by BC and is partly contributed by dust.
465 Other aerosols contribute to small amount of AAOD due to the internal mixing of
466 aerosols in the atmosphere (Zhao et al., 2013a). The model positive biases in AAOD in
467 the warm months may be partly related to the constant anthropogenic BC emissions

468 applied throughout the seasons while previous studies showed that anthropogenic BC
469 emissions may have seasonal variation with lower values in the warm months (Lu et al.,
470 2010).

471 It is noteworthy that the OMI retrieved AAOD is lower than that from AERONET
472 and WRF-Chem, particularly in JJA and SON. The lower OMI AAOD may indicate
473 positive biases in the OMI SSA retrievals over East Asia and West Pacific (Fig. 9) that is
474 significantly affected by the East Asian outflow. The difference between the simulation
475 and OMI retrievals over East Pacific may be partly due to negative biases in modeling
476 SSA; however, it is noteworthy that the OMI retrievals may have difficulty in
477 distinguishing the ocean color effects from those of low aerosol concentrations in the UV
478 spectral range and ignoring less-sufficient amounts of absorbing aerosols [Veihelmann et
479 al., 2007; Torres et al., 2013]. In addition, the OMI retrievals may also have cloud
480 contamination issue because of the large footprint.

481

482 **4.4 Aerosol vertical distributions**

483 Column integrated properties of aerosol (e.g., AOD and AAOD) provide useful
484 information in regard to atmospheric aerosol loading but little information on the vertical
485 distribution of aerosols. Previous studies found that simulated aerosol vertical
486 distributions differ significantly, which can affect the assessments of aerosol impacts on
487 climate and air quality (e.g., Schulz et al., 2006; Textor et al., 2006). CALIPSO with the
488 unique capability provides an opportunity to assess model simulation of aerosol vertical
489 distributions (e.g., Huang et al., 2013). Figure 11 shows the vertical distributions of
490 annual mean aerosol extinction coefficients for 2010-2014 averaged over the three sub-

491 regions from the CALIPSO retrievals and the corresponding WRF-Chem simulation
492 under cloud-free condition. The CALIPSO retrievals show clearly that aerosol extinction
493 coefficients peak near several hundred meters above the surface and then decrease with
494 the altitude over the three sub-regions. The extinction coefficients reduce from West to
495 East Pacific. The model generally reproduces the aerosol extinction vertical distributions.
496 The simulated mass fraction of each aerosol component (Fig. 12) show that below 1 km,
497 sea-salt dominates the total aerosol mass over Central and East Pacific, while the outflow
498 of anthropogenic aerosols and dust also make significant contributions over West Pacific.
499 Above 4 km, dust is the dominant aerosol over all three sub-regions. The simulation is a
500 little higher than the retrievals in the free troposphere (e.g., >4 km) and at the surface. In
501 the free troposphere, the difference may be due to the reduced sensitivity of CALIOP to
502 tenuous aerosol layers above 4 km. At the surface, the lower CALIPSO aerosol extinction
503 may result from a misclassification of polluted continental aerosol as marine aerosol
504 when pollution outflow occurs near the surface and surface contamination during the
505 retrievals (Yu et al., 2010). The model consistently underestimates the aerosol extinction
506 coefficients between surface and 1 km in all three sub-regions, which may indicate that
507 the model has negative biases for estimating marine aerosol emissions, as shown in Fig. 4.

508 The seasonal variation of aerosol extinction profiles averaged for 2010-2014 (Fig.
509 13) shows the spring maximum, particularly above 2 km, over all three sub-regions from
510 both the CALIPSO retrievals and the model simulation. This is likely due to the
511 seasonality of dust outflow over the Pacific (Fig. 14) that dominates the aerosol masses
512 above 2 km with a peak in spring (e.g., Huang et al. 2013). Over West Pacific, the model
513 reasonably reproduces the retrieved aerosol extinction profiles through the seasons with a

514 relatively larger negative bias below 1 km in DJF, when sea-salt has a relatively larger
515 contribution near the surface (Fig. 14). In JJA, similar amount of aerosols as that in
516 MAM has the largest contribution from the anthropogenic pollutant outflow among the
517 seasons with a peak at ~ 2 km above the surface. Over Central and East Pacific, the
518 model also well captures the vertical distributions with a relatively larger negative bias
519 below 1 km in DJF. Over these two regions, the seasonality of the vertical shape of each
520 aerosol component contribution is similar to that over West Pacific, except that the sea-
521 salt contribution is larger near the surface (Fig. 14).

