1 **Abstract.** We present an evaluation of the online regional model WRF-Chem over Europe with a fo-
2 cus on ground-level ozone (O₃) and nitrogen oxides (NO_x). The model performance is evaluated for
3 two chemical mechanisms, MOZART- 4 and RADM2, for year-long simulations. Model-predicted
4 surface meteorological variables (e.g., temperature, wind speed and direction) compared well overall
5 with surface-based observations, consistent with other WRF studies. WRF-Chem simulations em-
6 ploying MOZART- 4 as well as RADM2 chemistry were found to reproduce the observed spatial
7 variability in surface ozone over Europe. However, the absolute O₃ concentrations predicted by the
8 two chemical mechanisms were found to be quite different, with MOZART- 4 predicting O₃ concen-
9 trations up to 20 µg m⁻³ greater than RADM2 in summer. Compared to observations, MOZART- 4
10 chemistry overpredicted O₃ concentrations for most of Europe in the summer and fall, with a sum-
11 mertime domain-wide mean bias of +10 µg m⁻³ against observations from the AirBase network. In
12 contrast, RADM2 chemistry generally led to an underestimation of O₃ over the European domain in
13 all seasons. We found that the use of the MOZART- 4 mechanism, evaluated here for the first time
14 for a European domain, led to lower absolute biases than RADM2 when compared to ground-based
15 observations. The two mechanisms show relatively similar behavior for NO_x, with both MOZART- 4
16 and RADM2 resulting in a slight underestimation of NO_x compared to surface observations. Further
17 investigation into the differences between the two mechanisms revealed that the net midday photo-
18 chemical production rate of O₃ in summer is higher for MOZART- 4 than for RADM2 for most
19 of the domain. The largest differences in O₃ production can be seen over Germany, where net O₃
20 production in MOZART- 4 is seen to be higher than in RADM2 by 1.8 ppb hr⁻¹ (3.6 µg m⁻³ hr⁻¹)
21 or more. We also show that, while the two mechanisms exhibit similar NO_x-sensitivity, RADM2 is
22 approximately twice as sensitive to increases in anthropogenic VOC emissions as MOZART- 4. Ad-

23 ditionally, we found that differences in reaction rate coefficients for inorganic gas phase chemistry
24 in MOZART-4 vs. RADM2 accounted for a difference of $8 \mu\text{g m}^{-3}$, or 40% of the summertime dif-
25 ference in O_3 predicted by the two mechanisms. Differences in deposition and photolysis schemes
26 explained smaller differences in O_3 . Our results highlight the strong dependence of modeled surface
27 O_3 over Europe on the choice of gas phase chemical mechanism, which we discuss in the context
28 of overall uncertainties in prediction of ground-level O_3 and its associated health impacts (via the
29 health-related metrics MDA8 and SOMO35).

30 **1 Introduction**

31 Tropospheric ozone (O_3) is an air pollutant with adverse effects on human and ecosystem health
32 as well as a short-lived climate forcer with a significant warming effect (e.g., Monks et al., 2015;
33 Stevenson et al., 2013; WHO, 2003). In Europe, ozone pollution remains a problem: the European
34 Environmental Agency reports that between 2010 and 2012, 98% of Europe's urban population was
35 exposed to O_3 levels in exceedance of the WHO air quality guideline (EEA, 2014), leading to more
36 than 6000 premature deaths annually (Lelieveld et al., 2015). This is despite the fact that European
37 emissions of ozone precursors, in particular nitrogen oxides (NO_x) and volatile organic compounds
38 (VOCs), have decreased significantly since 1990. The persistence of unhealthy levels of ozone in
39 Europe can be attributed to increases in hemispheric background ozone (Wilson et al., 2012) as well
40 as the non-linear relationship between O_3 and levels of precursor species NO_x and VOC (EEA,
41 2014).

42 Air quality models are employed to understand the drivers of air pollution at a regional scale and to
43 evaluate the roles of and interactions between emissions, meteorology and chemistry. These models
44 fall into two broad categories: offline Chemistry-Transport Models (CTMs), in which meteorology is
45 calculated separately from model chemistry, and "online" models, the category to which WRF-Chem
46 belongs, in which the meteorology and chemistry are coupled, meaning they are solved together in
47 a physically consistent manner (e.g., Zhang, 2008). The meteorology and chemistry components in
48 WRF-Chem use the same horizontal and vertical grids and same timestep, eliminating the need for
49 temporal interpolation (e.g., Grell et al., 2004, 2005).

50 Air quality modeling studies over the European region have predominantly utilized CTMs, ex-
51 amples of which include EMEP (Simpson et al., 2012), CHIMERE (Terrenoire et al., 2015), and
52 LOTOS-EUROS (Schaap et al., 2008). The application of online coupled regional meteorology-
53 chemistry models in Europe, among them WRF-Chem, has been recently reviewed by Baklanov
54 et al. (2014). The use of WRF-Chem over Europe has increased in recent years (e.g., Forkel et al.,
55 2012; Žabkar et al., 2015; Solazzo et al., 2012a, b; Tuccella et al., 2012; Zhang et al., 2013a, b).
56 However, only a limited number of these studies are dedicated to the evaluation of WRF-Chem-
57 simulated meteorology and chemistry over the whole European domain. The study of Tuccella et al.
58 (2012) evaluated the performance of WRF-Chem using the RADM2 chemical mechanism by com-
59 paring domain-wide average values against observations of meteorology and chemistry. However,
60 an evaluation of the spatial distribution of model-simulated meteorology and trace gases is miss-
61 ing. This type of spatial information is extremely pertinent for air quality management applications,
62 where model performance at a national scale can become more relevant than performance metrics ap-
63 plied to the whole of Europe; this information gets lost when only comparing quantities that have
64 been averaged over the entire domain. Additionally, Tuccella et al. (2012) utilized time-invariant
65 chemical boundary conditions, which the authors suggested misrepresented the seasonal changes in
66 the intercontinental transport (Tuccella et al., 2012). The importance of temporally varying chemical

67 boundary conditions in air quality modeling has also been stressed in other studies (including Akri-
68 tidis et al., 2013; Andersson et al., 2015). In addition to the study of Tuccella et al. (2012), Zhang
69 et al. (2013b) evaluated the performance WRF-Chem-MADRID (Zhang et al., 2010), an unofficial
70 version of WRF-Chem coupled to the Model of Aerosol Dynamics, Reaction, Ionization, and Dis-
71 solution (MADRID), over Europe for the month of July 2001, employing the gas-phase mechanism
72 CB05 (Yarwood et al., 2005). This detailed study provides a valuable reference for comparison to
73 the present work, but their simulations are only for one month, rather than the complete seasonal
74 cycle.

75 Several groups contributed WRF-Chem simulations to the AQMEII project (phase 1 and phase 2)
76 for the European domain (Solazzo et al., 2012b; Im et al., 2015). In AQMEII phase 1, two differ-
77 ent WRF-Chem simulations were part of the model ensemble for Europe, but evaluation of model
78 performance for ozone focused on evaluation of the ensemble (Solazzo et al., 2012b), rather than
79 on individual members. In fact, in the analysis of Solazzo et al. (2012b), individual models were
80 anonymized, meaning the performance statistics for the WRF-Chem ensemble members are not ex-
81 plicitly presented. The evaluation of model performance with respect to ozone in AQMEII phase 2
82 (Im et al., 2015) provides more information on the model performance of the contributing WRF-
83 Chem ensemble members for the European domain. In AQMEII phase 2, seven different WRF-Chem
84 runs were part of the ensemble. Of these seven simulations, four of them used the gas phase chemical
85 mechanism RADM2 (Stockwell et al., 1990), two used the mechanism CBMZ (Zaveri and Peters,
86 1999), and one used the mechanism RACM (Stockwell et al., 1997; Geiger et al., 2003). All WRF-
87 Chem simulations for Europe in AQMEII phase 2 tended to underestimate ozone concentrations,
88 with annual average normalized mean bias ranging from -1.6 to -15.8 %, depending on the ensemble
89 member.

90 The purpose of the present study is to perform a detailed evaluation of meteorology and gas phase
91 chemistry simulated by WRF-Chem, including the spatial and seasonal variations over a full year
92 seasonal cycle using time-varying chemical boundary conditions. This evaluation is performed for
93 two different gas phase chemical mechanisms within WRF-Chem, MOZART- 4 (Emmons et al.,
94 2010) and RADM2 (Stockwell et al., 1990). As discussed above, the RADM2 mechanism has been
95 popularly used in WRF-Chem for simulation over Europe (Tuccella et al., 2012; Im et al., 2015). The
96 MOZART- 4 chemical mechanism has been widely used with WRF-Chem for regional air quality
97 applications outside of Europe (e.g., Pfister et al., 2013; Im et al., 2015). To the authors' knowledge,
98 however, WRF-Chem with MOZART- 4 has not yet been applied and evaluated over a European
99 domain.

100 The simultaneous evaluation of WRF-Chem with two different chemical mechanisms further al-
101 lows us to evaluate the sensitivity of O₃ and NO_x to the choice of chemical mechanism in a setup
102 where the differences in model physics and other parameters are minimized. This is in contrast to
103 the study of Im et al. (2015), where the various WRF-Chem ensemble members also used different

104 schemes for model physics. Coates and Butler (2015) recently investigated the sensitivity of the pro-
105 duction of odd oxygen (O_x , a proxy for production of O_3) to the choice of chemical mechanism using
106 a box model, and found that choice of chemical mechanism led to differences in O_3 concentrations
107 on the order of 10 ppb under idealized conditions, although differences between the MOZART- 4
108 and RADM2 chemical mechanisms tended to be closer to 5 ppb. In another box model study, Knote
109 et al. (2015) investigated the sensitivity of O_3 , NO_x , and other radicals to the different gas-phase
110 chemical mechanisms used in the models that contributed to the AQMEII phase-2 intercomparison
111 project. Knote et al. (2015) found that the choice of chemical mechanism is responsible for a 5%
112 uncertainty in predicted O_3 concentrations and a 25% uncertainty in predicted NO_x concentrations.

113 The present study builds on the work of Coates and Butler (2015) and Knote et al. (2015) by
114 comparing two chemical mechanisms within an online coupled regional air quality model. The use
115 of WRF-Chem provides an advantage in that it is compatible with multiple different chemical mech-
116 anisms, allowing us to test the effect of different chemistry with minimal confounding factors due to
117 differences in model physics, etc. Furthermore, the use of an online regional model rather than a box
118 model allows us to examine the sensitivity of model-predicted concentrations to the choice of chemi-
119 cal mechanism under more realistic conditions, in which variations in meteorology and dynamics are
120 fully included. Parameters such as radiation are allowed to vary realistically, and different chemical
121 regimes (NO_x - vs. VOC-limited) are present (e.g., in different seasons and in different parts of the
122 model domain).

123 Chemical mechanism comparisons have also been undertaken previously using 3-D regional air
124 quality models, though the majority have focused on comparing the SAPRC-99 mechanism (Carter,
125 1990) with versions of the Carbon Bond mechanism (Gery et al., 1989) over a U.S. domain (Luecken
126 et al., 2008; Faraji et al., 2008; Yarwood et al., 2003; Zhang et al., 2012). Two additional studies have
127 compared versions of the RACM mechanism with RADM2 (Mallet and Sportisse, 2006) and CB05
128 (Kim et al., 2010) using the model Polyphemus (Mallet et al., 2007) for a European domain. Typ-
129 ically, these studies found that simulations using two different chemical mechanisms led to differ-
130 ences in O_3 on the order of 5-10 ppb (Luecken et al., 2008; Zhang et al., 2012; Mallet and Sportisse,
131 2006; Kim et al., 2010), although extreme differences of 30-40 ppb were observed between SAPRC-
132 99 and CB-IV mechanisms when simulating high ozone episodes (Faraji et al., 2008; Yarwood et al.,
133 2003).

134 In this paper, the model configuration, including emissions and initial and boundary conditions, is
135 described in Section 2. A description of observational datasets for meteorology and chemistry and
136 the evaluation methodology is provided in Section 3. Results for the model evaluation and intercom-
137 parison of two chemical are presented in Section 4 followed by a summary and concluding remarks
138 in Section 5.

139 2 Model Description and Setup

140 2.1 WRF-Chem

141 This study utilizes the Weather Research and Forecasting with Chemistry (WRF-Chem) model
142 (<http://ruc.noaa.gov/wrf/WG11>) version 3.5.1. WRF-Chem has been developed collaboratively by
143 NOAA, DOE/PNNL, NCAR and other research institutes (<https://www2.acd.ucar.edu/wrf-chem>).

144 We defined our simulation domain on the Lambert projection. The model domain is centered at
145 15° E, 52° N, and covers nearly the entire European region. The horizontal resolution is chosen to
146 be 45 km × 45 km. The model domain has 115 and 100 grid points in the west-east and south-north
147 directions respectively.

