25 **Abstract.** Atmospheric greenhouse gas concentrations are at unprecedented, record-high levels compared to pre-industrial  
26 reconstructions over the last 800,000 years. Those elevated greenhouse gas concentrations warm the planet and together with  
27 net cooling effects by aerosols, they are the reason of observed climate change over the past 150 years. An accurate  
28 representation of those concentrations is hence important to understand and model recent and future climate change. So far,  
29 community efforts to create composite datasets with seasonal and latitudinal information have focused on marine boundary  
30 layer conditions and recent trends since 1980s. Here, we provide consolidated data sets of historical atmospheric (volume)  
31 mixing ratios of 43 greenhouse gases specifically for the purpose of climate model runs. The presented datasets are based on  
32 AGAGE and NOAA networks and a large set of literature studies. In contrast to previous intercomparisons, the new datasets  
33 are latitudinally resolved, and include seasonality over the period between year 0 to 2014. We assimilate data for CO<sub>2</sub>, methane  
34 (CH<sub>4</sub>) and nitrous oxide (N<sub>2</sub>O), 5 chlorofluorocarbons (CFCs), 3 hydrochlorofluorocarbons (HCFCs), 16 hydrofluorocarbons  
35 (HFCs), 3 halons, methyl bromide (CH<sub>3</sub>Br), 3 perfluorocarbons (PFCs), sulfur hexafluoride (SF<sub>6</sub>), nitrogen trifluoride (NF<sub>3</sub>)  
36 and sulfuryl fluoride (SO<sub>2</sub>F<sub>2</sub>). We estimate 1850 annual and global mean surface mixing ratios of CO<sub>2</sub> at 284.3 ppmv, CH<sub>4</sub> at  
37 808.2 ppbv and N<sub>2</sub>O at 273.0 ppbv and quantify the seasonal and hemispheric gradients of surface mixing ratios. Compared to  
38 earlier intercomparisons, the stronger implied radiative forcing in the northern hemisphere winter (due to the latitudinal  
39 gradient and seasonality) may help to improve the skill of climate models to reproduce past climate and thereby reduce  
40 uncertainty in future projections.

## 41 1 Introduction

42 The burning of fossil fuels, emissions related to deforestation and agricultural activities and synthetic greenhouse gas emissions  
43 are the reasons for the observed increases in greenhouse gas concentrations. Those elevated greenhouse gas mixing ratios in  
44 turn cause more than the observed recent climate change as some of the warming effect is dampened by aerosols (Fig. TS.10  
45 in IPCC WG1 AR4 (IPCC)). An accurate quantification of anthropogenic and natural climate drivers is crucial for general  
46 circulation and Earth System models. Simulations by these models for the historical time periods, e.g. since 1850, can only be  
47 meaningfully compared to observations (e.g. surface temperature, ocean heat uptake) to the degree that input forcings are an  
48 accurate representation of the past. The difficulty with many anthropogenic drivers is that their global-mean magnitude, their  
49 latitudinal gradient and seasonal cycle are uncertain further back in time, even for the main greenhouse gases carbon dioxide  
50 ( $\text{CO}_2$ ), methane ( $\text{CH}_4$ ) and nitrous oxide ( $\text{N}_2\text{O}$ ). Systematic observational efforts started in 1957-1958, measuring  $\text{CO}_2$  at the  
51 South Pole and Mauna Loa observatories. Measurements of archived air, and firn air and ice cores from both polar regions  
52 provide records for the pre-observational time. To date, there have been few attempts to reconstruct long-term global-mean  
53 timeseries based on ice and firn data, e.g. for  $\text{CO}_2$  over the last millennia (MacFarling Meure et al. 2006, Ahn et al. 2012,  
54 Rubino et al. 2013) or to provide latitudinally-resolved, monthly background mixing ratios of  $\text{CO}_2$ ,  $\text{CH}_4$  and  $\text{N}_2\text{O}$  over the  
55 instrumental record over the past 20 to 40 years (Cooperative Global Atmospheric Data Integration Project 2013, NOAA ESRL  
56 GMD 2014a, NOAA ESRL GMD 2014b, NOAA ESRL GMD 2014c). In light of the observational gaps further back in time,  
57 some studies, such as Keeling et al. (2011), used linear regressions between fossil fuel use and latitudinal  $\text{CO}_2$  concentration  
58 trends to separate natural from anthropogenically-induced effects, which allows to infer latitudinal gradients back in time.

59 In previous climate model inter-comparison projects (Meehl et al. 2005), global-mean concentrations have been prescribed  
60 (Meinshausen et al. 2011a), with some models constraining internally generated fields of greenhouse gas mixing ratios to  
61 match those global-mean values. Here, we update those global-mean and annual-mean greenhouse gas concentration time-  
62 series for the historical period over years 0 to 2014, with ‘historical’ simulations in the CMIP6 model intercomparison (Eyring  
63 et al. 2016) focussed on the most recent period 1850 to 2014. In addition, we provide hemispheric and latitudinal monthly-  
64 resolved fields for 43 greenhouse gases in total. In the past, the large latitudinal and seasonal gradient of greenhouse gas  
65 radiative forcing has not been consistently applied to model radiative forcing and climate change. Our new dataset provides a  
66 more consistent starting point for climate model experiments. The monthly and latitudinal resolution of this new greenhouse  
67 gas dataset is in line with monthly solar forcing (Matthes et al. 2016) and monthly and latitudinally resolved ozone and aerosol  
68 abundances. Many greenhouse gases also have significant longitudinal (land/ocean) and diurnal variations but we do not  
69 attempt to resolve these. Neither do we provide vertical gradients of the greenhouse gases mixing ratios and only discuss  
70 possible vertical extension methods (4.1) in case that models do not have their own methods to derive vertical gradients.

71 In this study, we compile one possible reconstruction of latitudinally and monthly resolved fields, as well as global annual  
72 means of surface greenhouse gas mixing ratios for 43 gases from Year 0 to 2014, as input for the forthcoming model inter-  
73 comparison experiments that are part of the Phase-6 Coupled Model Inter-comparison project (CMIP6) (Eyring et al. 2016),  
74 specifically the pre-industrial control runs at 1850 forcing levels (picontrol), the experiment with abruptly quadrupled  $\text{CO}_2$   
75 concentrations (abrupt4x), and the standard experiment of a 1% annual  $\text{CO}_2$  concentration increase (1pct2co2) as well as the  
76 historical runs that are driven with best-guess estimates of historical forcings since 1850. Species that are radiatively less  
77 important than  $\text{CO}_2$ ,  $\text{CH}_4$  and  $\text{N}_2\text{O}$  (‘importance’ here being measured as radiative forcing exerted in year 2014 compared to  
78 1750) are provided individually as well in aggregate as HFC-134a and CFC-12 equivalent mixing ratios.

79 The design principle for this long-term dataset is to provide a plausible reconstruction of past greenhouse gas mixing ratios to  
80 be used in climate models. Using various gap-filling procedures, reconstruction and extensions, this dataset aims to reflect  
81 observational evidence of both recent flask and *in situ* observations from the worldwide network of NOAA ESRL and AGAGE  
82 stations, as well as the Law Dome and Greenland ice core and firn data over the last two thousand years, where available.  
83 Furthermore, many detailed literature studies (Mühle et al. 2010b, Arnold et al. 2013, Velders et al. 2014, Vollmer et al. 2016)  
84 for radiatively less important species are taken into account and synthesised where direct observational records from the above  
85 networks were not available.

86 The predominant climate effect of greenhouse gas increases is captured by the global- and annual mean mixing ratios  
87 throughout the atmosphere. The surface global and annual mean mixing ratios provided here, in combination with the models'  
88 approximations for the vertical concentration profile, are the minimum standard for CMIP6 models. Assimilating a latitudinally  
89 and seasonally resolved data product serves two purposes. On the one hand, deriving the global and annual means from sparse  
90 observations rests on knowledge or assumptions about spatial and seasonal distributions. Secondly, a more resolved dataset  
91 will open the opportunity for some modelling groups to go beyond the prescription of global and annual mean mixing ratios.

92 Undoubtedly, some of the assumptions stretch into unknown territory, such as the seasonality of the CO<sub>2</sub> mixing ratios in pre-  
93 observational times or the time-variability of latitudinal gradients, let alone the higher frequency fluctuations of global-mean  
94 mixing ratios during the time, when only ice core data are available. Errors in the historical forcing do propagate and can  
95 hinder the comparison between observations and models. This study therefore had to find a workable compromise between  
96 providing a complete dataset that covers the whole time and space domain and being as close as possible to sparse observations.  
97 Hence, the remaining uncertainties in concentration gradients should be kept in mind, although they might not be of primary  
98 concern in regard to the inter-comparison aspect of the multi-model ensemble runs. Thus, while our CMIP6 community dataset  
99 will improve on the global- and annual-mean time-series prescribed for the last set of CMIP5 experiments on a number of key  
100 aspects, many research questions remain open.