522

523 **4.5 Aerosol surface mass concentrations over the West US**

524 For lack of in-situ observations of aerosol masses over the Pacific, measurements
525 of surface fine aerosol ($PM_{2.5}$) component mass concentrations from the IMPROVE
526 network over the western U.S. were widely used for model evaluation of trans-Pacific
527 transport (e.g., Chin et al., 2007; Hadley et al., 2007). Daily variation of surface fine
528 aerosols (dust, sulfate, nitrate, BC, and OC) averaged for 2010-2014 from the IMPROVE
529 measurements and the corresponding model simulations are illustrated in Figure 15. The
530 IMPROVE sites over the western U.S. (Fig. 1) that have measurements for the entire five
531 years (2010-2014) and with less noisy values are divided at $40^\circ N$ into two groups to
532 represent the Northwest and Southwest U.S. The averaged values over the Northwest and
533 Southwest sites are shown. At the Northwest sites, the model well captures the observed
534 seasonal variation of dust. Both the observations and simulation show the maximum dust
535 mass concentration in MAM. The observed surface sulfate concentrations are the lowest
536 in the cold season when photochemistry is least active, and the highest in the warm

537 season when the most active photochemistry occurs. This seasonality of sulfate may also
538 be contributed by the seasonality of wet removal (much more precipitation in DJF).
539 Nitrate shows a seasonality that is opposite to that of sulfate, with a maximum surface
540 concentration occurring in the cold season and a minimum in the warm season, which can
541 be explained by the combined effects of temperature and vertical turbulent mixing (Zhao
542 et al., 2013a). The simulation generally reproduces the magnitude and seasonality of both
543 sulfate and nitrate. At the Southwest sites, the simulation is consistent with the
544 observations on the magnitude and seasonality of surface concentrations of dust, surface,
545 and nitrate.

546 A sensitivity simulation without dust, fire, and anthropogenic emissions over
547 North America (10°N-70°N and 170°W-60°W) indicates that the trans-Pacific
548 transported dust dominates the total dust amount in all seasons at both the northern and
549 southern sites, particularly in MAM. At the southern sites, the North American dust
550 makes a significant contribution in DJF. The sensitivity simulation also shows that trans-
551 Pacific transported sulfate and nitrate can make significant contribution to their surface
552 concentration over the western U.S., and the relative contributions are larger when the
553 surface concentrations are lower (i.e., cold seasons for sulfate and warm seasons for
554 nitrate). During the cold seasons, the North American anthropogenic emissions determine
555 the nitrate surface concentrations. Some differences in dust, sulfate, and nitrate surface
556 concentrations also exist between the observations and simulation. These differences may
557 reflect partly the modeling biases of trans-Pacific aerosols, and also the uncertainties in
558 the North American dust and anthropogenic emissions. Another source of the difference
559 may be from the sub-grid variability of emissions and surface concentrations that

560 confounds the comparison of model simulation at one-degree horizontal grid resolution
561 and the point measurements from the individual sites.

562 There is a significant difference in BC and OC surface concentrations between the
563 observations and simulation. At the Northwest sites, the observed BC and OC show
564 significant seasonal variation with the highest surface concentration in June-September
565 (JJAS). This consistent peak of BC and OC surface concentrations is likely due to the
566 North American biomass burning that also reaches a maximum in JJAS (Chin et al.,
567 2007). The simulation captures this seasonality to some extent but significantly
568 underestimates the JJAS peak for both BC and OC. The sensitivity simulation shows that
569 the peak is dominated by the North American emissions. This significant negative bias in
570 the model is likely from uncertainties in the GFEDv3 biomass burning inventory for the
571 simulation period. The monthly mean emissions at a relatively coarse horizontal
572 resolution may not be able to capture the strong local fire events.