148 We have used 35 vertical levels in the model starting from surface to 10 hPa. The lowest model
149 level corresponds to an approximate altitude of 50 m above the surface. Tests have shown that surface
150 layer concentrations in this configuration are effectively the same as when the lowest model level
151 is at a height of 14 m, but with no urban surface physics scheme (the urban physics scheme is
152 incompatible with a 14-m model level). Geographical data including terrain height, soil properties,
153 albedo, etc. are interpolated primarily from USGS (United States Geological Survey data (Wang
154 et al., 2014)) at 30 sec resolution. The land use classification has been interpolated from the CORINE
155 data (EEA, 2012) at 250 m resolution, which was then mapped to the USGS land use classes used
156 by WRF (see Kuik et al., 2016).

157 Model simulations are conducted for the period of 23 December 2006 to 31 December 2007.
158 The first week of output was treated as model spin up and has been discarded. The instantaneous
159 model output, stored every hour, has been used for the analysis. The different options used in this
160 study to parametrize the atmospheric processes are listed in Table 1. A namelist is available in the
161 Supplementary Material.

162 The initial and lateral boundary conditions for the meteorological fields were provided from the
163 ERA-interim reanalysis dataset available from ECMWF (<http://www.ecmwf.int/en/research/climate-reanalysis/era-interim>). This data is available every 6 hours with a spatial resolution of approximately 80 km
164 (T255 spectral). In order to limit the errors in the WRF simulated meteorology the Four Dimensional
165 Data Assimilation (FDDA) has been applied. In the FDDA, temperature is nudged at all the vertical
166 levels with a nudging coefficient of 0.0003. The horizontal winds are nudged at all the vertical levels,
167 except within the PBL, with the nudging coefficient of 0.0003. Sensitivity studies performed showed
168 that nudging of water vapor highly suppressed the precipitation over Europe in a manner inconsis-
169 tent with observations. As such, water vapor is not nudged in our simulations. This also follows the
170 approach of, e.g., Miguez-Macho et al. (2004) and Stegehuis et al. (2014). The nudging coefficients
171 for temperature and winds have been chosen following previous studies (Stauffer et al., 1991; Liu
172 et al., 2012). The time step for the simulations has been set at 180 s.

174 Initial and boundary conditions for chemical fields in WRF-Chem are used from the MOZART-
175 4/GEOS5 simulations (<http://www.acd.ucar.edu/wrf-chem/mozart.shtml>), with a horizontal resolu-
176 tion of $1.9^\circ \times 2.5^\circ$ and 56 pressure levels. MOZART- 4/GEOS-5 simulations use meteorology from
177 the NASA GMAO GEOS-5 model and emissions based on ARCTAS inventory ([http://www.cgrer.
178 uiowa.edu/arctas/emission.html](http://www.cgrer.uiowa.edu/arctas/emission.html)).

179 **2.2 Emissions**

180 Anthropogenic emissions of CO, NO_x, SO₂, NMVOCs, PM₁₀, PM₂₅, and NH₃ are used from the
181 TNO-MACC II emission inventory for Europe (Kuenen et al., 2014), for the year 2007. These emis-
182 sions are provided as yearly totals by source sector on a high-resolution (7 km × 7 km) grid. The
183 TNO-MACC II emission inventory is based on emissions reported by member countries to the Eu-
184 ropean Monitoring and Evaluation Program (EMEP), which are then further refined to fill gaps and
185 correct errors and obvious inconsistencies. Emissions are temporally disaggregated based on sea-
186 sonal, weekly and diurnal cycles provided by Denier van der Gon et al. (2011); Schaap et al. (2005).
187 These temporal profiles vary by source sector according to the SNAP (Selected Nomenclature for
188 Sources of Air Pollution) convention. NMVOC emissions are split into modeled NMVOC species
189 (e.g., ethane, aldehydes) based on von Schneidemesser et al. (2016). NO_x is emitted as 90% NO and
190 10% NO₂ by mole. Emissions are distributed into the first seven model vertical layers (the surface
191 and the first 6 model layers above the surface) based on sectoral averages from (Bieser et al., 2011),
192 although model runs showed little sensitivity to the distribution of emissions above the surface layer.

193 The model domain used in this study is larger than the European domain used in the TNO-
194 MACC II inventory (Kuenen et al., 2014). Emissions at our domain edges were filled using the
195 Hemispheric Transport of Air Pollution (HTAP v2.2) emission inventory for the year 2008 ([http:
196 //edgar.jrc.ec.europa.eu/htap_v2/index.php](http://edgar.jrc.ec.europa.eu/htap_v2/index.php)). The HTAP v2 data, described in detail by Janssens-
197 Maenhout et al. (2015), is harmonized at a spatial resolution of $0.1^\circ \times 0.1^\circ$ and available with
198 monthly time resolution. In our model simulations, no additional weekly or diurnal profiles were
199 applied to the HTAP v2 emissions. Furthermore, all emissions from HTAP were emitted into the
200 surface model layer. Because HTAP emissions were only used at the grid "edge," the differences in
201 temporal and vertical resolution of emissions used for HTAP is not expected to have a significant
202 impact on model results. An example of emissions processed for model input is shown Figure S1 in
203 the Supplementary Material.

204 Biomass burning emissions are from the Fire Inventory from NCAR (FINN), Version 1 (Wiedin-
205 myer et al., 2011). To avoid the double counting of emissions from agricultural burning (i.e., assum-
206 ing that the FINN product captures large-scale agricultural burning), emissions of the combustion
207 species CO, NO_x, and SO₂ from SNAP category 10 (Agriculture) in the TNO-MACC II inventory
208 were not included in model simulations, at the suggestion of H.A.C. van der Gon (personal commu-

209 nication, 2015). Biogenic Emissions are calculated online based on weather and land use data using
210 the Model of Emissions of Gases and Aerosols from Nature (MEGAN) (Guenther et al., 2006).

211 **2.3 Model Chemistry**

212 The two year-long WRF-Chem simulations performed for this study are summarized in Table 2. In
213 the MOZART simulation, gas phase chemistry is represented by the Model for Ozone and Related
214 chemical Tracers, version 4 (MOZART- 4) mechanism (Emmons et al., 2010). Tropospheric chem-
215 istry is represented by 81 chemical species, which participate in 38 photolysis and 159 gas-phase
216 reactions. The MOZART- 4 mechanism includes explicit representation of the NMVOCs ethane,
217 propane, ethene, propene, methanol, isoprene, and α -pinene. Other NMVOC species are represented
218 by lumped species based on the reactive functional groups. In the WRFV3.5.1 code, two bug fixes
219 have been included for the MOZART- 4 mechanism: the NH_3+OH rate coefficient has been cor-
220 rected following Knote et al. (2015), and a correction has been made to treatment of the vertical
221 mixing of MOZART- 4 species (A.K. Peterson, personal communication). In the WRF-Chem sim-
222 ulations, we use the version of MOZART- 4 coupled to the simple GOCART aerosols mechanism
223 (Ackermann et al., 1998b), known as the MOZCART mechanism. In this paper, we limit our anal-
224 ysis to gas-phase species. Because of this focus, and to simplify the interpretation the mechanism
225 intercomparison (see below), all aerosol radiative feedbacks (i.e., both direct and indirect effects) are
226 turned off in all model simulations in this study.

227 In the RADM2 simulation, gas phase chemistry is represented by the second generation Regional
228 Acid deposition Model (RADM2) (Stockwell et al., 1990). This mechanism has 63 chemical species
229 which participate in 21 photolysis and 136 gas phase reactions. The NMVOC oxidation in RADM2 is
230 treated in a less-explicit fashion than in MOZART, in which ethane, ethene and isoprene are the only
231 species treated explicitly and all other NMVOCs are assigned to lumped species based on OH reac-
232 tivity and molecular weight. In WRF-Chem, RADM2 is coupled to the MADE/SORGAM aerosol
233 module, which is based on the Modal Aerosol Dynamics Model for Europe (MADE) (Binkowski
234 and Shankar, 1995; Ackermann et al., 1998a) and Secondary Organic Aerosol Model (SORGAM)
235 (Schell et al., 2001). However, as noted above, in this study we focus our analysis on gas-phase
236 chemistry.

237 In both the RADM2 and MOZART simulations, the chemical mechanism code was generated
238 with the Kinetic Pre-Processor (KPP) (Damian et al., 2002; Sandu and Sander, 2006), and equations
239 are solved using a Rosenbrock-type solver. Note that when using RADM2 chemistry, there are two
240 different solvers available within WRF-Chem. We chose to use the KPP chemistry and Rosenbrock
241 solver to be consistent with the MOZART runs, and also because the alternative QSSA chemistry
242 solver has been shown to have problems representing NO_x titration (Forkel et al., 2015). In partic-
243 ular, the QSSA treatment of RADM2 chemistry was found to result in an under-representation of
244 nocturnal ozone titration for areas with high NO emissions.

245 **3 Observational datasets**

246 A summary of the observational datasets used for model evaluation can be found in Table 3.

247 **3.1 Meteorology**

248 Since WRF-Chem couples the meteorology simulations online with the chemistry, we begin by eval-
249 uating the modeled meteorological fields against observations which are driving the simulations of
250 chemical fields. In this study, the WRF-Chem simulated meteorological fields are evaluated against
251 the in situ measurements of mean sea level pressure (MSLP), 2-meter temperature (T2) and 10-meter
252 wind speed and direction (WS10 and WD10, respectively) from the Global Weather Observation
253 dataset provided by the British Atmospheric Data Center (BADC). We chose these meteorologi-
254 cal variables for the evaluation as these are expected to have the most significant influence on the
255 gas-phase chemistry, which is the main focus of this study.

256 **3.2 Chemistry**

257 **3.2.1 EMEP Network**

258 The EMEP observational dataset provides surface measurements of pollutant concentrations, in-
259 cluding tropospheric ozone and its precursors, at stations chosen to be representative of regional
260 background pollution (see, e.g., Tørseth et al., 2012). The regional focus is in keeping with the goals
261 of the Convention on Long-range Transboundary Air Pollution (CLRTAP), under which this network
262 is administrated.

263 **3.2.2 AirBase Network**

264 AirBase is the public air quality database of the European Environmental Agency (EEA), and repre-
265 sents a much denser network of monitoring than the EMEP network ([http://www.eea.europa.eu/data-
266 and-maps/data/airbase-the-european-air-quality-database-7](http://www.eea.europa.eu/data-and-maps/data/airbase-the-european-air-quality-database-7)). Because of the relatively coarse hori-
267 zontal resolution in this model study, model output is only compared against AirBase stations that
268 are classified as "rural background." The station classification was taken from the metadata provided
269 by the EEA for AirBase. Some AirBase stations are also part of the EMEP network; the subset of
270 AirBase stations used in this study exclude any stations that are also part of the EMEP network
271 (since they are already included in the evaluation against EMEP observations).

272 **3.3 Evaluation methodology**

273 Stations were excluded from our season-by-season analysis if the temporal coverage was less than
274 75%, i.e., if missing or flagged hourly (or 3-hourly) data represented more than 25% of the hourly
275 (or 3-hourly) time series over the entire season. For sensitivity studies that consider the month of

276 July only, stations were considered that had at least 75% temporal coverage for the month. This
 277 criteria was applied for all meteorological and chemistry observations. For comparison of model
 278 output to in situ observations, the model gridcell that is closest to the latitude, longitude location
 279 of the measurement station was chosen. Statistics calculated include the mean, mean bias (MB),
 280 normalized mean bias (NMB), mean fractional bias (MFB) and the temporal correlation coefficient
 281 (r). The domain-wide statistics presented in Tables 4 - 9 were calculating by first calculating the
 282 statistical quantity hour-by-hour at each station, and then averaging these values over all times (in
 283 the season) and all stations. Definitions of calculated statistical quantities can be found in Appendix
 284 B. When applying these statistics to wind direction, wind direction was treated as a scalar quantity,
 285 when in fact it is a vector. This simple approach was favored rather than applying a correction (as
 286 done by, e.g., Zhang et al. (2013a) in cases where the difference in modeled vs. observed wind
 287 direction were greater than 180°). This is not expected to make an important impact on our analysis,
 288 especially since northerly winds (i.e., centered around 0° , or equivalently 360°) are not prevalent in
 289 Europe (see Figure 3 and Figure S2 in the Supplementary Material).