101 The underlying reason for meridional gradients of annual-mean mixing ratios is manifold (Keeling et al. 1989a, Keeling et al.  
102 1989b, Tans et al. 1989). For one, the sources of anthropogenic greenhouse gases from fossil fuel burning and cement  
103 production or industrial activities are not evenly distributed with latitude, but concentrated in the mid-northern land masses. In  
104 the case of CO<sub>2</sub>, emissions from deforestation are not uniformly distributed with latitude either. The pattern of land use-related  
105 emissions is even less stationary, with CO<sub>2</sub> uptakes and sources predominantly focussed in the mid-northern latitudes up until  
106 earlier in the 20<sup>th</sup> century, shifting more towards lower latitudes in recent decades (Hurt et al. 2011). This study uses an  
107 approach based on simple regressions that implicitly rest on the assumption of a fixed pattern approximation (such as Keeling  
108 et al. 2011). One complication to retrieve the latitudinal pre-industrial CO<sub>2</sub> concentration profile is that CO<sub>2</sub> fertilization and  
109 temperature effects on the carbon cycle are changing both magnitude and spatial patterns of natural CO<sub>2</sub> fluxes. Lastly, both  
110 the diurnal and seasonal cycle of photosynthesis and its covariance with vertical atmospheric mixing can have a pronounced  
111 effect on measured surface mixing ratios (the so-called 'rectifier' effect), increasing northern hemispheric CO<sub>2</sub> mixing ratios  
112 by up to 2.5 ppmv (Denning et al. 1999).

113 In order to dissect and analyse the different causes for temporal and spatial heterogeneity in surface mixing ratios, a rich body  
114 of literature analyses observed latitudinal and seasonal gradients with various inversion techniques. Recent research provides  
115 a clearer picture in regard to the root causes of the change in seasonality of CO<sub>2</sub> mixing ratios (Forkel et al. 2016), a topic

116 researched already in 1989 (Kohlmaier et al. 1989) based on the CO<sub>2</sub> fertilization effect on northern hemispheric terrestrial  
117 biota. Generally, the research into meridional and seasonal variations employs various atmospheric inversion techniques  
118 (Enting and Mansbridge 1989, Enting and Mansbridge 1991, Enting et al. 1995, Enting 1998, Rayner et al. 1999) to match  
119 observed mixing ratios with source and sink pattern estimates (Keeling et al. 1989a, Keeling et al. 1989b, Tans et al. 1990a,  
120 Enting et al. 1995, Rayner et al. 1999, Gurney et al. 2002, Gurney et al. 2003, Gurney et al. 2004, Baker et al. 2006, Peylin et  
121 al. 2013). Similarly to CO<sub>2</sub>, the spatial variation in CH<sub>4</sub> mixing ratios is used for model synthesis inversions (Fung et al. 1991).

122 There is a substantial lack of observational evidence of both seasonality and latitudinal CO<sub>2</sub> gradients in pre-industrial times.  
123 Given that atmospheric CO<sub>2</sub> is not well preserved in the Greenland ice (Anklin et al. 1995, Barnola et al. 1995), the pre-  
124 observational north-south gradient cannot be calculated from the Greenland and Antarctic ice core records. Alternatively,  
125 understanding biospheric sink and source dynamics could provide vital evidence to infer pre-industrial surface concentration  
126 patterns. In this study, we do not employ any such inversion models or results, and only note that our pre-industrial meridional  
127 and seasonal variations should be regarded as highly uncertain. However, some plausibility of the CO<sub>2</sub> gradients is gained by  
128 comparison with some model studies (Discussion). High-latitude records of CH<sub>4</sub> and N<sub>2</sub>O are available from both hemispheres  
129 (Fluckiger et al. 2002, Schilt et al. 2010b, Rhodes et al. 2013) allowing to estimate pre-industrial large-scale concentration  
130 gradients.

131

## 132 2 Methods

133 In order to pursue the primary purpose of this study, namely the provision of a consistent set of historical surface greenhouse  
134 gas mixing ratios, a number of analytical steps were taken to assimilate the observational data. Although global-mean and  
135 annual mean mixing ratios are of primary interest, the discussion covers latitudinal and seasonal variations in part because the  
136 assimilation procedure for sparse observational data does require accounting for this spatio-temporal heterogeneity in order to  
137 derive global and annual means.

138 We consider a total of 43 greenhouse gases in this study, namely CO<sub>2</sub>, CH<sub>4</sub>, N<sub>2</sub>O, a group of 17 ozone depleting substances,  
139 namely CFC-12, CFC-11, CFC-113, CFC-114, CFC-115, HCFC-22, HCFC-141b, HCFC-142b, CH<sub>3</sub>CCl<sub>3</sub>, CCl<sub>4</sub>, CH<sub>3</sub>Cl,  
140 CH<sub>2</sub>Cl<sub>2</sub>, CHCl<sub>3</sub>, CH<sub>3</sub>Br, Halon-1211, Halon-1301, Halon-2402, and 23 other fluorinated compounds, namely 11 HFCs (HFC-  
141 134a, HFC-23, HFC-32, HFC-125, HFC-143a, HFC-152a, HFC-227ea, HFC-236fa, HFC-245fa, HFC-365mfc, HFC-43-  
142 10mee), NF<sub>3</sub>, SF<sub>6</sub>, SO<sub>2</sub>F<sub>2</sub>, and 9 PFCs (CF<sub>4</sub>, C<sub>2</sub>F<sub>6</sub>, C<sub>3</sub>F<sub>8</sub>, C<sub>4</sub>F<sub>10</sub>, C<sub>5</sub>F<sub>12</sub>, C<sub>6</sub>F<sub>14</sub>, C<sub>7</sub>F<sub>16</sub>, C<sub>8</sub>F<sub>18</sub>, and c-C<sub>4</sub>F<sub>8</sub>).

### 143 2.1 Summary of assimilation approach.

144 We perform three consecutive steps to synthesize the global mixing ratio fields over the full time horizon from year 0 to year  
145 2014. First, we aggregate the available observational data over a recent instrumental period. Second, we estimate three  
146 components of the global surface mixing ratio fields from these data, namely global mean mixing ratios, latitudinal gradients  
147 and seasonality. Thirdly, we extend those components back in time with – *inter alia* – ice-core or firn data. The full historical  
148 GHG concentration field can then be generated by the time-varying components.

149 Under this basic assimilation model, the concentration  $\hat{C}(l, t)$  at any point in time  $t$  and in a latitudinal band  $l$  can be written  
150 as:

$$151 \hat{C}(l, t) = \overline{C_{global}}(t) + \hat{S}_{l,m}(y) + \hat{L}_l(y) \quad (1)$$

152 Where  $\overline{C_{global}}(t)$  is the global-mean mixing ratio at time  $t$ , and  $\hat{S}_{l,m}$  is the seasonality in each latitude  $l$  and month  $m$ , and  
153  $\hat{L}_l(y)$  is the latitudinal annual-mean deviation in year  $y$  at latitude  $l$ . With this assimilation model, and the optimal low rank  
154 approximations of seasonality and latitudinal gradients, a regularisation of the data is performed by a principal components  
155 analysis, which creates a certain degree of robustness against data gaps or outliers. Other methods, like a harmonic  
156 representation of station data, have, in principle, a similar smoothing and regularisation effect (Masarie and Tans 1995),  
157 although quantitative differences exist (section 5.3).

158 A detailed data flow diagram of how the historical greenhouse gas mixing ratios are derived in this study is provided in Figure  
159 22. The subsequent section will describe the method step-by-step, as indicated by the green circles in Figure 22.

#### 160 2.1.1 Step 1: Aggregating raw station data.

161 Atmospheric measurements are taken in remote environments or locations that are closer to pollution sources, in continental  
162 or marine areas, at different times of the day or night, at different altitudes, and different seasons of the year, often using  
163 different calibration scales. This poses challenges for any synthesis of observational data.