573 At the Southwest sites, the impact of biomass burning on the BC and OC surface
574 concentrations seems relatively small. The simulation can well capture the magnitude and
575 seasonality of surface BC concentration that shows the maximum in DJF and the
576 minimum in JJA, which is likely due to stronger vertical turbulent mixing in JJA
577 compared with DJF. The observed OC still shows peak concentrations in JJA, and the
578 model significantly underestimates the peak OC concentrations. However, this negative
579 bias seems not to be related to the underestimation of biomass burning because BC is
580 reasonably simulated. This seasonal variability may be determined by the secondary
581 production of OC, which peaks in JJA because of more active photochemistry and higher
582 emissions of biogenic VOCs. The underestimation of secondary organic aerosol (SOA)

583 may be due to uncertainty of biogenic emissions (Zhao et al., 2015) and the outdated
584 SOA mechanism used in the current version of WRF-Chem (Shrivastava et al., 2011). On
585 the other hand, it is also noteworthy that uncertainties in the IMPROVE carbonaceous
586 aerosol data are also relatively high because they are inferred from optical/thermal
587 measurements. The sensitivity simulation again shows that the peaks of BC and OC
588 surface concentrations are dominated by the North American emissions.

589

590 **5 Summary and conclusion**

591 A fully coupled meteorology-chemistry model (WRF-Chem) has been configured
592 to conduct quasi-global simulation for the 5 years of 2010-2014. The simulation results
593 are evaluated for first time with various reanalysis and observational datasets, including
594 precipitation from GPCP, wind fields from MERRA, AOD, EAE, and AAOD from
595 MODIS, MISR, OMI, and AERONET, aerosol extinction profiles from CALIPSO, and
596 aerosol surface mass concentrations from IMPROVE. In this study, the evaluation and
597 analysis focus on the trans-Pacific transport region for the purpose of demonstrating the
598 capability of using the quasi-global WRF-Chem simulation to provide consistent lateral
599 chemical boundaries for nested regional WRF-Chem simulations that can be used to
600 investigate the impact of trans-Pacific transported aerosols on the regional air quality and
601 climate over the western US. The main conclusion is summarized below:

- 602 ■ The comparison of simulated AOD with the satellite and AERONET retrievals
603 reveals that the model can well capture the spatial gradient of aerosol mass loading
604 decreasing from West to East Pacific, resulting from the sea-salt loading and the
605 Asian pollutant outflow. The seasonal variation of aerosols across Pacific with the

606 maximum AOD in MAM is also reproduced by the model. The model underestimates
607 AOD over the ocean to the south of 20°N and over the continent of North America
608 against the satellite retrievals. This discrepancy may reflect the model
609 underestimation of marine emissions and/or overestimation of aerosol wet removal or
610 the positive retrieval errors due to cloud-contamination. Compared with the
611 AERONET retrievals, the difference of AOD over the western US between the
612 simulation and satellite retrievals may be due to uncertainty in the satellite retrievals
613 over the continent.

614 ■ The assessment of simulated EAE indicates that the model captures the observed
615 smaller-size aerosols over West Pacific contributed by the Asian pollutant outflow
616 compared to the relatively larger particles over Central and East Pacific with more
617 contributions from sea-salt. The model also simulates the consistent seasonality of
618 EAE with observations showing a minimum in DJF and a maximum in JJA due to the
619 active production of small particles in warm seasons.

620 ■ The model reasonably simulates the decreasing gradient of OMI derived AAOD from
621 East to West of Pacific, and the seasonality with a peak in MAM due to the strong
622 outflow of dust and anthropogenic pollutants. The comparison with AERONET
623 retrieved AAOD over East Asia may indicate that the OMI SSA retrievals have
624 positive biases over East Asia and also West Pacific that is significantly affected by
625 the East Asian outflow, particularly in JJA. Over East Asia, the model positive biases
626 in AAOD in the warm months may be partly due to the neglect of the seasonal
627 variability of anthropogenic BC emissions in this study.