290 From hourly concentrations of O_3 , both observed and modeled, additional ozone metrics for
 291 health impacts are calculated. MDA8 is defined as the maximum daily 8-hour mean ozone, in ac-
 292 cordance with the European Union's Air Quality Directive. Note that, for calculation of MDA8,
 293 a missing value was assigned if one or more hours of data in the 8-hour average were missing.
 294 SOMO35 is an indicator of cumulative annual ozone exposure used in health impact assessments.
 295 The accumulated health impact is assumed to be proportional to the sum of concentrations above
 296 a cutoff of 35 ppb, chosen because the relationship between O_3 and adverse effects is very uncer-
 297 tain below this threshold (WHO, 2013). Mathematically, SOMO35 is defined as the sum of MDA8
 298 levels over 35 ppb ($70 \mu\text{g m}^{-3}$) over a year, in units of concentration-days, following Amann et al.
 299 (2008).

$$300 \quad \text{SOMO35} = \frac{365}{N_{\text{valid}}} \sum_{\text{iday}} \max(0, C_{\text{iday}} - 70 \mu\text{g m}^{-3})$$

301 where N_{valid} is the number of valid (i.e., non-missing) daily values.

302 **4 Results and Discussion**

303 **4.1 Evaluation of Meteorology**

304 Table 4 shows a summary of domain-wide statistics evaluating the MOZART model simulation
 305 against observations of meteorological variables MSLP, T2, WS10 and WD10; the spatial distri-
 306 bution of these statistics shown in Figures 1-3 for temperature and wind variables. Differences in
 307 predicted meteorology between the MOZART and RADM2 simulations are small, with differences
 308 in MSLP less than one hundredth of 1%, and differences in T2, WS10, and WD10 generally far
 309 below 1%. Since the simulations were run without aerosol-radiative feedbacks, it was expected that

310 the two simulations would show minimal differences in meteorology, and we conclude that differ-
311 ences in O_3 and NO_x predicted in the MOZART and RADM2 simulations (Section 4.2) are a direct
312 result of differences in the chemistry, rather than chemistry-radiative feedbacks. Statistics for me-
313 teorology for the RADM2 simulation can be found in the Supplementary Material, Table S1 and
314 Figures S4-S7.

315 MSLP has been reproduced over the entire European domain with a high degree of skill in every
316 season for both simulations, with negligible bias (domain-averaged NMB and MFB are zero in all
317 seasons) and temporal correlation coefficients (r values) of 0.98 or greater (see also Figures S3 and
318 S7 in the Supplementary Material).

319 The spatial distribution of seasonal average T2 in the model and observations is shown in Figure 1,
320 along with the spatial variation in mean bias and temporal (3-hourly) correlation. Overall, the spatial
321 variability in measured T2 is found to be well-reproduced by WRF-Chem during all the seasons. The
322 absolute values of mean biases in T2 were generally found to be lower than $1^\circ C$. Larger biases in T2
323 can be found in the Alps, in particular during winter, where T2 is often overpredicted by more than
324 $1^\circ C$ (Figure 1). This larger bias over mountainous regions, also found in a previous study (Zhang
325 et al., 2013a), is likely due to the complex mountain terrain and related unresolved local dynamics.
326 The r values are generally found to be more than 0.9 in all the seasons and show no significant
327 geographical variation, indicating that the model is able to reproduce the hourly variations in near
328 surface temperature. Averaged over the entire domain, the mean bias in T2 varies from -0.4 to +
329 $0.3^\circ C$ depending on the season (Table 4).

330 The spatial variability in wind speeds, including the seasonality, with strongest winds during the
331 winter, have been reproduced by the model (Figure 2). However, the model tends to overestimate
332 winds speeds with larger biases (2 m/s or more) during the winter and fall. The regions showing
333 greater bias in wind speed include the Alps, coastal regions, and the low-lying areas of northern
334 Germany and Denmark (Figure 2). The temporal correlation of wind speed is generally above 0.7 in
335 the northern half of the domain, but is lower (0.4-0.6) in the southern part of the domain, in areas
336 in the Alps and close to the Mediterranean (Figure 2). Similar behavior for modeled wind speed is
337 reported by Zhang et al. (2013a), who attributes the overestimation in wind speeds primarily to poor
338 representation of surface drag exerted by unresolved topographical features, which results in model
339 limitations in simulating circulation systems such as sea breeze and bay breeze. An overview of the
340 statistics for wind direction is presented in Table 4, with the spatial distribution shown in Figure 3.
341 Wind direction over the continent is predominantly from the west and south, and the mean bias in
342 wind direction is between 20 and 30 degrees depending on the season. Similar to the patterns seen
343 for wind speed, areas with complex topography (the Alps, the Balkans, the Mediterranean coast)
344 show the largest biases and the lowest correlations for wind direction.

345 Overall, we find that WRF-Chem is capable of reproducing the spatial and temporal variations
346 in the European meteorological conditions reasonably well, in a manner consistent with previous
347 studies (e.g. Zhang et al., 2013a).

348 4.2 Evaluation of Chemistry

349 4.2.1 Ozone

350 We begin the evaluation of chemistry by examining the seasonal average surface O_3 distribution
351 over Europe from the MOZART simulation, as shown in Figure 4. Predicted surface O_3 distributions
352 show a clear seasonality, with maximum concentrations during summer. In all seasons, surface O_3
353 concentrations are highest over the Mediterranean region, with values during the spring and summer
354 greater than $110 \mu\text{g m}^{-3}$. Simulated concentrations reproduce the north-south gradient in O_3 seen
355 in the ground-based observations. Figure 5 provides another comparison of seasonal average O_3
356 distributions in the model vs. the observations (from both the AirBase and EMEP networks) and
357 additionally shows the spatial distribution of MB and r, the temporal (hourly) correlation coefficient;
358 performance statistics are shown in Table 5 (against observations from the AirBase network) and
359 Table 6 (against observations from the EMEP network). MOZART overpredicts O_3 concentrations
360 for most of Europe in the summer and fall. In winter and spring, MOZART tends to underestimate O_3
361 in north-central Europe, but overestimate O_3 in southern Europe. Hourly correlation coefficients for
362 O_3 are highest (greater than 0.6) in northern Europe (especially France, Germany, and the Benelux
363 region) and in Spain, but are lower (with values of approximately 0.4) throughout Italy and the
364 mountainous regions of the Alps. Notably, Italy and the Alps are the regions within our domain
365 that exhibit the highest biases and lowest correlations with respect to wind direction and speed
366 (Section 4.1), which could explain the poorer temporal correlation for O_3 in these areas.

367 Looking at Tables 5 and 6, we see some differences in the statistical performance of the MOZART
368 simulation when compared to the EMEP vs. the AirBase observational datasets. Considering the
369 EMEP observations over the whole domain (Table 6), MOZART slightly overpredicts O_3 in sum-
370 mer, with a summertime mean bias of $4 \mu\text{g m}^{-3}$, whereas the summertime mean bias when compared
371 the AirBase network is $10 \mu\text{g m}^{-3}$ (Table 5). In winter and spring, the bias (MB, NMB, and MFB)
372 in MOZART-predicted O_3 is more negative when compared to EMEP observations than to AirBase
373 observations. In fall, the sign of the domain-average bias changes if considering the model perfor-
374 mance against EMEP vs. AirBase observations. These differences likely reflect differences in the
375 character of the two observational networks. First, we expect that the Airbase rural background sites
376 considered here may be, on average, more influenced by local pollution sources than the EMEP
377 sites, which are selected to be representative of more remote regional background. Secondly, the ge-
378 ographical coverage of AirBase vs. EMEP sites for O_3 is slightly different (Figure S8). In particular,
379 coverage of the U.K. and the Nordic countries is almost exclusively via the EMEP network, poten-

380 tially giving the EMEP observations a northern bias in comparison to the AirBase-only sites. Both
381 features of the measurement networks could explain the lower values of the domain-wide average
382 O_3 observed at the EMEP vs. the AirBase stations.

383 In addition to evaluating the model's ability to simulate hourly O_3 concentrations, we also con-
384 sider MDA8 and SOMO35, two metrics designed to evaluate the impact of ozone on health. The
385 distribution of seasonal average values of MDA8 is shown in Figure 6 for the MOZART simulation.
386 The European Union's Air Quality Directive states that, as a long-term objective, MDA8 should not
387 exceed the threshold value of $120 \mu\text{g m}^{-3}$; as a target value this long-term objective should not be
388 exceeded on more than 25 days per year, averaged over 3 years. Figure 6 shows that, at some stations
389 in the Alps and in southern Italy during summer, the average value of MDA8 exceeds $120 \mu\text{g m}^{-3}$.
390 As seen in Figure 7, the number of days when MDA8 exceeds the $120 \mu\text{g m}^{-3}$ is greater than 25 in
391 spring alone for much of southern Europe, which is also captured well by the MOZART simulation.
392 MOZART tends to overpredict MDA8 and the days in exceedance of the target value in summer and
393 fall, consistent with the overestimation of hourly average O_3 during this season. Since the metric
394 MDA8 is, in effect, a measure of daytime ozone, it is always higher than the straight average of
395 hourly concentrations. As a consequence, MOZART shows greater bias in MDA8 than in average
396 O_3 in seasons where average O_3 is already overpredicted (Tables 5 and 6). In general, regional and
397 seasonal patterns for MDA8 simulated by MOZART are similar to those for simulated average O_3 .
398 SOMO35, an indicator for cumulative annual exposure, is shown in Figure 8 for the year 2007.
399 MOZART is able to reproduce the north-south gradient of SOMO35 seen in the observations quite
400 well, while overpredicting the magnitude of SOMO35 by $2 \text{ mg m}^{-3} \cdot \text{days}$ (Table 7).

401 WRF-Chem simulations using the RADM2 chemical mechanism show a spatial and seasonal
402 distribution of surface O_3 over Europe (Figures 9 and 10) that is qualitatively similar to that for
403 MOZART. The correlation coefficients for the MOZART and RADM2 simulations are also similar
404 in both magnitude in distribution (Figures 5 and 10). Absolute O_3 concentrations are most similar
405 (i.e., less than 5% different) between the mechanisms near the northwest edges of the domain (see
406 Figures 4 and 9), where the prevailing westerly winds (Supplementary Material, Figure S2) mean
407 that O_3 imported from the boundary conditions plays a dominant role. However, it is striking to
408 note that the surface O_3 concentrations predicted by two different chemical mechanisms are gen-
409 erally quite different, with RADM2 predicting average surface O_3 values that are approximately
410 $20 \mu\text{g m}^{-3}$ lower than those predicted by MOZART in spring and summer (c.f. Figures 4 and 9,
411 Tables 5 and 8, and Tables 6 and 9). In contrast to MOZART, RADM2 underpredicts O_3 through-
412 out most of Europe in all seasons. An exception to this is in southern Europe in winter, where
413 RADM2, like MOZART, shows some overprediction of O_3 concentrations in southern Europe, par-
414 ticularly near the Mediterranean. RADM2 also overpredicts O_3 near the Mediterranean in fall (a
415 season where MOZART overpredicts O_3 Europe-wide). The general underprediction of O_3 con-
416 centrations in RADM2 means that the health metrics MDA8 and SOMO35 are also underpredicted

417 (Tables 7- 8 and Figure 8). Overall, absolute biases (i.e., the absolute value of MB, NMB, and MFB)
418 are smaller for MOZART than for RADM2, indicating that MOZART is more successful overall in
419 reproducing European ground-level O₃.

420 Model biases for O₃ in both the MOZART and RADM2 simulations are in line with biases found
421 in other regional modeling studies for Europe. For instance, values for the NMB in European sum-
422 mertime O₃ ranged from less than -20% to greater than +20% depending on the ensemble member
423 in AQMEII (Solazzo et al., 2012b; Im et al., 2015), compared to values of -18% and +14% for the
424 RADM2 and MOZART simulations, respectively, in the present study. Zhang et al. (2013b) found
425 domain-wide values for NMB for O₃ ranging from +4.2% to +19.1% for the month of July 2001,
426 depending on their model configuration. Tuccella et al. (2012) report a domain-average mean bias in
427 O₃ of -1.4 μg m⁻³ averaged over the whole year. Although the work of Tuccella et al. (2012) uses
428 the RADM2 chemical mechanism and simulates the year 2007, similar to the RADM2 simulation in
429 the present study, there are several differences in model configuration that could explain the observed
430 differences in predicted O₃, including the use of time-invariant chemical boundary conditions, the
431 use of the QSSA rather than the Rosenbrock chemical solver (which has been shown to make a
432 difference Forkel et al. (see 2015)), and the use of an alternate emissions inventory (from EMEP).

433 The temporal correlation with hourly measurements for O₃ in this study are also in line with
434 other regional modeling studies of O₃ for Europe. Simulations with both chemical mechanisms lead
435 to reasonable correlations between the model-predicted and observed O₃ concentrations over the
436 entire domain, with r values generally in the range of 0.6-0.8 (Figures 5 and 10, Tables 5 and 8).
437 This is consistent with the hourly correlation coefficient for O₃ of 0.62 reported by Tuccella et al.
438 (2012), where their r value represents an average over the entire year of 2007. Zhang et al. (2013b)
439 also report correlation coefficients of 0.6-0.7 for hourly O₃ over the European domain (horizontal
440 resolution 0.5°) using the CB05 gas-phase chemical mechanism in WRF-Chem.