164 The observational station data over the recent decades used in this study are predominantly sourced from the networks operated  
165 by NOAA (Earth System Research Laboratories: ESRL), and AGAGE. In general, we use monthly station data provided by

166 the respective networks as a starting point. In the case of the AGAGE network, monthly averages are provided with and without  
167 pollution events. We chose the monthly averages that include pollution events (file-endings ‘.mop’, with the exception of  
168 CH<sub>2</sub>Cl<sub>2</sub>, in which case data issues warranted the use of monthly station averages without pollution events). The approach that  
169 we do not restrict our source data to background conditions is consistent with our approach elsewhere – and the NOAA network  
170 monthly station averages - which do not screen out pollution events (although the dominant number of NOAA flask  
171 measurements might be slightly biased towards background conditions rather than pollution events). In total, CO<sub>2</sub> data from  
172 81 stations from the NOAA flask network, and 3 stations from the NOAA *in situ* data stations are used (Table 2). For CH<sub>4</sub>, 87  
173 sampling stations from the NOAA flask network and 5 stations from the AGAGE *in situ* network are compiled (Table 8). For  
174 N<sub>2</sub>O, data from flask and in situ measurements at 13 stations of the NOAA HATS global network are combined with data from  
175 5 stations from the AGAGE network (Table 9). For other gases, the AGAGE and NOAA coverage and timeframes vary, with  
176 individual station’s codes provided in panels f of the individual gases’ factsheets (Figure 23 to Figure 62). The complete  
177 AGAGE network is further described in Prinn et al. (2000a), with specific information for CFC-11 and CFC-12 provided in  
178 Cunnold et al. (1997), CH<sub>3</sub>CCl<sub>3</sub> in Prinn et al. (2001, 2005) and Reimann et al. (2005), CCl<sub>4</sub> in Simmonds et al. (1998), CFC-  
179 113 in Fraser et al. (1996), CHCl<sub>3</sub> in O’Doherty et al. (2001), CH<sub>3</sub>Br and CH<sub>3</sub>Cl in Simmonds et al. (2004) and Cox et al.  
180 (2003), and HFC-134a, HCFC-141b, HCFC-142b and HCFC-22 in O’Doherty (2004) and Miller et al. (1998).

181 Calibration scales, i.e. the standardized gas mixtures that allow to calibrate the instrumentation used for in-situ or flask  
182 measurements, are different between the NOAA and AGAGE networks. While we use the station data that has already been  
183 converted to the latest scales of the respective networks, some older comparison data products use previous scales (as the one  
184 published in the latest ozone assessment report (WMO 2014)). Thus, where necessary, we convert those older data to the newer  
185 scales. For 7 gases, we use scale conversion factors to convert to the SIO14 scale, specifically 1.0826 for HFC-125 (from  
186 University of Bristol scale: UB98), 1.1226 for HFC-227ea (from Empa-2005), 1.1970 for HFC-236fa (from Empa-2009-p),  
187 and 1.1909 for HFC-245fa (from Empa-2005), 1.1079 for HFC-365-mfc (from Empa-2003), 1.0485 for HFC-43-10-mee (from  
188 SIO-10-p), and 0.9903 for CH<sub>2</sub>Cl<sub>2</sub> (from UB98), with all conversion factors taken from the Appendix in WMO (2012).

189 Apart from those scale conversions to the latest NOAA and SIO scales mentioned above, we only make sure that the three  
190 main gases each are on a unified scaled. As we source all our CO<sub>2</sub> station data from the NOAA network, there is no scale  
191 conversion necessary. In the case of CH<sub>4</sub>, we account for different calibration scales by converting AGAGE CH<sub>4</sub> data (Tohuko  
192 University scale) to the NOAA scale (NOAA04) (multiplication by 1.0003). Both the AGAGE (SIO1998) and NOAA network  
193 calibration scales (NOAA-2006) for N<sub>2</sub>O are compatible without the need for a conversion factor (WMO 2012).

194 Apart from those three main gases, we do not apply further scale conversions. Thus, given that our results are based on a  
195 mixture of the AGAGE and NOAA networks, they are de facto a weighted average between the respective two standard scales  
196 (SIO and NOAA) for each gas. The effective weight in this “weighted mean” depends on the station numbers and each  
197 networks’ station distribution given that our assimilation method implicitly weights stations less that are geographically close,  
198 i.e. in the same latitude-longitude box. This mixture of scales is different from previous studies that either applied empirical  
199 scale conversions (so that global-mean or station averages are identical) or used both scales in parallel to estimate a  
200 measurement uncertainty error (WMO 2014), for example when estimating emission with inverse techniques. Mathematically,  
201 our approach is similar to an approach, where a station-by-station scale conversion would be applied towards an intermediate  
202 scale between NOAA and AGAGE. However, for some applications, this approach is clearly a limitation as it hides the  
203 uncertainty and would for example warrant a new data assimilation if one network updates its scales (section 6). The reason

204 this “weighted mean” approach is chosen in the context of this study is that we intend to reconstruct a single mixing ratio  
205 history making use of the station data from both major measurement networks without giving preference to the one or other  
206 measurement scale. Given that scale differences amount to generally below 2% differences, often for radiatively less important  
207 substances, this “middle of the road” approach seems justified given the other uncertainties in climate models (vertical  
208 distributions, radiative forcing routines, other radiative forcings such as aerosols). Any conversion to a single scale would ease  
209 comparisons, but would not be able to address the inherent measurement uncertainty, and might even face a stronger bias  
210 (assuming that the two scales SIO and NOAA are equally plausible representations of the “truth”) (see limitations).

211 In regard to the time of the day, month or year, we do however not apply interpolation or adjustment techniques other than a  
212 simple monthly binning of all available data. The spatial and temporal coverages of the raw data used in this study are depicted  
213 in Figure 17, Figure 18, and Figure 19 for CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O data, respectively.

#### 214 **2.1.2 Step 2-4: Binning and spatial interpolation**

215 We employ a simple monthly mean binning of all available data, separately averaged for each station. In each latitudinal /  
216 longitudinal box, all available monthly mean station data are averaged, with the mean being assigned to the grid box centre  
217 before employing a 2-dimensional spatial interpolation to extend available data points to longitudinal and latitudinal grid points  
218 that do not have observed data for any particular month. Our method provides equal weight to each station within a longitude-  
219 latitude box, no matter whether the station reports a few flask measurement samples or sub-hourly *in situ* instrument readings.  
220 The chosen assimilation grid has 72 boxes with 12 equal-latitude bands of 15 degrees and 6 longitudinal bands of 30 degree.  
221 Following the temporal monthly binning and subsequent spatial linear interpolation, we average all data across the longitudes  
222 to obtain 12 latitudinally resolved monthly time series of surface mixing ratios.

#### 223 **2.1.3 Step 5: Global mean mixing ratios**

224 The annual-global mean concentration  $\overline{C_{global}}(y)$  is simply derived as the area-weighted arithmetic mean of the binned  
225 latitudinal data (grey small “5” in Figure 22). In addition to the annual global mean, a time series of monthly values is derived  
226 as a smooth spline interpolation between the annual data points, with the constraint of being mean-preserving, i.e. that the  
227 average of the 12 monthly values is again the global annual average value initially-derived. Thus, the trend in the mixing ratio  
228 data is reflected in the global-mean time series from month to month.

#### 229 **2.1.4 Step 6: Latitudinal Gradient**

230 The annual-mean latitudinal gradients are derived as first and second EOFs from the annual-average residuals per latitude after  
231 subtracting the global annual mean (step 6 in Figure 22). Let  $G$  be the  $n \times m$  matrix of  $n$  years with observations, and  $m$   
232 latitudinal boxes, then  $G$  can be decomposed into its EOFs and scores by calculating the singular value decomposition of  $G =$   
233  $UDV^T$ , where  $U$  and  $V$  are orthogonal matrices in  $\mathbb{R}^n$  and  $\mathbb{R}^m$ , respectively, and  $D$  is the  $n \times m$  matrix with non-zero elements  
234 only on the diagonal. EOF <sub>$i$</sub>  is the  $i^{\text{th}}$  column of  $V$ , and the score  $S_i(y)$  of EOF <sub>$i$</sub>  in year  $y$  is given as the  $(y,i)$  entry of the  $UD$   
235 matrix. In other words, the EOFs are the eigenvectors of the gram matrix  $1/m * G'G$  and the scores are the projections of the  
236 observations  $G$  onto the EOFs.

237 Those EOF scores are regressed with suitable predictors or extended constantly. Thus, the term  $\hat{L}(y)$  is the optimal low rank  
238 approximation of the latitudinal deviations from the global mean over time  $y$ . The leading EOF of latitudinal annual-mean  
239 variation multiplied with the observed or regressed score  $S$  of that year  $y$ .

$$240 \quad \hat{L}(y) = \sum_{i=1}^{imax} EOF_i * S_i(y) \quad (2)$$

241 with *imax* being 1 or 2 if only the leading or the two leading EOFs are taken into account, respectively.

### 242 **2.1.5 Step 7-10: Seasonality**

243 The seasonality fulfils the condition that the sum of seasonal variations at each latitude is zero over the year, i.e.

$$244 \quad \sum_{m=1}^{12} \hat{S}_{l,m} = 0 \quad (3)$$

245 This seasonality  $\hat{S}_{l,m}(t)$  at time *t* is calculated as the relative seasonality  $\frac{d\hat{S}_{l,m}}{dC_{global}}$ , i.e. the seasonal deviation in mole fraction  
246 divided by the global-mean mole fraction, multiplied by the global-mean mixing ratio at time *t* (step 7 and 10 in Figure 22).