- 628 ▪ The model generally captures the CALIPSO retrieved vertical distributions of aerosol
629 extinction coefficients roughly decreasing with the altitude over the Pacific. Near the
630 surface, retrieval uncertainties and model biases in estimating marine aerosol
631 emissions may both contribute to the discrepancy between the simulation and
632 retrievals. The difference between the simulation and retrievals in the free
633 troposphere may be due to the reduced sensitivity of CALIOP to the aerosol layers
634 above 4 km. The model well captures the seasonality of aerosol extinction profiles
635 with a maximum in MAM, which is largely controlled by the activity of dust outflow
636 events over the Pacific.
- 637 ▪ Compared with the measurements from the IMPROVE sites over the western US, the
638 model reproduces the observed magnitude and seasonality of dust, sulfate, and nitrate
639 surface concentrations, with peaks in MAM, JJA, and DJF, respectively. Over the
640 southwestern U.S., the simulation reproduces the magnitude and seasonality of
641 surface BC concentrations that show the maximum in DJF, but significant
642 underestimates the surface OC concentrations in JJA likely due to the negative biases
643 in SOA production. Over the northwestern U.S., the simulation significantly
644 underestimates surface BC and OC concentrations likely due to the uncertainties in
645 fire emissions of which the monthly variation and the half-degree horizontal
646 resolution may not be sufficient to capture the strong local fire events. Another source
647 of the difference may be due to the discrepancy in spatial scales between site
648 observations and model output for grid cell area of one-degree resolution. In addition,
649 uncertainties in IMPROVE may also contribute to the discrepancy, in particular for
650 carbonaceous aerosols that are inferred from optical/thermal measurements.

651 ▪ The sensitivity simulation shows that the trans-Pacific transported dust dominates the
652 dust surface concentrations in the western US, particularly in MAM. The trans-
653 Pacific transported sulfate and nitrate can also make significant contribution to their
654 surface concentration over the rural areas of the western US, in particular when their
655 surface concentrations are relatively low. The peaks of BC and OC surface
656 concentrations over the western US are dominated by the North American emissions.
657 These sensitivity simulation results may be different to some extent from other
658 models (e.g., Chin et al., 2007), which could result from the considerable differences
659 in aerosol composition and vertical distributions due to differences in model
660 treatments of emissions and removal processes as revealed by several inter-
661 comparison studies (Barrie et al., 2001; Penner et al., 2002; Textor et al., 2006). More
662 detailed model inter-comparison of the trans-Pacific transport of aerosols deserves
663 further study.

664 Although dust and biomass burning emissions in general have considerable year-
665 to-year variations, the interannual variability of seasonal AOD for 2010-2014 averaged
666 over the three sub-regions of Pacific is small as indicated by the retrievals and simulation.
667 It is noteworthy that the trans-Pacific aerosols identified in this study include not only the
668 outflow of Asian pollutants and dust but also European pollutants and African dust that
669 are transported to Asia and then merged with the Asian outflow. This has been
670 recognized by previous studies (e.g., Chin et al., 2007) and also our on-going research
671 (Hu et al., 2015). The evaluation in this study successfully demonstrates that the WRF-
672 Chem quasi-global simulation can be used for studying trans-Pacific transport of aerosols
673 and providing reasonable inflow chemical boundaries for the western U.S. to further

674 understand the impact of transported pollutants on the air quality and regional climate
675 with high resolution nested regional modeling. It needs to be noted that the aerosol
676 optical properties, such as AOD, AAOD, and EAE, derived from the retrievals and
677 simulations have some different assumptions of the physical and optical parameters, so
678 that the link between the model and the satellite data are only qualitative or semi-
679 quantitative. Evaluation of model results with in-situ observations, particularly for a
680 specific event may also be needed, especially over Asia and Pacific, where data are
681 sparse or inaccessible.

682

683 **Code availability**

684 The WRF-Chem version 3.5.1 release can be obtained at
685 http://www2.mmm.ucar.edu/wrf/users/download/get_source.html. A general WRF-Chem
686 user's guide is also available online (<http://ruc.noaa.gov/wrf/WG11/>). Code modifications
687 and model configuration for conducting quasi-global WRF-Chem simulations here are
688 available upon request by contacting the corresponding author and will be incorporated in
689 the future available release of WRF-Chem.

692 This research was supported by the Office of Science of the U.S. Department of Energy
693 (DOE) as part of the Regional & Global Climate Modeling (RGCM) program. J. Huang
694 acknowledges support from the National Basic Research Program of China
695 (2012CB955301). H. Yu was supported by NASA CALIPSO project (NNX14AB21G)
696 managed by Dr. David Considine. This study used computing resources from the PNNL

697 Institutional Computing. Pacific Northwest National Laboratory is operated by Battelle
698 Memorial Institute for the DOE under contract DE-AC05-76RL01830. The CALIPSO
699 data were obtained from the NASA Langley Research Center Atmospheric Sciences Data
700 Center. MODIS and MISR data were obtained from the NASA Atmospheric Science
701 Data Center. OMI data were obtained from the NASA Goddard Earth Sciences Data and
702 Information Services Center.