441 In addition to evaluating the performance of the MOZART and RADM2 simulations on their abil-
442 ity to reproduce ground-level ozone concentrations, we compare the observed sensitivity of modeled
443 O₃ to the choice of chemical mechanism to other studies that have investigated the uncertainty in 3-D
444 model predictions associated with the choice of chemical mechanism. Knote et al. (2015) used box
445 model simulations based on AQMEII phase 2, and concluded that the uncertainty in predicted O₃ in
446 a 3-D model solely due to the choice of gas phase chemical mechanism should be of the order of 5%,
447 or 4 ppbv (8 μg m⁻³). This is quite a bit smaller than the sensitivity to chemical mechanism found
448 in this study, where we see differences in summertime average O₃ of 20 μg m⁻³, corresponding to a
449 relative difference of approximately 40%. Coates et al. (2016) have shown that adding representation
450 of stagnant conditions (which were not represented in Knote et al. (2015)) to a box model increased
451 the sensitivity of predicted O₃ to the chemical mechanism, and also improved model agreement
452 with observations. This result suggests that day-to-day variability in meteorological conditions and

453 transport can enhance the sensitivity of O_3 to chemical mechanism compared to what is seen in box
454 models.

455 Another interesting basis for comparison is the study of Mallet and Sportisse (2006), who investi-
456 gate uncertainty in the CTM Polyphemus due to various physical parameterizations, including chem-
457 ical mechanism (comparing RACM and RADM2), using an ensemble approach. They estimated an
458 overall uncertainty in O_3 concentrations of 17% based on choices for physical parameterizations in
459 general, but identified the choice of chemical mechanism along with the turbulent closure parame-
460 terization as the two most important drivers of this uncertainty. Simulations using the RACM vs.
461 RADM2 mechanisms yielded differences in average O_3 concentrations of 7-13 $\mu\text{g m}^{-3}$, depending
462 on the other parameterizations used. It is clear that the sensitivity of O_3 to the use of the MOZART
463 vs. RADM2 chemical mechanism in this study is large compared to other studies of mechanism
464 comparisons in 3-D models (see also Luecken et al., 2008; Kim et al., 2010)), though even larger
465 absolute differences in hourly O_3 concentrations (up to 40 ppb, or 80 $\mu\text{g m}^{-3}$) have been found in
466 studies of episodic ozone (Faraji et al., 2008; Yarwood et al., 2003). It is possible that MOZART
467 and RADM2 as implemented in this study are examples of chemical mechanisms that are extremely
468 different from one another on a spectrum of other commonly-used mechanisms; the differences be-
469 tween the two mechanisms will be further explored in Section 4.3.

470 **4.2.2 Nitrogen oxides**

471 Seasonal average surface-level NO_x for the MOZART simulation are shown in Figure 11. Several
472 hotspots in the spatial distribution of NO_x mixing ratios are apparent, as expected based on the
473 intensity of emissions in these areas. NO_x hotspots with concentrations of more than 30 $\mu\text{g m}^{-3}$
474 are visible over parts of France, Belgium, Germany and Russia. Similar high concentrations are
475 also seen over the marine regions close to Barcelona, Monaco, and southern France. As shown
476 in Table 5, the MOZART simulation slightly underpredicts domain-average NO_x concentrations
477 for all seasons when comparing to AirBase observations. In Figures 12 and 13 we examine the
478 spatial distribution of NO_x broken down into its components, NO_2 and NO , together with the spatial
479 distribution of MB and r. The MOZART simulation overestimates NO_2 in the U.K., northern France,
480 Belgium, and central Germany, all of which are regions known for having high NO_x emissions and
481 concentrations. However this does not hold true for the Netherlands, a neighboring region with high
482 emissions where MOZART tends to underpredict rather than overpredict NO_2 concentrations. NO ,
483 on the other hand, is significantly underpredicted compared to surface measurements throughout
484 the domain. This may be partially due to the relatively coarse horizontal resolution of the model, in
485 which fresh NO emissions are immediately diluted over a large area, and could also be a consequence
486 of model deficiencies in representing NO_x chemical cycles. Artifacts related to reporting of low
487 NO concentrations approaching measurement detection limits could also play a role (observed time

488 series for NO typically show a baseline of 1-2 $\mu\text{g m}^{-3}$, whereas modeled concentrations reach a
489 baseline of zero).

490 Domain average temporal correlation coefficients (r) against hourly measurements of NO_x , NO_2 ,
491 and NO (Tables 5 and 6) range from approximately 0.2 to 0.5, which is lower than correlations for
492 O_3 but consistent with other studies, discussed further below. In all seasons, the domain-averaged
493 temporal correlation coefficient is higher when compared to EMEP vs. AirBase observations. This
494 is attributed to lesser local influences and therefore better regional representativeness of the EMEP
495 stations. No exceptional patterns are seen in the spatial distribution of r for NO_2 or NO, although
496 correlation appears slightly better in the northern part of the domain. The MOZART simulation
497 shows the highest domain-average correlation coefficients (r) for NO_x , NO_2 , and NO in winter and
498 fall, and the lowest domain-average r values in summer.

499 NO_x predicted by the RADM2 simulation shows fairly similar behavior to NO_x predicted by
500 the MOZART simulation (cf. Figures 12 and 14 and additional Figures S10-S11 in the Supple-
501 mentary Material). In general, simulated NO_x concentrations are slightly higher for MOZART than
502 for RADM2. Domain-wide average NO_x concentrations predicted by MOZART are approximately
503 2 $\mu\text{g m}^{-3}$ higher than for RADM2 in all seasons except winter, where the difference is approximately
504 3 $\mu\text{g m}^{-3}$ (cf. Tables 5 and 8). The spatial distribution of MB for NO_2 for the RADM2 simulation
505 generally shows the same patterns as observed for the MOZART simulation, namely a slight over-
506 estimation in the U.K., northern France, Belgium, and central Germany. Like for MOZART, NO
507 for RADM2 is underpredicted throughout the domain, with NO concentrations slightly more neg-
508 atively biased than in MOZART in all seasons except Fall, when NO concentrations are higher for
509 RADM2 than for MOZART and show better agreement with the observations. Temporal correlation
510 for NO_2 and NO in RADM2 is also found to show similar behavior to the MOZART simulation.
511 An exception to the similarity observed between the mechanisms for NO_x can be seen over central
512 Germany in winter, where MB values for NO_2 are 6-10 $\mu\text{g m}^{-3}$ for MOZART (Figure 12), but in the
513 range of 0-6 $\mu\text{g m}^{-3}$ for RADM2 (Figure 14). Differences in NO_x concentrations predicted by the
514 MOZART vs. RADM2 simulations are generally less than 20%, consistent with Knote et al. (2015),
515 who conclude that uncertainty due to choice in chemical mechanism leads to an uncertainty of up to
516 25% in 3-D model simulations.

517 Performance of the present simulations with respect to NO_2 can also be compared to previous
518 published studies (note that none of the above-cited studies perform a validation for NO or NO_x).
519 Zhang et al. (2013b) reports NMB values of approximately -15% for NO_2 for WRF-Chem simu-
520 lations against hourly AirBase measurements for July 2001, in line with values of -12% and -19%
521 for the MOZART and RADM2 simulations in this study, respectively. Tuccella et al. (2012) report a
522 MB for NO_2 of -0.9 $\mu\text{g m}^{-3}$ averaged over the whole year; for comparison the RADM2 simulation
523 in this study shows a MB in the range of -2.5 to -1 $\mu\text{g m}^{-3}$ for fall, spring and summer, but a MB of

524 $+0.67 \mu\text{g m}^{-3}$ in summer. Evaluation of NO_2 was not treated in detail in the AQMEII studies, but
525 Im et al. (2015) report that the models for the European domain underestimate NO_2 by 9% to 45%.

526 **4.3 Characterization of MOZART vs. RADM2 differences**

527 In this section, we explore the differences in surface O_3 between the MOZART and RADM2 simula-
528 tions by examining net O_3 , NO_2 , and NO production rates as well as the NO_x - and VOC-sensitivity
529 of the two mechanisms. We further conducted sensitivity simulations to investigate the relative con-
530 tributions of different sources to the observed differences in surface O_3 predicted by MOZART and
531 RADM2. The month of July was chosen for the sensitivity simulations since O_3 concentrations over
532 Europe are highest during summer, and thus summer is most the most important season when con-
533 sidering air quality exceedances and health impacts of O_3 . Additionally, MOZART and RADM2
534 show the largest differences in predicted O_3 during this season (see Tables 5 and 8).

535 To gain insight into model behavior for O_3 , we added terms to the model output representing
536 hourly accumulated tendencies, i.e., the change in concentration of a species due to photochemistry
537 only, for July simulations using MOZART and RADM2. The hourly net photochemical production
538 rate was calculated as the difference in the accumulated tendency from one timestep to another. Fig-
539 ure 15 shows the average of the midday (11:00-14:00 CEST, or 9:00-12:00 UTC) photochemical
540 production rate of O_3 and NO_x components for both the MOZART and RADM2 simulations. (Note
541 that the net photochemical production rate is shown here in ppb hr^{-1} for more intuitive comparison
542 of production and loss of the different species on a mole basis; $\mu\text{g m}^{-3}$ was used in Section 4.2 be-
543 cause this is the unit in which limit and target values in the EU Air Quality Directive are expressed.)

544 Overall, the spatial variability as well as the magnitudes of net O_3 production rates are found to
545 be similar for MOZART-4 and RADM2 chemistry (Figure 15). For both mechanisms, the greatest
546 midday net O_3 production rates are found in southern Europe, particularly over the Mediterranean
547 and Atlantic coasts. The difference in net O_3 production rate between the two mechanisms is also
548 shown in Figure 15. MOZART exhibits greater net O_3 photochemical production rates than RADM2
549 for most of Europe, with the exception of the southeast corner of the domain (Greece, Turkey, and
550 the nearby Mediterranean), where net O_3 production rates are greater for RADM2. The difference
551 in net O_3 production rate (MOZART-RADM2) shows a large maximum over central Europe, cen-
552 tering over Germany and extending west and east into France and Poland. Over Germany, net O_3
553 production in MOZART is seen to be higher than in RADM2 by 1.8 ppb hr^{-1} or more.

554 As expected, regions of high NO_2 production in both MOZART and RADM2 simulations are seen
555 over the high NO_x -emission regions including Benelux, southern England, western Germany, the
556 Po Valley, and major cities including Paris and Moscow. The difference in net NO_2 production rate
557 between the two mechanisms is also highest where the absolute NO_2 production rates are highest;
558 in these areas the net NO_2 production rate is lower for MOZART than for RADM2 by greater than
559 0.25 ppb hr^{-1} . Furthermore, areas where the two mechanisms show the greatest differences in net

560 NO₂ production rate tend to be the areas where the net O₃ production rate is most different between
561 the two mechanisms, including the large maximum over the Netherlands and northwest Germany.

562 To further investigate the differences between ozone chemistry in MOZART vs. RADM2, we
563 performed two additional sensitivity studies with each mechanism: one in which all anthropogenic
564 NO_x emissions were increased by 30%, and one in which all anthropogenic VOC emissions were
565 increased by 30%. We then examined the change in O₃ concentrations due to these emission per-
566 turbations to diagnose whether the chemical mechanisms were operating in a NO_x-sensitive or a
567 VOC-sensitive regime. Results are shown in Figure 16. For the simulations where NO_x emissions
568 were increased by 30%, MOZART and RADM2 show very similar behavior. Most of the domain
569 is NO_x sensitive, with increased NO_x emissions resulting in increased modeled O₃. Notably, the
570 U.K., Benelux, northern France and Paris, and northwest Germany show NO_x-saturated behavior,
571 in which increased NO_x emissions lead to decreased O₃ concentrations. NO_x-saturated regimes are
572 also seen around the area of the Mediterranean between Monaco, Genoa and Corsica. An alternate
573 approach to identify areas of NO_x-sensitive vs. NO_x-saturated regimes is to use indicator ratios (in
574 the base simulation) following Sillman (1995). We have applied this approach with the indicator ratio
575 CH₂O/NO_y (Figure S12) and find that areas identified as NO_x sensitive using the indicator ratio are
576 the same as those identified using the simulation with +30% NO_x emissions. These results are also
577 consistent with the areas of Europe found to be NO_x saturated in the model study of Beekmann and
578 Vautard (2010). Magnitudes of the observed change in O₃ in response to increased NO_x emissions
579 are quite similar for both mechanisms, although RADM2 shows slightly stronger NO_x saturation
580 (i.e., a stronger decrease in O₃ given a 30% increase in NO_x emissions) in the area centered around
581 Benelux, and stronger NO_x sensitivity over Scandinavia and northwest Russia.