247 An exception is the case of CO<sub>2</sub> (step 8 and 9 in Figure 22). In this case, the seasonality pattern over the observational period  
248 is held fixed as mole fractions, i.e. not relative to the global mean. However, the residuals between this fixed seasonality and  
249 the seasonality, which is derived from the observations by subtracting the latitudinal averages, is used for a singular value  
250 decomposition. Let  $R_{l,m}(t)$  be the residuals at latitude *l* and month *m* at time *t*, the optimal lower rank representation of this  
251 seasonal change is then given by the first EOF of the gram matrix  $1/n * R * R$  with *n* being the number of observational data  
252 points. The derived score, i.e. the projection of the residuals onto the first EOF, is regressed against a time series *P*, a composite  
253 of global-mean CO<sub>2</sub> concentration and historical observed global-mean surface air temperatures. This simplified choice is  
254 taken as previous studies identified warmer temperatures and elevated CO<sub>2</sub> mixing ratios as dominant reason for increased  
255 seasonality (Graven et al. 2013, Forkel et al. 2016, Welp et al. 2016) although anthropogenically induced cropland productivity  
256 increases are suggested to play also some role (Gray et al. 2014). Specifically, *P* is assumed as a composite of the product and  
257 the sum of normed global-mean surface air temperature and normed CO<sub>2</sub> mixing ratio deviations from pre-industrial levels.  
258 The temperature and mixing ratio deviations are normalized such that the 2000-2010 deviation from the 1850-1880 base period  
259 is set to one. Thus, the regressor *P* can be described as:

$$260 \quad P(t) = \frac{\Delta T(t) * \Delta C(t)}{2} + \frac{\Delta T(t) + \Delta C(t)}{2} \quad (4)$$

261 With  $\Delta T$  being the normed temperature deviation from the 1850-1880 period, specifically

$$262 \quad \Delta T(t) = \frac{(T(t) - \sum_{t=1850}^{1880} T(t))}{\sum_{t=2000}^{2010} (T(t) - \sum_{i=1850}^{1880} T(i))} \quad (5)$$

263 And  $\Delta C$  being synonymously the normed mixing ratio deviation. Note that this regressor *P* is one of multiple options that were  
264 tested and could be regarded as a plausible regressor for seasonality changes. However, given that seasonality changes in the  
265 case of CO<sub>2</sub> depend on a complex interaction of CO<sub>2</sub> fertilization of temperate, seasonal gross primary productivity, as well as  
266 the influence of temperature, precipitation on biomass growth and respiration, this extension of the observed seasonality  
267 changes beyond the observational period is just that: a plausible extrapolation that needs to be refined by further and research  
268 to replace this study's *ad hoc* assumption.

269 The empirical seasonality of CH<sub>4</sub> and N<sub>2</sub>O over the observational time period is found to be closely approximated by our  
270 default assumption of a seasonality that is proportional to global mean mixing ratios. For a number of substances, however,

271 seasonality has been assumed to be zero – either because the diagnosed seasonality was very small or due to a lack of  
272 observational data.

### 273 **2.1.6 Step 11-13: Extension of latitudinal gradients and global means with ice core and firn data**

274 Historical GHG records from ice and firn provide high-latitude estimates of atmospheric greenhouse gas mixing ratios before  
275 the instrumental record from air sampling stations. We rely mainly on the Law Dome (Etheridge et al. 1998b, MacFarling  
276 Meure et al. 2006, Rubino et al. 2013) and, for CH<sub>4</sub>, Greenland NEEM ice core data (Rhodes et al. 2013). Although we did  
277 not directly use their data, we acknowledge multiple other efforts, including, but not limited to Mitchell et al. (2013), and  
278 Bauska et al. (2015), Schilt et al. (2010b), Flueckiger et al. (2002), and Sowers et al. (2003) (Figure 1). Law Dome atmospheric  
279 composition records have the advantage of a very narrow air age spread that provides measurements with high temporal  
280 resolution and mean air ages up to the 1970s, where they overlap with the beginning of atmospheric observations for many  
281 gases. The Law Dome data used here have been updated for minor dating changes and upgrades to NOAA scales (Rubino et  
282 al., 2013; <http://www.esrl.noaa.gov/gmd/ccl/index.html>).

283 Having obtained estimates of the latitudinal gradients over the observational period and having derived approximations back  
284 in time by regressing latitudinal gradients EOF scores with emissions (step 11 in Figure 22), this allows estimating global  
285 mean mixing ratios based on the Law Dome data in the case of both CO<sub>2</sub> and N<sub>2</sub>O (step 12 in Figure 22). In the case of CH<sub>4</sub>,  
286 the advantage is that there are northern hemispheric data points available from NEEM (Greenland) (Rhodes et al. 2013) that  
287 complement the Law Dome record over the past 2000 years. This NEEM record hence allows an optimisation of both the EOF  
288 scores and global means at past time points to match both the Law Dome and NEEM records (step 13 in Figure 22). Some data  
289 periods with gaps in the NEEM record are filled by linearly interpolating the optimised EOF scores of the latitudinal gradient.  
290 With an interpolated EOF score, the global-mean mixing ratio can then be directly inferred from the Law Dome record. All  
291 optimisations are performed by minimising area-weighted squared residuals.

292 The Law Dome ice core data are smoothed with a piecewise local 3<sup>rd</sup> degree polynomial median regression, using ad hoc  
293 expert judgement assumptions of errors and smoothing window widths specific to each gas in order to approximately reflect  
294 their long-term median evolution. In the case of CO<sub>2</sub>, a random error of 2 ppmv was assumed, a percentage age error (60 years  
295 at age 2000 years before present) with a bagging of 250 ensembles, a kernel width of 120 years, minimal number of data points  
296 of 7 and maximum of 25 (panel a in Figure 6). Likewise, CH<sub>4</sub> Law Dome data ice core data are smoothed with a 3<sup>rd</sup> degree  
297 polynomial median regression with a maximum kernel width of 100 years, 4 minimal data points (a constraint that overwrites  
298 the maximum kernel width, if necessary) and 10 maximal data points. Like for CO<sub>2</sub>, 250 ensembles were averaged, after adding  
299 noise of 3ppb, and an age uncertainty of 50 years for 2000 years. For N<sub>2</sub>O, a kernel width of 300 years was chosen with a  
300 minimum number of 7 and maximum number of 15 data points to be included in the piecewise 3<sup>rd</sup> degree polynomial  
301 regression. As for CO<sub>2</sub> and CH<sub>4</sub>, 250 ensembles were used for bagging after injecting a random noise of 3 ppbv and an age-  
302 dependent x-axis uncertainty of 90 years per 2000 years.

303 The Greenland NEEM ice core CH<sub>4</sub> data (Rhodes et al. 2013) exhibits some outliers in the recent period (Figure 1d) due to  
304 incursion of modern air into still-open pores of shallow ice. Spikes in deeper ice are likely due to impurities. Hence, we use  
305 the 5-year smoothed data provided by Rhodes et al. (2013) as a proxy for atmospheric background mixing ratios. We dated the  
306 NEEM firn air samples (Buizert et al. 2012) using the effective age procedure as in Trudinger et al. (2002) with the ages

307 published in Gosh et al. (2015), with a small correction to the NOAA 2006 scale data applied for gravity effects (as applied in  
308 other ice and firn data), using here only firn samples from the 2008 campaign.

#### 309 **2.1.7 Step 14: Extension of latitudinal gradients and global means with literature data**

310 For several gases, including ozone depleting substances, halons and PFCs, the available AGAGE and NOAA station data is  
311 sparse spatially. Before the start of systematic instrumental measurements, we use literature studies which make use of various  
312 data sources, such as air sample archives or firn records (step 14 in Figure 22). Specifically, if a global mean is provided, we  
313 use that global mean in conjunction with our derived and regressed latitudinal gradients. In case of hemispheric data-points,  
314 we adapt the latitudinal gradient to match the literature studies, as in the case of  $C_4F_{10}$ ,  $C_5F_{12}$ ,  $C_6F_{14}$ ,  $C_7F_{16}$  or  $C_8F_{18}$ , where we  
315 based both the global mean and latitudinal gradients on the data of Ivy et al. (2012). Other key studies used were Velders et al.  
316 (2014), the data underlying the WMO Ozone Assessment Report (2014), Arnold et al. (2013, 2014), Trudinger et al. (2004),  
317 Mühle et al. (2009, 2010a), Montzka et al. (2011), updated time series by Montzka et al. (1999) (updated at:  
318 [ftp://ftp.cmdl.noaa.gov/hats/Total\\_Cl\\_Br/](ftp://ftp.cmdl.noaa.gov/hats/Total_Cl_Br/)), the recent Halon study by Vollmer et al. (2016) and PFC study by Trudinger et al  
319 (2016), as indicated in the gas-specific factsheet figures (Figure 23 to Figure 62). In the case of  $N_2O$  and  $CH_2Cl_2$  we assumed  
320 a constant latitudinal gradient back in time before ongoing measurement records are available (Figure 5, and Figure 29,  
321 respectively).

#### 322 **2.1.8 Step 15: Extrapolation**

323 For some limited data segments, an extrapolation has been used. Either a piecewise smoothing spline to converge mixing ratios  
324 back to zero or pre-industrial background mixing ratios, e.g. before the WMO (2014) or Velders et al. (2014) data started.  
325 Furthermore, a linear extrapolation was applied, when there were not sufficient 2014 data available.

#### 326 **2.1.9 Step 16-19: Creating the composite surface mixing ratio field**

327 Following equation (1), the surface mixing ratio fields over the full time span are now synthesized from the lower rank  
328 representations of seasonality, latitudinal gradient and the smooth monthly representation of global mean mixing ratios. As per  
329 the original station data aggregation, the latitudinal resolution is 15 degrees and time resolution is monthly. In order to assist  
330 the application in climate models with finer grids, we produced also a finer grid interpolation to 0.5 degree latitudinal resolution  
331 using a mean-preserving smoothing. This finer grid interpolation should not be mistaken as mixing ratio field containing actual  
332 information at 0.5 degree level. The purpose is simply to offer a smooth interpolation that avoids errors that will arise from,  
333 e.g., a linear interpolation between the provided 15 degree latitude points, as the mean across those (linearly) interpolated  
334 values, would not match the original field. The mean-preserving smoothing code is available from the authors on request.  
335 Finally, the 15 degree fields are aggregated towards global, northern and southern hemisphere monthly and annual means.

#### 336 **2.1.10 Step 20: Aggregating equivalent mixing ratios**

337 It is computationally inefficient to model the radiative effect of 43 individual greenhouse gases in today's Earth system models  
338 or general circulation models. Climate models use different pathways to approximate the radiative effects of the full set of  
339 greenhouse gases. As one strategy, only the radiatively-major greenhouse gases are explicitly modelled, such as  $CO_2$ ,  $CH_4$ ,  
340  $N_2O$ , CFC-12, CFC-11, which together cause 94.5% of GHG warming effect (measured in radiative forcing) in 2014 rel. 1750  
341 and 98% of the total radiative effect compared to the full set of 43 GHGs (Table 10). Alternatively, radiatively-minor GHGs  
342 can be approximated by equivalent greenhouse gas concentrations of a marker gas. In this way, the radiative effect of the group  
343 of gases is expressed by a single gas mixing ratio. One definitional issue is whether the radiative forcing since 1750, i.e. only

344 the changes since pre-industrial levels, are expressed by the marker gas (here called ‘marginal equivalence’  $C_{eq,i}$ ). In this case,  
 345 the marker gas’ concentrations  $C_{eq,i}$  are sought that would exert the same aggregate radiative forcing since 1750 as the group  
 346 of summarized gases. Thus, let  $C_j(t)$  be the concentration (volumetric or mole mixing ratio) of a greenhouse gas and  $C_{0,j}$  the  
 347 pre-industrial level, i.e. in year 1750 that is routinely used as base year for radiative forcing (IPCC 2013). A marker equivalence  
 348 mixing ratio by gas  $C_{eq,i}$  for group  $C_j$  with  $j = 1, \dots, n$  is then given by:

$$349 \quad C_{eq,i}(t) = R_i^{-1} \left( R_i(C_{0,i}) + \sum_{j=1}^n \left( R_j(C_j(t)) - R_j(C_{0,j}) \right) \right) \quad (6)$$

350 With  $R_j(C)$  being the radiative forcing function relating mixing ratios  $C(t)$  at time  $t$  to radiative forcing for gas  $j$ , in the linear  
 351 case  $R_j(C) = C * E_j$  with  $E_j$  being the radiative efficiency.  $R_i^{-1}(F)$  is the inverse of this radiative forcing function, so that the  
 352 mixing ratio  $C$  that corresponds to a forcing  $F$  is given by  $C = R_i^{-1}(F)$ .

353 In contrast, equivalent mixing ratios can express the radiative effects of the summarized greenhouse gases including their  
 354 natural background levels (here called ‘full equivalence’  $C'_{eq,i}$ ).

$$355 \quad C'_{eq,i}(t) = R_i^{-1} \left( \sum_{j=1}^n R_j(C_j(t)) \right) \quad (7)$$

356 While the former definition ‘marginal equivalence’ is often used to express the total greenhouse gas forcing in CO<sub>2</sub> equivalence  
 357 mixing ratios, the latter ‘full equivalence’ is the more appropriate quantity to drive climate models, given that natural  
 358 background mixing ratios of not-explicitly considered gases should nevertheless exert a radiative effect even in a pre-industrial  
 359 control, even though that radiative effect does not count under a radiative forcing definition that looks at changes from 1750.

360 In the linear case, in which case radiative forcing is proportional to the gas’ mixing ratios, equation (7) can be written as:

$$361 \quad C'_{eq,i}(t) = \frac{\sum_{j=1}^n r_j^{eff} * C_j(t)}{r_i^{eff}} \quad (8)$$

362 With  $r_i^{eff}$  being the radiative efficiency of the gas  $i$  in W/m<sup>2</sup> per ppbv.

363 Thus, climate models have the option to reduce the complexity of 43 GHGs and the associated computational burden by  
 364 reducing the number of GHGs that are taken into account. With the top 5 GHGs, CO<sub>2</sub>, CH<sub>4</sub>, N<sub>2</sub>O, CFC-11 and CFC-12, climate  
 365 models would capture 98% of the total radiative effect in year 2014 and 94.5% of the radiative forcing since 1750, i.e. the  
 366 change of the radiative effect between 1750 and 2014 (see Table 10). As alternative, there is the option to use equivalent  
 367 mixing ratios. For two such equivalence options, this study provides input data sets. Modelling groups should indicate the  
 368 combination of files they employed:

- 369 a) **Option 1:** Climate models implement a subset of 43 greenhouse gases.
- 370 b) **Option 2:** Climate models implement the four most important GHGs with their actual mixing ratios explicitly,  
 371 namely CO<sub>2</sub>, CH<sub>4</sub>, N<sub>2</sub>O and CFC-12 and summarize the effect of all other 39 gases in an equivalence mixing ratio  
 372 of CFC-11. For this purpose, we provide CFC-11-eq mixing ratios (‘full equivalence’).
- 373 c) **Option 3:** Like option 2, but with a different split up of gases other than CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O. Climate models  
 374 implement the three most important GHGs with their actual mixing ratios explicitly, namely CO<sub>2</sub>, CH<sub>4</sub>, and N<sub>2</sub>O

375 and summarize the radiative effect of the ozone depleting substances in a CFC-12-eq mixing ratio and the radiative  
376 effect of all other fluorinated gases as a HFC-134a-eq mixing ratio. For this purpose, we provide CFC-12-eq and  
377 HFC-134a-eq mixing ratios ('full equivalence').  
378

## 379 **2.2 Data analysis for comparisons**

380 We compare our results to a number of comparison products, namely the CO<sub>2</sub> fields from CMIP5 Earth System Models  
381 (ESMs). Here, we briefly describe the analytical steps that we performed for retrieving the CMIP5 ESM data.

382 Analyzed are ten CMIP5 ESMs models that have an interactive carbon cycle model and provided the mole fraction of carbon  
383 dioxide in the air as function of different pressure surfaces for the *esmhistorical* experiment. We diagnosed those *esmhistorical*  
384 experiments in terms of the simulated CO<sub>2</sub> mixing ratio at surface pressure (1bar = 100000 Pa) for 10 CMIP5 ESM models,  
385 for which data were available: (1) BNU-ESM (BNU, China), (2) CanESM2 (CCCMA, Canada), (3) CESM1-BGC (NSF-DOE-  
386 NCAR, USA), (4) FIO-ESM (FIO, China), (5) GFDL-ESM2G (NOAA GFDL, USA), (6) GFDL-ESM2M (NOAA GFDL),  
387 (7) MIROC-ESM (MIROC, Japan), (8) MPI-ESM-LR (MPI, Germany), (9) MRI-ESM1 (MRI, Japan), (10) NorESM1-ME  
388 (NCC, Norway). For the models CanESM2, MIROC-ESM and MPI-ESM-LR more than one realization is available. We  
389 calculated an ensemble mean based on the all available ensemble members. The climatological seasonal cycle (Figure 13,  
390 Figure 14) is calculated relative to the linear trend of the corresponding 30-year periods.

391

### 392 3 Results

393 Here, we describe the historical mixing ratios of the main greenhouse gases and provide a fact sheet for all 43 individual gases.

#### 394 3.1 Carbon Dioxide

395 The 800-thousand-year EPICA composite ice-core record (Lüthi et al. 2008) indicates that CO<sub>2</sub> mixing ratios have fluctuated  
396 between 170 and 270ppmv (Figure 1a) in conjunction with glacial- and inter-glacial temperature variations. From the year 0  
397 to 1000, our piecewise fit of the 3<sup>rd</sup> degree polynomial of Law Dome ice core data allows a derivation of global mean mixing  
398 ratios of around 278.6 ppmv (min-max range of 277.0 to 280.2 ppmv).