582 In contrast to the similar behavior seen for NO_x sensitivity, the VOC sensitivity exhibited by the
583 two mechanisms is quite different (Figure 16, lower panel). For both MOZART and RADM2, the
584 effect of increased anthropogenic VOC emissions on O₃ is smaller than the effect of increased NO_x
585 emissions. The MOZART simulation shows very little impact of increased VOC emissions on O₃,
586 with differences in average O₃ concentration generally confined to ± 2% of the base simulation.
587 In contrast, increasing VOC emissions in the RADM2 simulations leads to increased O₃ concentra-
588 tions throughout nearly the entire domain. Areas where MOZART and RADM2 are in agreement in
589 predicting VOC sensitivity (increased O₃ concentrations in response to increased VOC emissions)
590 are generally those with high NO_x emissions, where one would expect the highest VOC sensitivity
591 based on theory; these areas include Benelux, northern France, northwest Germany, and shipping
592 tracks in the Mediterranean. However, the increase in O₃ concentration is modest for both mecha-
593 nisms; for RADM2 it is generally limited to increases of 2-4% over the base simulation. The results
594 of the +30% VOC sensitivity studies for July indicate that d[O₃]/d[VOC] is higher (more positive)
595 for RADM2 than for MOZART for the chemical regime represented by the models in July 2007.
596 This shows that the two mechanisms are simulating different O₃ chemical regimes – in the case of

597 RADM2, there is greater VOC sensitivity, meaning that addition of VOC emissions moves the chem-
598 istry in the direction of maximum O₃ production efficiency; this is not the case for MOZART over
599 much of the domain. A more extensive study would be needed to evaluate whether the conclusion
600 that $d[\text{O}_3]/d[\text{VOC}]$ is higher for RADM2 than for MOZART can be applied more generally.

601 Taken as a whole, Figure 16 shows that MOZART behaves in a classically NO_x-sensitive manner
602 for most of domain, with O₃ responding to changes in NO_x but showing little response to changes
603 in anthropogenic VOC. NO_x-saturated behavior is also observed, particularly around the area of
604 U.K., Benelux, and northern France and Germany. RADM2, on the other hand, exhibits more of
605 a mixed NO_x- VOC-sensitivity for much of the domain. The NO_x sensitivity seen in RADM2 is
606 very similar to that seen in MOZART, but the response of RADM2 to changes in VOC is much
607 stronger (by about a factor of two) than observed in MOZART. With the exception of some small
608 areas in the North and Baltic Sea south of Norway and Sweden, RADM2 predicts O₃ increases
609 with VOC increases throughout the entire domain. This difference in VOC sensitivity seen between
610 the mechanisms has implications for policy decisions, as it indicates uncertainty in the European
611 response of O₃ to policies designed to reduce anthropogenic VOC emissions.

612 In addition to characterizing mechanism behavior with respect to net photochemical O₃ produc-
613 tion and NO_x- and VOC-sensitivity, we evaluate the contribution of other sources that could ex-
614 plain the large differences in predicted O₃ between the MOZART and RADM2 simulations. First,
615 MOZART and RADM2 use different rate coefficients for several inorganic gas phase chemical re-
616 actions. To test the effect of these differences, all RADM2 inorganic reaction rate coefficients were
617 changed so that they matched those used in MOZART simulations in the cases where the reactions
618 are the same in both mechanisms (Section S3 in the Supplementary Material). The differences in
619 inorganic rate coefficients between the two mechanisms explain a significant difference in predicted
620 O₃ concentrations: when RADM2 is run with inorganic rate coefficients from MOZART, the result-
621 ing domain-mean O₃ is higher by more than 8 μg m⁻³ for the month of July, approximately 40% of
622 the difference in predicted O₃.

623 Besides the gas-phase chemistry itself, there are some differences in the implementation of MOZART-
624 4 vs. RADM2 in WRF-Chem that could also contribute to the observed differences in modeled O₃:
625 in particular, in the treatment of dry deposition and photolysis (described in the Supplementary Ma-
626 terial, Section S2). To test the effect of differences in treatment of dry deposition, we conducted
627 an additional sensitivity in which we modified the RADM2 simulation to treat dry deposition in
628 the same way as it is treated in MOZART. However, this led to only a small difference in average
629 ozone (an increase of 1 μg m⁻³), indicating that modeled surface O₃ concentrations are relatively
630 insensitive to these differences in the treatment of dry deposition, at least in the summer. In a sen-
631 sitivity test where we modified the model code so that the MOZART simulation ran with the same
632 photolysis scheme as used in our RADM2 simulation (i.e., with the Madronich TUV scheme and
633 without reading in climatological O₃ and O₂ columns), we found that average O₃ for July decreases

634 by $3 \mu\text{g m}^{-3}$. This indicates that modeled O_3 is also somewhat sensitive to differences in the treat-
635 ment of photolysis in MOZART and RADM2. However, taken together, our sensitivity simulations
636 suggest that the differences in the inorganic reaction rate coefficients are more important than the
637 differing treatments of dry deposition and photolysis in explaining the differences in predicted O_3
638 between the RADM2 and MOZART simulations.

639 **5 Summary and Conclusions**

640 In this paper, we present a detailed description of a WRF-Chem setup over the European domain
641 and provide an evaluation of the simulated meteorological and chemical fields with an emphasis
642 on model's ability to reproduce the spatial and temporal distribution of ground-level O_3 and NO_x .
643 Within WRF-Chem we compare the performance of two different chemical mechanisms: MOZART-
644 4, for which we present the first model evaluation for a European domain, and RADM2. Overall, we
645 found that our WRF-Chem setup reproduced the spatial and seasonal variations in the meteorological
646 parameters over Europe, with biases and correlations consistent with previous studies. Simulations
647 using the MOZART- 4 as well as RADM2 chemical mechanisms were found to reproduce the spatial
648 and temporal distributions in ground-level O_3 over Europe, based on observations from the EMEP
649 and Airbase networks. However, we find significant differences in O_3 concentrations predicted by the
650 two chemical mechanisms, with RADM2 predicting as much as $20 \mu\text{g m}^{-3}$ less O_3 than MOZART
651 during the spring and summer seasons. In general, MOZART- 4 chemistry overpredicts O_3 concen-
652 trations for most of Europe in the summer and fall, whereas RADM2 leads to an underestimation of
653 O_3 over the European domain in all seasons. Taken as a whole, use of MOZART- 4 chemistry per-
654 forms better, leading to lower absolute model biases in O_3 . This is the case when considering hourly
655 O_3 concentrations as well as metrics relevant for human health, such as MDA8 and SOMO35. De-
656 spite the large differences in predicted O_3 , the two mechanisms show relatively similar behavior for
657 NO_x , with both MOZART and RADM2 simulations resulting in a slight underestimation of NO_x
658 compared to surface observations.

659 The net midday photochemical production rate of O_3 in summer is found to be higher for MOZART
660 than for RADM2 for most of the domain, with the largest differences between the mechanisms seen
661 over Germany, where the net O_3 photochemical production for MOZART is higher than for RADM2
662 by greater than 1.8 ppb hr^{-1} ($3.6 \mu\text{g m}^{-3} \text{ hr}^{-1}$). However, we have shown that RADM2 is approx-
663 imately twice as sensitive to increases in anthropogenic VOC emissions as MOZART, suggesting
664 that, under local VOC-limited conditions not seen at the regional scale of our simulations, RADM2
665 is likely to produce O_3 at a greater rate than MOZART. Despite the differences in sensitivity to
666 changes in VOC emissions exhibited by the two mechanisms, sensitivity to changes in NO_x emis-
667 sions in MOZART and RADM2 are found to be similar.

668 Our results indicate that modeled surface O₃ over Europe is sensitive the choice of gas phase
669 chemical mechanism, with observed differences in O₃ between mechanisms that are larger than
670 those seen in many past studies. Although the most fundamental differences between MOZART- 4
671 and RADM2 (and other chemical mechanisms used in regional modeling) is the representation of
672 VOC oxidation chemistry, we find that approximately 40% of the difference seen in predicted O₃
673 seen in this study can be explained by differences in inorganic reaction rate coefficients employed
674 by MOZART- 4 and RADM2. This result suggests that harmonization of inorganic rate coefficients
675 among chemical mechanisms used for regional air quality modeling might be valuable, and could
676 potentially lead to a smaller spread in model-predicted O₃ compared to that seen in, e.g., the multi-
677 model studies of AQMEII (Solazzo et al., 2012b; Im et al., 2015). Further investigation of chemical
678 mechanism behavior within 3-D models in general would be helpful to constrain uncertainties in
679 regional air quality modeling.

680 **6 Code availability**

681 The WRF-Chem model is an open-source, publicly available software. The code is being continually
682 improved, with new releases approximately twice per year. WRF-Chem code can be downloaded at
683 (http://www2.mmm.ucar.edu/wrf/users/download/get_source.html). The corresponding author will
684 provide the bug fixes to version 3.5.1 used in this study, described in Section 2.3, upon request.

685 **Appendix A: Abbreviations and Acronyms**

686 DJF: December-January-February (winter)
687 EDGAR: Emission Database for Global Atmospheric Research
688 EEA: European Environmental Agency
689 EOS: Earth Observing System
690 GEOS5: Goddard Earth Observing System Model, Version 5

699 SON: September-October-November (fall)
700 SORGAM: Secondary Organic Aerosol Model
701 WRF-Chem: Weather Research and Forecasting with Chemistry

702 **Appendix B: Definitions of statistical quantities**

703 The statistical quantities used for model evaluation are defined below. Let Obs_i^j and Mod_i^j be the
 704 observed and modeled quantities at time i and station j , respectively. N_{obs}^j represents the number of
 705 temporal data points evaluated at station j , and N_{obs} represents the total number of data points (each
 706 representing a time i and a station j) evaluated in the domain.

707 The Mean Bias (MB) at a specific station (e.g., Figure 5) is calculated as

$$708 \quad MB^j = \frac{1}{N_{obs}^j} \sum_{i=1}^{N_{obs}^j} Mod_i^j - Obs_i^j$$

709 and the domain-wide Mean Bias (e.g., Table 5) as

$$710 \quad MB = \frac{1}{N_{obs}} \sum_{i,j=1}^{N_{obs}} Mod_i^j - Obs_i^j$$

711 Domain-wide values for Normalized Mean Bias (NMB) and Mean Fractional Bias (MFB) are
 712 calculated analogously.

$$713 \quad NMB = \frac{\sum_{i=1}^{N_{obs}} Mod_i^j - Obs_i^j}{\sum_{i=1}^{N_{obs}} Obs_i^j}$$

$$714 \quad MFB = \frac{1}{N_{obs}} \sum_{i,j=1}^{N_{obs}} \frac{Mod_i^j - Obs_i^j}{\frac{Mod_i^j + Obs_i^j}{2}}$$

715 Temporal correlation between model results and observation is evaluated using the Pearson corre-
 716 lation coefficient (r). The value of r is calculated at each station using

$$717 \quad r^j = \frac{\sum_{i=1}^{N_{obs}^j} (Mod_i^j - \overline{Mod^j}) (Obs_i^j - \overline{Obs^j})}{\sigma_{mod} \times \sigma_{obs}}$$

718 Here, the numerator represents the covariance between the model and observations, $\overline{Mod^j}$ and
 719 $\overline{Obs^j}$ represent the mean of the model and observations, respectively, and σ is the standard deviation.

720 The domain-wide correlation coefficients (e.g., Table 5) is then calculated as

$$721 \quad r = \frac{1}{N_j} \sum_j^{N_j} r^j$$

722 where N_j is the total number of stations.

723 *Acknowledgements.* The authors would like to thank Renate Forkel for valuable discussions regarding the setup
724 of our WRF-Chem simulation, and two anonymous reviewers for their feedback. The authors also thank Jane
725 Coates for sharing her technique for VOC speciation and valuable discussions regarding chemical mecha-
726 nisms. We thank TNO for access to the TNO-MACC II emissions inventory, and Hugo Denier van der Gon
727 for helpful discussions regarding emissions. The HTAP v2.2 anthropogenic emissions were obtained from
728 http://edgar.jrc.ec.europa.eu/htap_v2/index.php. The authors thank Christophe Knote and Anna Katinka Pe-
729 tersen for sharing bug fixes for the WRF-Chem MOZART code. WRF-Chem tools for preprocessing bound-
730 ary conditions as well as biogenic, fire, and anthropogenic emissions were provided by NCAR ([http://www.](http://www.acom.ucar.edu/wrf-chem/download.shtml)
731 [acom.ucar.edu/wrf-chem/download.shtml](http://www.acom.ucar.edu/wrf-chem/download.shtml)). Initial and boundary conditions for meteorological fields were ob-
732 tained from ECMWF, <http://www.ecmwf.int/en/research/climate-reanalysis/era-interim>. Initial and boundary
733 conditions for chemical fields were from MOZART- 4/GEOS5, provided by NCAR at [http://www.acd.ucar.edu/](http://www.acd.ucar.edu/wrf-chem/mozart.shtml)

Table 1. WRF-Chem options used in model simulations.