399 Our smoothed Law Dome results do not reflect the higher frequency variations suggested by the individual data points  
400 ((Etheridge et al. 1996, MacFarling Meure et al. 2006, Rubino et al. 2013) and are comparable to the frequency spectrum that  
401 would result from a smoothed median estimate of WAIS data by Bauska et al. (2015) and Ahn et al. (2012). The WAIS record  
402 is generally 3-6 ppmv higher than the Law Dome record and is also higher than South Pole and EPICA DML ice cores (Ahn  
403 et al. 2012). The cause for this difference is not yet known (Figure 1b). In terms of the various possible frequency spectra,  
404 modelling groups might want to test an alternative data set that captures those higher frequency characteristic of the Law Dome  
405 record (data can be generated by the authors on request). In that higher frequency data set, the minimum of global mean CO<sub>2</sub>  
406 mixing ratios is close to 270 ppmv around the year 1615. The smoother version now provided for CMIP6 has its minimum in  
407 year 1666 at 276.27 ppmv (Figure 1b). The reason for the 1610 dip in the Law Dome record and why this does not show in the  
408 WAIS record is not yet fully understood. The current understanding of how the age kernel is different for the two sites cannot  
409 yet explain this difference in mixing ratios around 1610.

410 In regard to the latitudinal gradient, we explored various options. If we regress the first EOF of the latitudinal gradient (Figure  
411 2d) against global fossil CO<sub>2</sub> emissions, the pre-industrial latitudinal minimum of surface CO<sub>2</sub> mixing ratios would be  
412 estimated in the mid-northern latitudes (approximately 1.8 ppmv below the global-mean), where the maximum was observed  
413 in recent decades (e.g. 4.8 ppmv above the global-mean in 2010). Previously a similar regression approach between mixing  
414 ratios and CO<sub>2</sub> emissions was used by Keeling et al. (2011) to separate the anthropogenic from the natural component in the  
415 mixing ratio difference between Mauna Loa and the South Pole. While this approach is not perfect due to the covariance of  
416 regional fossil fuel emissions with natural sinks over the same period, different patterns of anthropogenic land-use emissions,  
417 and a latitudinal gradient component that merely results from seasonal CO<sub>2</sub> exchange (e.g. Denning et al. 1995), it can  
418 nevertheless provide a first indication of the influence of anthropogenic emissions on the latitudinal gradient. Furthermore,  
419 this approach would have resulted in an approximately 0.4 ppmv higher pre-industrial Antarctic CO<sub>2</sub> mixing ratios compared  
420 to the global mean coinciding with the assumption taken by Rubino et al. (2013).

421 However, given the evidence by CMIP5 ESM models of a slight tropical local maximum (Figure 2b) and large uncertainties  
422 with regard to pre-industrial sinks and source distributions and hence the latitudinal gradients of CO<sub>2</sub>, we assumed a zero pre-  
423 industrial latitudinal gradient. Thus we performed a zero-intercept regression of the latitudinal gradient EOF1 with global fossil  
424 CO<sub>2</sub> emissions and converging the score of the second EOF towards zero, resulting in a flat latitudinal gradient in pre-industrial  
425 times.

426 The second EOF of the latitudinal gradient of CO<sub>2</sub> does not exhibit the same linearity over time as the first EOF, and the  
427 reasons are currently unknown. Potential candidates for this pronounced spike of mid-northern latitude mixing ratios in the

428 case of CO<sub>2</sub> are a shift in station sampling locations with more ‘polluted’ land-station coming on line after 1995, the ‘rectifier’  
429 effect due to an enhanced seasonal cycle (Denning et al. 1995), and the rise of Chinese emissions (albeit the onset of the recent  
430 surge in Chinese CO<sub>2</sub> emissions is often demarked to start slightly later, only by 2003 (Francey et al. 2013)). One suggested  
431 explanation for this 2010 change in north-south gradients are changes in interhemispheric transport (Francey and Frederiksen  
432 2016). Recently, i.e. after 2010, this spike in mid-latitude northern mixing ratios seemed to somewhat subside again according  
433 to our analysis (see scores for EOF1 and EOF2 in Figure 2d). Future research could further investigate the underlying reasons  
434 of this change in latitudinal patterns and a physical explanation will allow a more appropriate backward extension in time.

435 The diagnosed average seasonality of atmospheric CO<sub>2</sub> mixing ratios over the observational period reflects the standard carbon  
436 cycle pattern of strong CO<sub>2</sub> uptake in spring and release in autumn due to photosynthesis and heterotrophic respiration in the  
437 northern hemispheres ecosystems. Our EOF analysis of the residuals then shows (Figure 2a.2 and a.3) that the seasonality has  
438 increased over recent decades in line with previous studies, which explore the link to increased ecosystem productivity (Graven  
439 et al. 2013, Forkel et al. 2016, Welp et al. 2016) and increased cropland productivity (Gray et al. 2014). Specifically, our  
440 analysis shows a slight shift of the seasonality to earlier months in the year, i.e. the negative and positive deviations of the EOF  
441 pattern are shifted by a month compared to the average seasonality (cp. Figure 2a.1 and a.2). The strongest change in CO<sub>2</sub>  
442 seasonality is derived for the latitudinal bins centered around 37.5 to 67.5 degree north bins with a maximum strengthening of  
443 negative deviations in the 52.5 degree north latitudinal band in July by around 4 ppmv over 1984 to 2013 (4 ppmv results from  
444 multiplying the EOF pattern value in July in the 52.5-degree bin with the EOF score difference of around 10, see Figure 2a.2  
445 and a.3). Although the maximum strengthening of the seasonal cycle happens in July in the 52.5-degree latitudinal band, the  
446 maximum seasonal cycle deviation is still observed slightly later in August and extends also slightly more towards the northern  
447 latitudes (Figure 2a.1).

448 In 1850, the start of the historical CMIP6 simulations, the estimated global-mean CO<sub>2</sub> mixing ratio is 284.32ppmv, rising to  
449 295.67 ppmv in 1900, 312.82 ppmv in 1950, 369.12 ppmv in year 2000 up to 397.55 ppmv in 2014 (Table 7). Here and  
450 elsewhere (e.g. Table 7) we provide more significant figures than customary - not to claim a 5-digit precision of the data (which  
451 is not given), but to avoid unnecessary (even if small) step changes in mixing ratios between the pre-industrial run and the  
452 historical and other runs. Variations in the increase of global-mean surface CO<sub>2</sub> mixing ratios are a slight flattening in the  
453 1930s and then a stronger flattening during the World War II until the 1950s. The increase from 1970 onwards has a slightly  
454 positive curvature (accelerating trend) with small deviations around 1973, 1981 and the temporary flattening of CO<sub>2</sub> mixing  
455 ratios after the 1991 Pinatubo eruption (Jones and Cox 2001, Peylin et al. 2005) (Figure 2 and Figure 3).

### 456 3.2 Methane

457 Over the 800 thousand years before Year 0, atmospheric CH<sub>4</sub> mixing ratios varied between 348.7 ppbv and 728.4 ppbv  
458 according to the EPICA ice core composite (Barbante et al. 2006, Loulergue et al. 2008, Capron et al. 2010) (Figure 1c and  
459 Figure 4). The Law Dome record (Etheridge et al. 1998a, MacFarling Meure et al. 2006) indicates an onset of increasing  
460 mixing ratios around the year 1720 (Figure 1d, and Figure 4). From Year 1850 with slightly higher than 800 ppbv mixing  
461 ratios, a slight rise is observed until the 1950s, when CH<sub>4</sub> mixing ratios markedly increase first in the latter half of the 1950s,  
462 then again from 1965 onwards. The Greenland firn and ice core data (Rhodes et al. 2013) are more difficult to interpret because  
463 part of the record is affected by high frequency ice core CH<sub>4</sub> signals possibly of non-atmospheric origin. CH<sub>4</sub> spikes are  
464 accompanied by elevated mixing ratios of black carbon, ammonium and nitrate, suggesting that biological *in situ* production  
465 may be responsible – particularly in the later years of the record since 1940. Taking here the 5-yearly average measurement

466 values with outliers removed (Rhodes et al. 2013) that approximate the lower bounds of the raw data points until 1942, we can  
467 then infer global gradients back in time and derive an estimate of global-mean mixing ratios. These global-mean mixing ratios  
468 are estimated to be around 30 ppbv higher than the Law Dome record by 1850, with the difference growing to 45 ppbv by  
469 1940s, increasing further from there (Figure 1d). This approximately matches the findings by Mitchell et al. (2013) of inter-polar  
470 differences between 35 and 45 ppbv since 400 BC.

471 Our analysis of CH<sub>4</sub> mixing ratios in the recent decades is based on a large number of stations (Table 8 and Figure 4f). While  
472 the annual increase of global CH<sub>4</sub> mixing ratios slowed over the 1980s and markedly after 1992 towards stabilized mixing  
473 ratios between 1999 to 2005, CH<sub>4</sub> increased again after 2006 at about 5.4 ppbv/yr (Figure 4f).

474 We retrieve a seasonal cycle of CH<sub>4</sub> that is similar in the spatial-temporal seasonality pattern as that of CO<sub>2</sub> (Figure 4a). Each  
475 hemisphere exhibits its lowest CH<sub>4</sub> mixing ratios just after the summer solstice, up to 1.6% or 28 ppbv lower than the global  
476 mean in the case of the high-latitude northern summer (Figure 4a). Quantifying the underlying reasons is beyond the scope of  
477 this study, although the seasonally varying atmospheric sinks by OH oxidization are likely the main contributor to that pattern  
478 – in combination with seasonally varying natural and anthropogenic sources.

479 The latitudinal annual-mean gradient of CH<sub>4</sub> mixing ratios is separated into its first two EOFs, with the first EOF being a  
480 continuous north-to-south gradient of about 90 ppbv in the recent observational period (combination of EOF and its score, see  
481 Figure 4c and d). The second EOF is a distinct mid-northern latitude local maximum with a high-latitude low, showing a slight  
482 but marked rise in 2008 within the 1985 to 2014 observational data window. Quantifying the reasons for this hump are again  
483 beyond the scope of this study, with the possibility of a shift in locations of sampling stations or coal-seam gas-fracking related  
484 fugitive emissions being possible contributors. While we optimize the first EOF, the general north-south gradient to match the  
485 Greenland data and Antarctic Law Dome data in the past, we keep the second EOF of the latitudinal gradient constant at its  
486 1985 value.

487 As a result of the constant extrapolation of the second EOF, and the optimization of the first EOF's score (Figure 4d), we yield  
488 a total annual-mean meridional gradient for the last decades that features around 80 ppbv higher surface CH<sub>4</sub> mixing ratios in  
489 mid-to-high northern latitudes compared to the global mean and around 60 ppbv lower CH<sub>4</sub> mixing ratios at the high southern  
490 latitudes (Figure 4b). In pre-industrial times, our approach of regressing the score of EOF1 with global emissions suggests this  
491 gradient to be smaller, with only approximately 20-30 ppbv higher northern and 20 ppbv lower southern latitude surface mixing  
492 ratios (Figure 4b). These mean inter-polar differences and their variations have earlier been quantified by Etheridge (1998a)  
493 and Mitchell et al. (2013), yielding similar results (between 30 to 60 ppbv) compared to our 40 to 50 ppbv estimate.

### 494 3.3 Nitrous Oxide

495 N<sub>2</sub>O mixing ratios from ice cores dating back 800 thousand years (Fluckiger et al. 2002, Schilt et al. 2010b) varied  
496 approximately between 200 ppbv and 300 ppbv, with most recent glacial mixing ratio minima of 180 ppbv around 23 thousand  
497 years ago (Sowers et al. 2003) (Figure 1e). The ice core record over the last 2000 years indicates marked difference between  
498 the Law Dome and GISPII record (Sowers et al. 2003), with the latter being up to 10 ppbv lower. Here, as with CH<sub>4</sub>, we use  
499 again a median quantile piecewise polynomial regression on the Law Dome record, assuming constant N<sub>2</sub>O mixing ratios  
500 between year 0 and the first Law Dome data point in Year 154. In contrast to CH<sub>4</sub>, there is not a monotonic increase of mixing  
501 ratios, but rather an initial slight decrease until year 630 down to a minimum mixing ratio of 265 ppbv in our smoothed  
502 timeseries with a subsequent slow increase until the 9<sup>th</sup> century AD, then a slight decrease until 1650 in the smoothed global-

503 mean mixing ratios. A temporary local maximum indicated by individual Law Dome data in the 15<sup>th</sup> century is not resolved  
504 by our smoothing, and a similar spike in the 17<sup>th</sup> century is only just reflected (Figure 1f). Several data points indicate a small  
505 decrease after a 1750 maximum, with a minimum in 1850 of around 273.02 ppbv. After that, N<sub>2</sub>O mixing ratios increased  
506 markedly, reaching 1900, 1950, 2000 and 2014 values of 279.45, 289.74, 315.76 and 326.99 ppbv, respectively (Table 7).

507 Compared to CH<sub>4</sub> and CO<sub>2</sub>, the seasonality and latitudinal gradient of N<sub>2</sub>O are relatively small. The N<sub>2</sub>O seasonality is only  
508 0.1% of global mixing ratios and is almost symmetric and seasonally time-synchronized between the northern and southern  
509 hemispheres with minima in the southern hemisphere late autumn and northern hemisphere summer/autumn (Figure 5a). The  
510 seasonality is currently of the same size as the underlying trend, leading to global mean N<sub>2</sub>O mixing ratios increasing in the  
511 latter months of any year with a subsequent flattening in the first half of any calendar year (e.g. Figure 5h). Given a counter-  
512 intuitive slight decrease of the north-south gradient with increasing global N<sub>2</sub>O emissions in recent years, we assumed constant  
513 scores for the latitudinal gradient EOFs for times before 1996 (Figure 5d). Due to measurement fluctuations in the first years  
514 when systematic measurements started in 1978 that are larger compared to the recent period, we chose to interpolate N<sub>2</sub>O  
515 global-mean mixing ratios over 1966 to 1987. For the period between 1978 and 1987, this interpolation is closely aligned with  
516 and can be seen as smooth representation of the atmospheric measurements (Figure 5f, cf. ALE/GAGE/AGAGE data as shown  
517 at [http://agage.eas.gatech.edu/data\\_archive/data\\_figures/gcmd\\_month/n2o\\_monS5.pdf](http://agage.eas.gatech.edu/data_archive/data_figures/gcmd_month/n2o_monS5.pdf)).

### 518 **3.4 Ozone Depleting Substances and other chlorinated substances**

519 Ozone depleting substances (ODSs), i.e. the substances destroying ozone and being controlled under the Montreal Protocol,  
520 have a large warming effect. In particular CFC-12 and CFC-11 are important greenhouse gases, as well as the replacement  
521 substance HCFC-22, which, unlike CFCs, continues to increase in the atmosphere, albeit at a declining rate. The radiative  
522 forcing of CFC-12 alone since 1750 is equivalent to that of N<sub>2</sub>O, which is usually considered the third most important  
523 greenhouse gas after CO<sub>2</sub> and CH<sub>4</sub> (Table 10). The impact of ODSs on climate is somewhat complicated by their destruction  
524 of ozone, which leads to a cooling of the global climate. The latest estimates suggest that this cooling might offset roughly  
525 two-thirds of the warming of the entire class of ODSs (Shindell et al. 2013). Note that we consider here also methylene chloride  
526 and methyl chloride, although these chlorinated substances are not controlled by the Montreal Protocol and hence often not  
527 termed ozone depleting substances (WMO 2014).

528 The most abundant ozone depleting substances in the atmosphere (in 2014) are CFC-12 (520.6 pptv), CFC-11 (233.1 pptv)  
529 and HCFC-22 (229.5 pptv), with their mole fractions being about six orders of magnitude lower than currently measured for  
530 CO<sub>2</sub> (Table 3). In addition, methyl chloride CH<sub>3</sub>Cl has a high mole fraction (539.54 pptv), although is not considered an ODS  
531 here as it is not controlled by the Montreal Protocol. Out of the 17 considered chlorinated and ozone depleting substances, only  
532 6 have currently increasing mixing ratios. Those are the three HCFCs, of which the increase in HCFC-22 alone has offset the  
533 reducing radiative forcing of all other ozone depleting substances (ODS) over the past decade (Figure 6m). The other three  
534 substances that are still increasing are Halon-1301, methylene chloride (CH<sub>2</sub>Cl<sub>2</sub>) and chloroform (CHCl<sub>3</sub>). Chloroform had  
535 been decreasing in the 1990s and stabilized in the 2000s, but again recently showed an increase (Figure 33).

536 Four of the considered chlorinated and ozone depleting substances are assumed to have natural emissions and hence non-zero  
537 pre-industrial mixing ratios. Specifically, methyl chloride (CH<sub>3</sub>Cl) is assumed to have pre-industrial global-mean mixing ratios  
538 of 457 pptv, carbon tetrachloride (CCl<sub>4</sub>) of 0.025 pptv, and methyl bromide (CH<sub>3</sub>Br) of 5.3 pptv. Chloroform (CHCl<sub>3</sub>) is  
539 assumed to have a pre-industrial mixing ratio of about 6 pptv, approximately in line with findings by Worton et al. (2006) and

540 the estimation by Aucott et al. (1999) that in 1990  $\text{CHCl}_3$  was at about 8 pptv, 80% are of natural origin. Lastly, methylene  
541 chloride ( $\text{CH}_2\text{Cl}_2$ ) is estimated to have a 6.9 pptv pre-industrial mixing ratio with a strong latitudinal gradient that results in  
542 northern (southern) hemisphere average mixing ratios of 12.8 (1.0) pptv, even though this isn't well described by observational  
543 data. The transition of mixing ratios of some species between the observational station data and pre-industrial levels are also  
544 uncertain. For  $\text{CH}_2\text{Cl}_2$ , our derivation is in line with the smooth trajectory of Trudinger et al. (2004), indicating an almost  
545 monotonic transition between 1997 values and pre-industrial mixing ratios (Figure 29f).