Atmospheric Process	Option used
Cloud microphysics	Lin et al. scheme (Lin et al., 1983)
Longwave radiation	RRTMG (Iacono et al., 2008)
Shortwave radiation	Goddard shortwave scheme (Chou and Suarez, 1994)
Surface Layer	MM5 Similarity based on Monin-Obukhov scheme (Beljaars, 1995)
Land-surface Physics	Noah Land Surface Model (Chen and Dudhia, 2001)
Urban surface physics	Urban Canopy Model (Kusaka and Kimura, 2004)
Planetary boundary layer	Yonsei University scheme (Hong et al., 2006)
Cumulus parametrization	Grell 3D scheme (Grell and Dévényi, 2002)

Table 2. Description of WRF-Chem simulations performed for this study.

Simulation Name	Model Chemistry	Photolysis Scheme
(1) MOZART	MOZART- 4 chemistry with gocart aerosols, KPP solver	Madronich F-TUV photolysis
(2) RADM2	RADM2 chemistry with MADE/SORGAM aerosols, KPP solver	Madronich photolysis (TUV)

Table 3. Observational datasets used for model evaluation.

Database	Parameter	Temporal Resolution	Data Source
BADC Global Weather Observation Data	MSLP, T2, WS10, WD10	3-hourly	http://badc.nerc.ac.uk/home/
AirBase v7	O ₃ , NO ₂ , NO, NO _x	hourly	http://www.eea.europa.eu/data-and-maps/data/airbase-the-european-air-quality-database-7
EMEP	NO ₂ , NO, NO _x	hourly	http://ebas.nilu.no/

Table 4. Domain-wide statistical performance of WRF-Chem against 3-hourly meteorological observations from BADC. Modeled quantities are from the MOZART simulation.

Figure 1. Seasonal average values of 2-meter temperature (T2) in degrees Celcius. Model results and statistics are shown for the MOZART simulation at the locations of the observations.

Figure 2. Seasonal average values of 10-meter wind speed (WS10) in m/s. Model results and statistics are shown for the MOZART simulation at the locations of the observations.

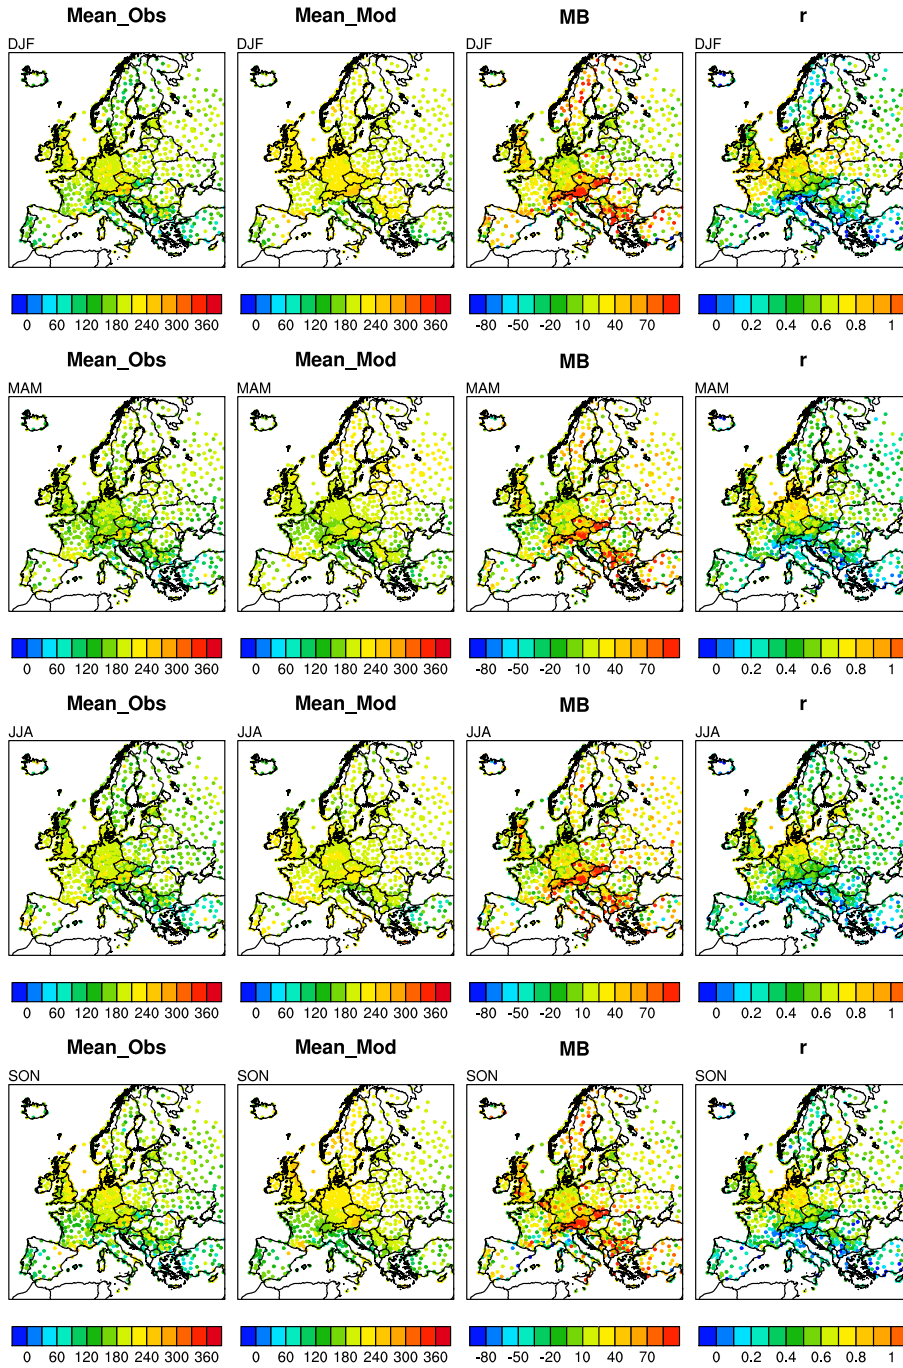

Figure 3. Seasonal average values of 10-meter wind direction (WD10) in degrees. Model results and statistics are shown for the MOZART simulation at the locations of the observations.

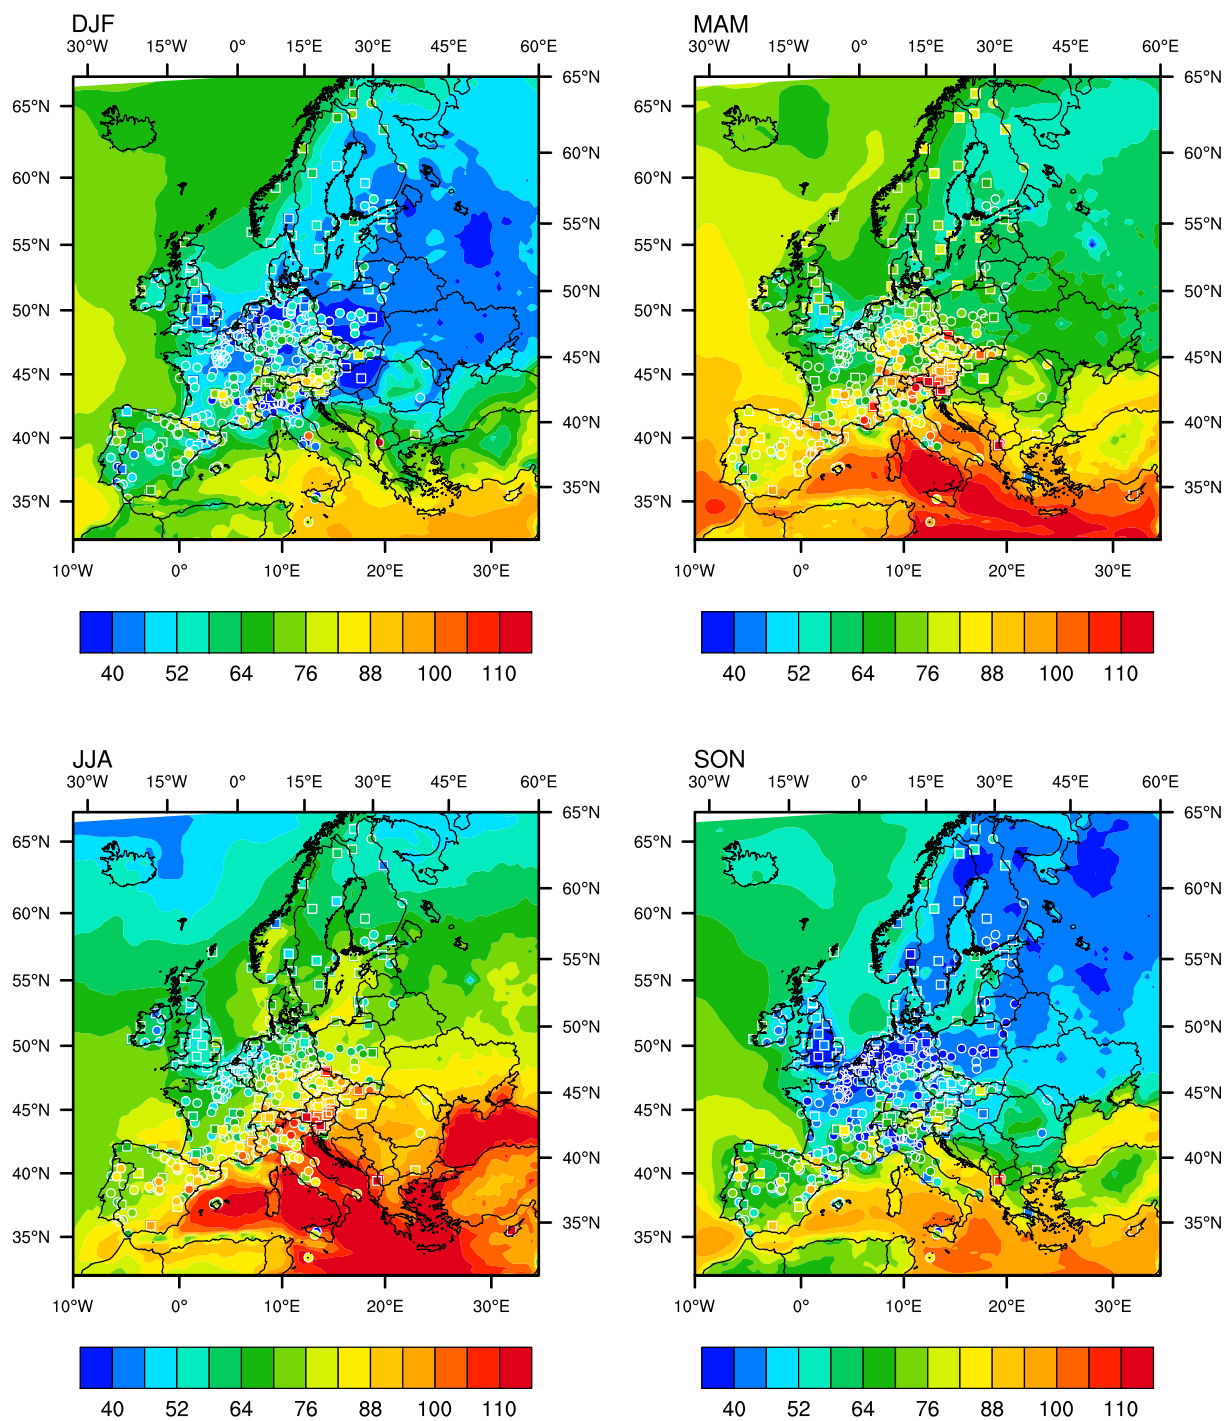

Figure 4. Seasonal average values of surface O_3 in $\mu g m^{-3}$. Contours are model output from the MOZART simulation. Filled dots represent hourly measurements at AirBase rural background stations, filled squares represent measurements at EMEP stations.

Figure 5. Seasonal average values of surface O_3 in $\mu\text{g m}^{-3}$ from hourly measurements at AirBase (circles) and EMEP (squares) stations, and modeled values from MOZART for corresponding locations. The Mean Bias (MB, in $\mu\text{g m}^{-3}$) and temporal correlation coefficient (r) for hourly values are also shown at the location of station observations.

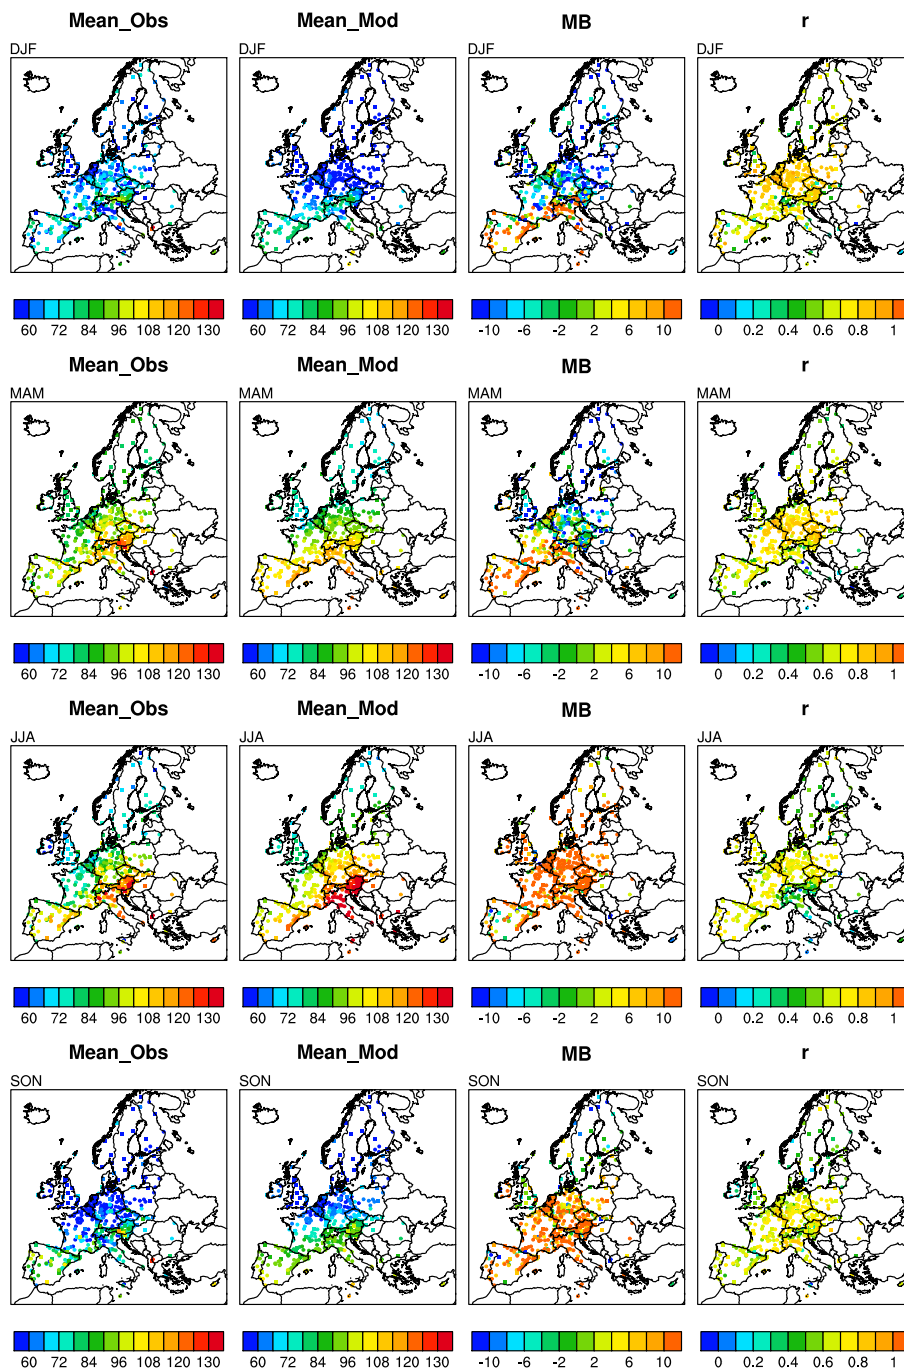

Figure 6. Seasonal average values of MDA8 in $\mu\text{g m}^{-3}$ calculated from hourly measurements at AirBase (circles) and EMEP (squares) stations, and modeled values from MOZART for corresponding locations. The Mean Bias (MB, in $\mu\text{g m}^{-3}$) and temporal correlation coefficient (r) for daily values are also shown at the location of station observations.

Figure 7. Number of days of exceedances of the EU long-term objective value for MDA8 ($120 \mu\text{g m}^{-3}$) at AirBase (circles) and EMEP (squares) station locations. Shown are totals by season for observations and the MOZART and RADM2 simulations. For simplicity of viewing the data, stations with no exceedances are not plotted.

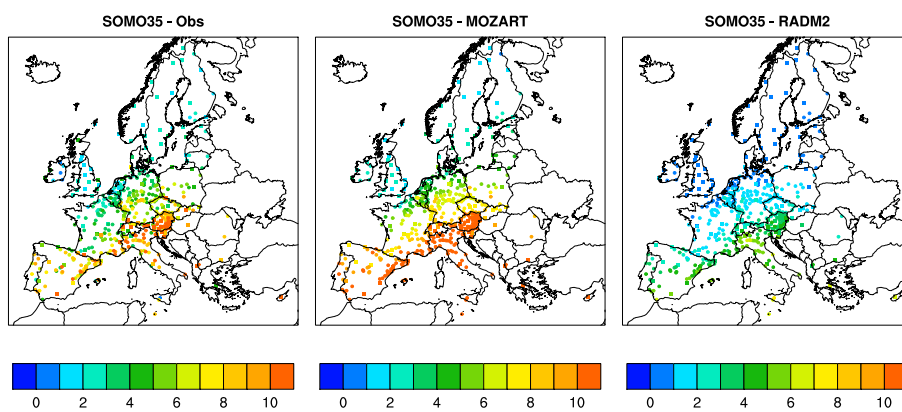

Figure 8. Yearly values of SOMO35 in $\text{mg m}^{-3} \cdot \text{days}$ calculated from hourly measurements at AirBase (circles) and EMEP (squares) stations, and modeled values for corresponding locations.

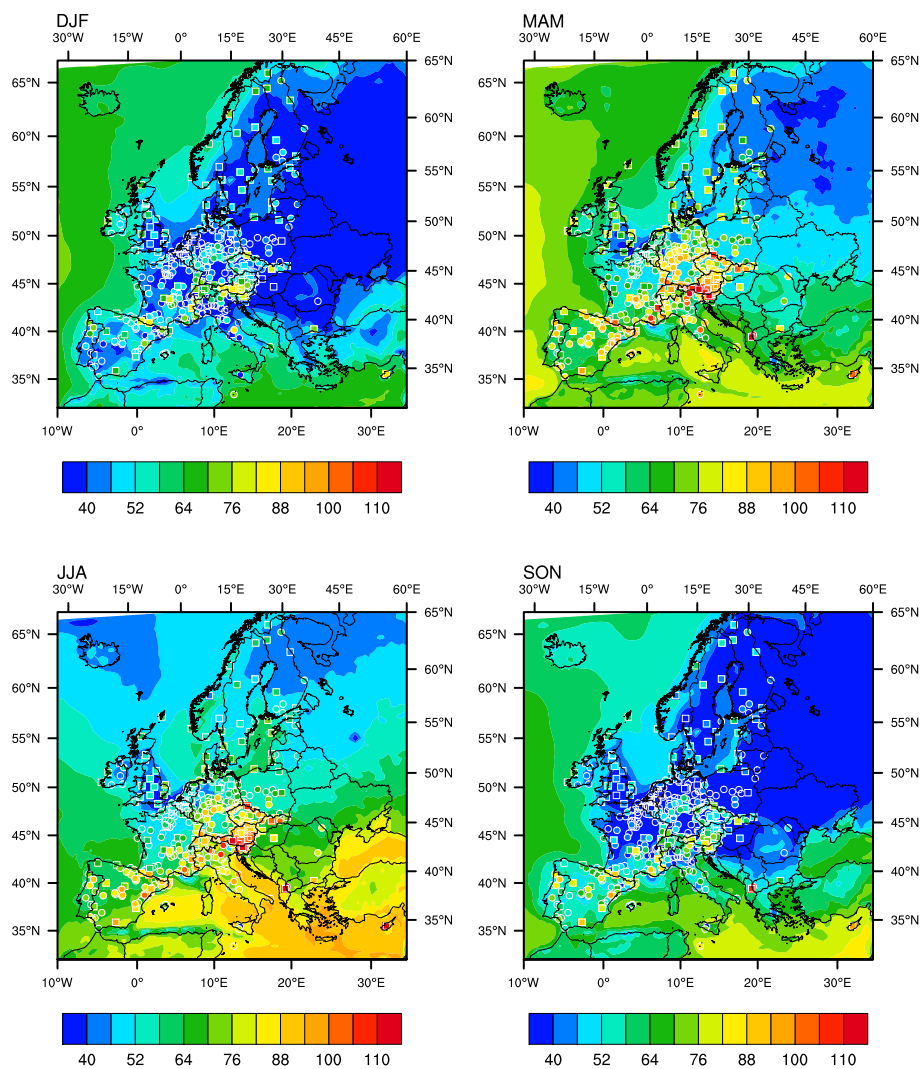

Figure 9. Seasonal average values of surface O₃ in µg m⁻³. Contours are model output from the RADM2 simulation. Filled dots represent hourly measurements at AirBase rural background stations, filled squares represent measurements at EMEP stations.

Figure 10. Seasonal average values of surface O_3 in $\mu\text{g m}^{-3}$ from hourly measurements at AirBase (circles) and EMEP (squares) stations, and modeled values from RADM2 for corresponding locations. The Mean Bias (MB, in $\mu\text{g m}^{-3}$) and temporal correlation coefficient (r) for hourly values are also shown at the location of station observations.

Figure 11. Seasonal average values of surface NO_x in µg m⁻³. Contours are model output from the MOZART simulation. Filled dots represent hourly measurements at AirBase rural background stations, filled squares represent measurements at EMEP stations.

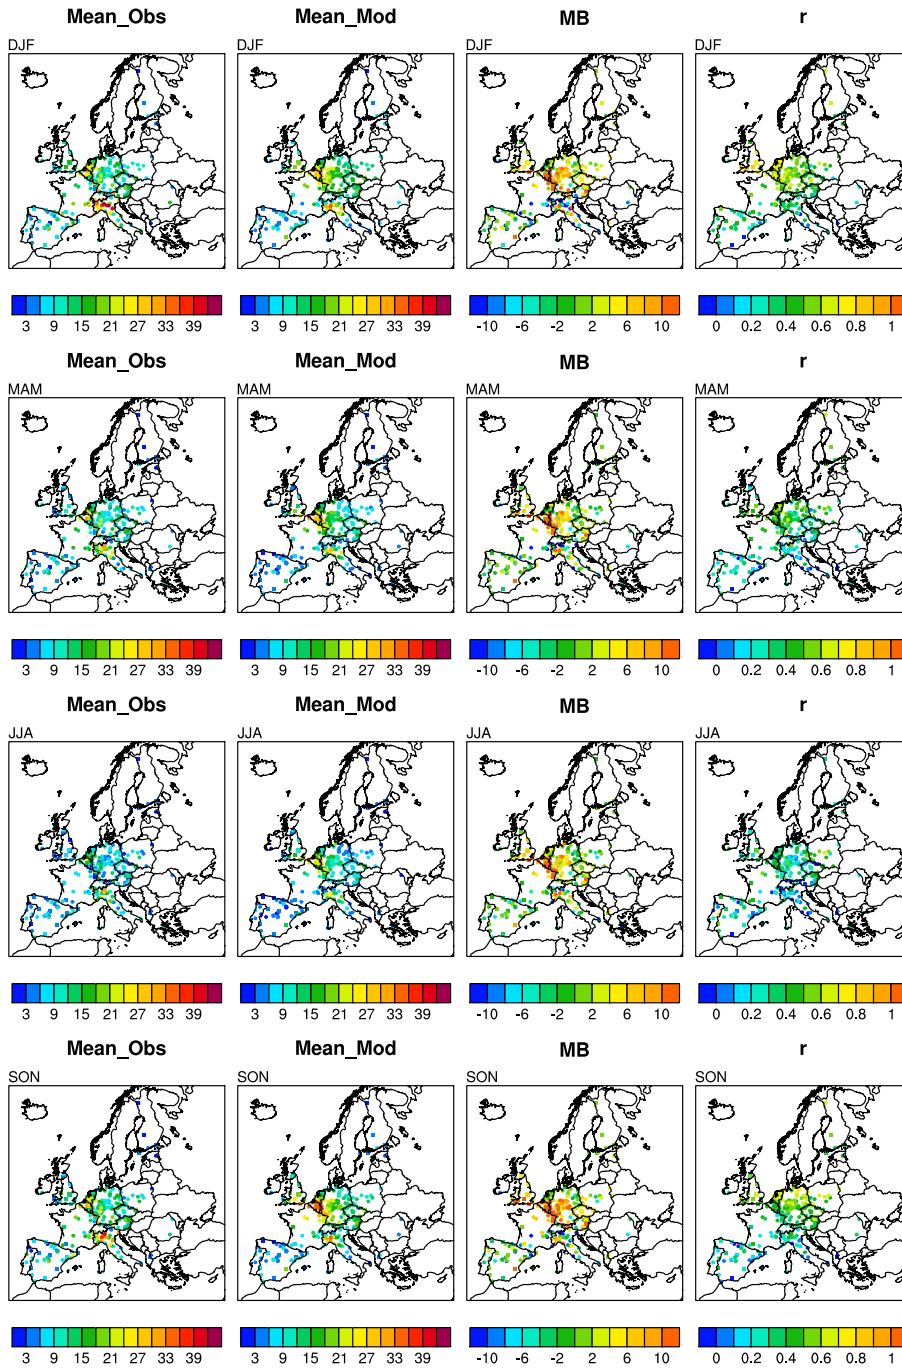

Figure 12. Seasonal average values of surface NO_2 in $\mu\text{g m}^{-3}$ from hourly measurements at AirBase (circles) and EMEP (squares) stations, and modeled values from MOZART for corresponding locations. The Mean Bias (MB) and temporal correlation coefficient (r) for hourly values are also shown at the location of station observations.

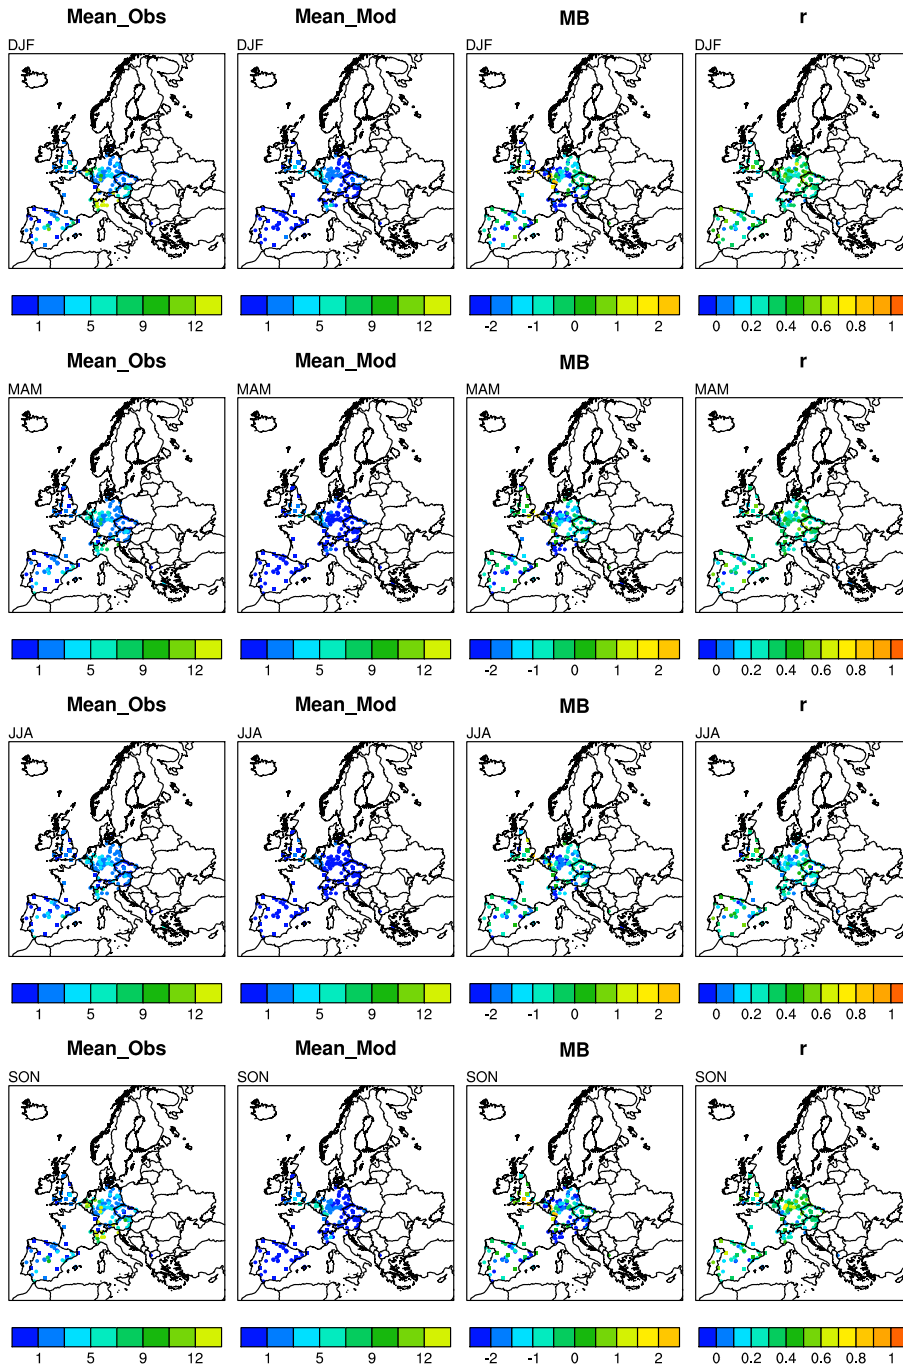

Figure 13. Seasonal average values of surface NO in $\mu\text{g m}^{-3}$ from hourly measurements at AirBase (circles) and EMEP (squares) stations, and modeled values from MOZART for corresponding locations. The Mean Bias (MB) and temporal correlation coefficient (r) for hourly values are also shown at the location of station observations.

Figure 14. Seasonal average values of surface NO_2 in $\mu\text{g m}^{-3}$ from hourly measurements at AirBase (circles) and EMEP (squares) stations, and modeled values from RADM2 for corresponding locations. The Mean Bias (MB) and temporal correlation coefficient (r) for hourly values are also shown at the location of station observations.

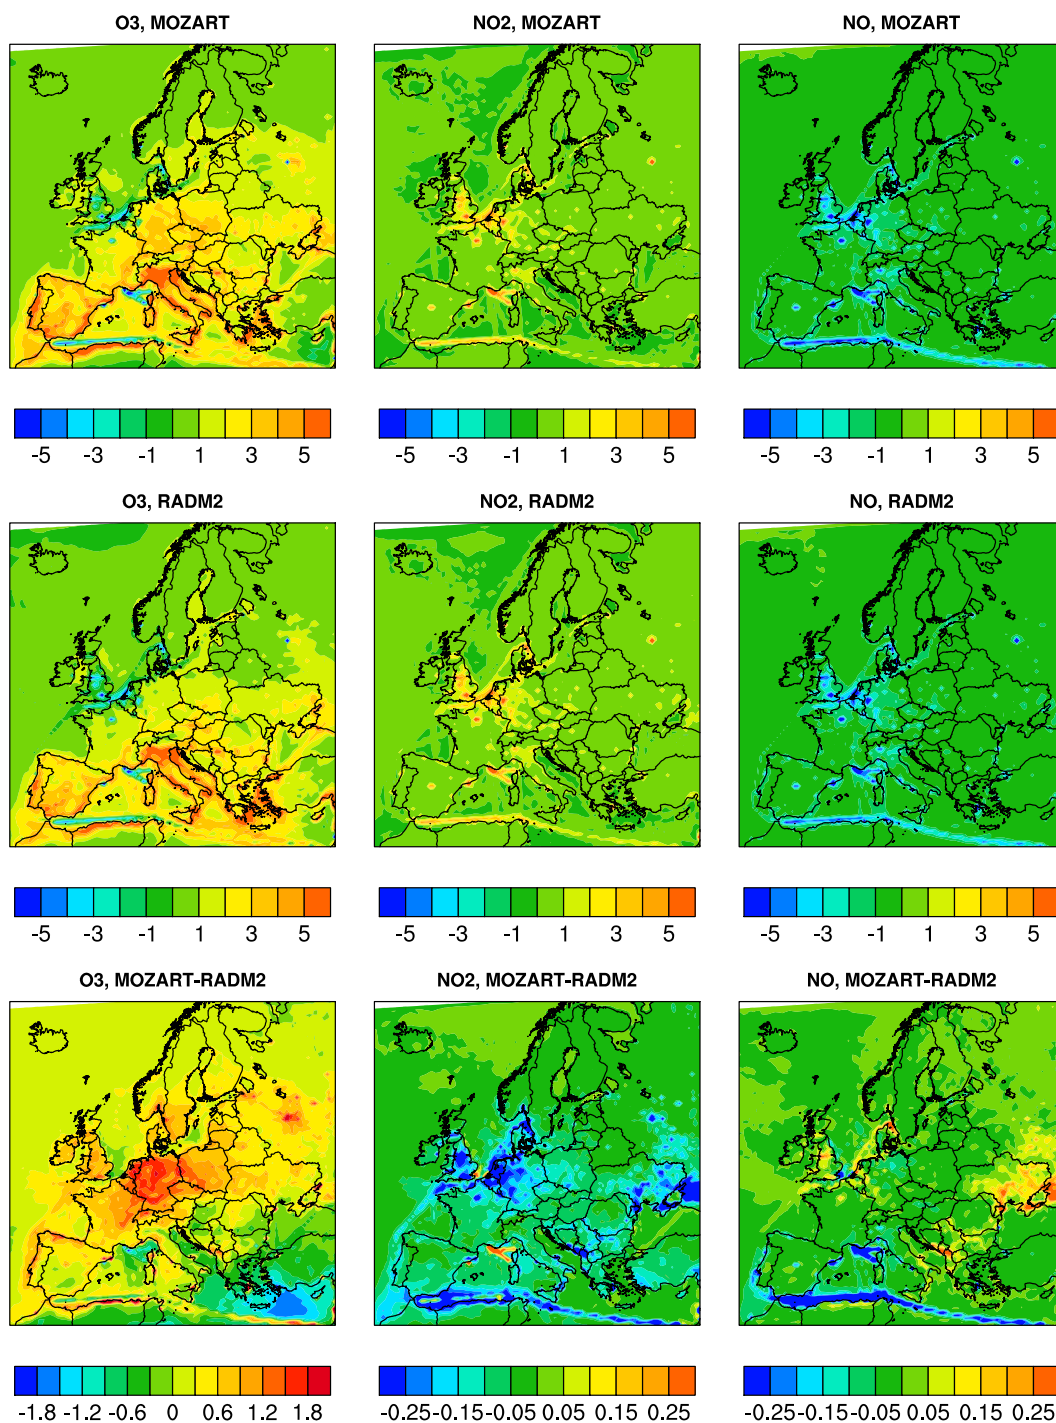

Figure 15. Net midday (11:00 - 14:00 CEST) photochemical production rate in ppb hr⁻¹ for O₃, NO₂, and NO shown for MOZART and RADM2 for July 2007. The last row shows the difference in net production rate in ppb hr⁻¹ (RADM2 subtracted from MOZART).

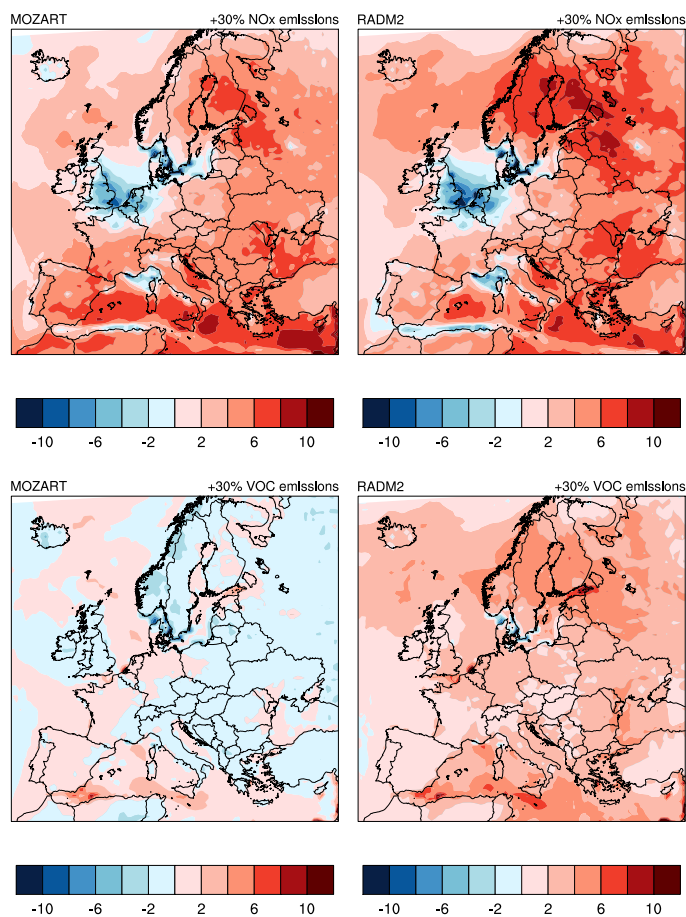

Figure 16. Sensitivity of average O₃ for July 2007 to a 30% increase in emissions of NO_x (upper row) or VOC (lower row), shown for the MOZART and RADM2 chemical mechanisms. Shown here is the percent change in O₃ concentration, i.e., $100 \times ([O_3]_{+30\%emissions} - [O_3]_{base}) / [O_3]_{base}$.