546 The seasonal cycle of ozone depleting substances and other synthetic GHGs can be influenced by seasonally varying  
547 stratospheric-tropospheric air exchanges, interhemispheric transport, tropopause heights, emissions and, for those substances  
548 with OH-related sinks, the seasonally varying OH mixing ratios. For 11 out of the 17 considered ozone depleting substances  
549 we find some indication of seasonal cycles based on the analyzed station data, namely for  $\text{CCl}_4$ , CFC-11, CFC-12, CFC-113,  
550  $\text{CH}_2\text{Cl}_2$ ,  $\text{CH}_3\text{Br}$ ,  $\text{CH}_3\text{CCl}_3$ ,  $\text{CH}_3\text{Cl}$ ,  $\text{CHCl}_3$ , Halon-1211, and HCFC-11. Our analysis indicates that HCFC-141b also shows  
551 some signs of a seasonal cycle, although we here assumed a zero seasonal cycle due to data sparsity (see Figure 38a). We find  
552 the strongest seasonal cycles in case of the short-lived species  $\text{CH}_3\text{Cl}$ ,  $\text{CHCl}_3$ ,  $\text{CH}_3\text{Br}$  and  $\text{CH}_2\text{Cl}_2$  with absolute maximal  
553 seasonal deviations of -11%, -12%,  $\pm 9\%$ , -32% compared to the annual mean, respectively. For the radiatively important and  
554 longer-lived species CFC-12, CFC-11 and HCFC-22, the seasonal cycle is much smaller, with  $\pm 0.2\%$ ,  $\pm 0.4\%$ ,  $\pm 0.8\%$ ,  
555 respectively.

556 Similar to the seasonality, the latitudinal gradient is found to be especially pronounced for the short lived substances.  
557 Specifically,  $\text{CH}_2\text{Cl}_2$  with a lifetime of 0.4 years,  $\text{CH}_3\text{Br}$  with a lifetime of 0.8 years,  $\text{CH}_3\text{CCl}_3$  with a lifetime of 5 years and  
558  $\text{CH}_3\text{Cl}$  with a lifetime of approximately 1 year and  $\text{CHCl}_3$  with a lifetime of 0.4 years show substantial latitudinal gradients  
559 due to spatially heterogeneous sinks and sources (lifetimes following Table 8.A.1 in IPCC WG1 AR5 (2013)). While normally  
560 the mid to high northern latitudes experience the highest mixing ratios for these compounds, the measurements for several  
561 substances suggest a pronounced high-latitude northern hemisphere decline in annual average mixing ratios (see e.g.  $\text{CH}_3\text{Cl}$  in  
562 Figure 32b and c).

### 563 3.5 Other fluorinated greenhouse gases

564 The 23 other gases in this study whose production and consumption is not controlled under the Montreal Protocol are the  
565 hydrofluorocarbons (HFCs), perfluorocarbons (PFCs) as well as Sulphur hexafluoride ( $\text{SF}_6$ ), nitrogen trifluoride ( $\text{NF}_3$ ), and  
566 sulphuryl fluoride ( $\text{SO}_2\text{F}_2$ ). Except for the latter, the emissions of all these species are controlled under the Kyoto Protocol and  
567 covered by most “nationally determined contributions” (NDCs) under the Paris Agreement. In aggregate, this group of  
568 synthetic GHGs however exerts an almost factor of 10 smaller greenhouse gas effect to date compared to the ozone depleting  
569 substances (cp. Figure 6g and m). In contrast to the gases controlled under the Montreal Protocol, nearly all of these other  
570 fluorinated gas mixing ratios are still rising, however, with the exception of HFC-152a, which has stopped growing since 2012  
571 and may now be in decline, Figure 55f). Thus, a primary concern with these gases is the potential for substantial climate forcing  
572 in the future if uncontrolled growth continues.

573 The most abundant of these gases is the refrigerant HFC-134a with 2014 mixing ratios estimated to be 80.5 pptv, followed by  
574 HFC-23 (26.9 pptv), HFC-125 (15.4 pptv) and HFC-143a (15.2 pptv). At the other end of the mixing ratio spectrum, we include  
575 results from Ivy et al. (2012) for some PFCs that exhibit low mixing ratios of 0.13 pptv ( $\text{C}_5\text{F}_{12}$  and  $\text{C}_7\text{F}_{16}$ ) or 0.09 pptv ( $\text{C}_8\text{F}_{18}$ )

576 (Table 3). The only gas considered to have natural sources and hence a pre-industrial background concentration is CF<sub>4</sub> with an  
577 assumed pre-industrial mixing ratio of 34.05 pptv (see Figure 48) in line with findings by (Trudinger et al. 2016).

578 For a number of substances, especially the PFCs with lower abundances, there were not sufficient data available to estimate  
579 the seasonality of atmospheric mixing ratios. We consider seasonality only for 3 of the 23 species. HFC-134a has a somewhat  
580 atypical pattern of lowest mixing ratios in the spring northern hemisphere (-2.6% compared to annual mean) as other gases  
581 normally show a summer or autumn low point of mixing ratios. This spring minimum results from a seasonality of sources of  
582 this refrigerant (Figure 53a), although seasonality in loss also likely plays a role (Xiang et al. 2014). Secondly, the short-lived  
583 HFC-152a (lifetime 1.5 years) shows seasonal variations of up to -13% while the very long lived SF<sub>6</sub> (lifetime of 3200 years)  
584 exhibits a much smaller seasonality of up to -0.5%.

585 For most of the considered substances, the latitudinal gradient is rather small. Exceptions are the shorter-lived species like  
586 HFC-32, whose mixing ratio rose quickly since 2000 due to rapidly increasing northern hemispheric sources (Figure 50b),  
587 HFC-152a, and some other shorter lived HFCs. For the three heavier PFCs with very low abundances of well below 1 pptv in  
588 2014, namely C<sub>6</sub>F<sub>14</sub>, C<sub>7</sub>F<sub>16</sub> and C<sub>8</sub>F<sub>18</sub>, we incorporated hemispheric data from Ivy et al. (2012). Before about 1990, those three  
589 gases are suggested to have reverse latitudinal gradients with higher southern hemispheric mixing ratios. Due to the very low  
590 mixing ratios near the limit of measurement, future studies may need to confirm whether those reverse gradients existed (and  
591 if so, why). Given the negligible radiative forcing from these gases to date, this uncertainty does not affect the overall results.

#### 592 **4 The CMIP6 recommendation and data format**

593 We present the community CMIP6 data sets of historical GHG mixing ratios. In conjunction with other data, these greenhouse  
594 gas surface mixing ratio data sets are to be used in the concentration-driven runs for the climate model inter-comparison project  
595 phase 6 (CMIP6) (Eyring et al. 2015), specifically the historical run, and the idealized runs of abrupt4x, 1pctCO<sub>2</sub> as well as  
596 the picontrol. The CMIP6 recommendation as decided by the CMIP Panel is: “In the CO<sub>2</sub>-concentration-driven historical  
597 simulations, time-varying global annual mean mixing ratios for CO<sub>2</sub> and other long-lived greenhouse gases are prescribed. If  
598 a modelling center decides to represent additional spatial and seasonal variations in prescribed greenhouse gas forcings, this  
599 needs to be adequately documented.” (Eyring et al. 2016).

600 This study provides the data for both the simple global annual mean mixing ratios as well as the mixing ratio histories that take  
601 latitudinal and seasonal variations into account (see data description further below). CMIP6 modelling groups should indicate  
602 which time and space resolution of the data version they applied. All data are freely available via the PCMDI servers  
603 (<https://pcmdi.llnl.gov/search/input4mips/>) as netcdf files. In addition, summary tables and csv, xls and MATLAB mat versions  
604 of the data files are provided at [climatecollege.unimelb.edu.au/cmip6](http://climatecollege.unimelb.edu.au/cmip6).

605 In terms of the spatio-temporal resolution, four files for each of the 43 greenhouse gases and the three equivalence species  
606 CFC-12-eq, HFC-134a-eq and CFC-11-eq (section 2.1.10) are provided as:

- 607 I. latitudinal 15-degree bins with monthly resolution (filename-code: '\_15degreelatXmonth'), with monthly means for  
608 each latitudinal band provided at the centre of the box, i.e. -82.5, -67.5, ... 67.5, 82.6.

- 609 II. interpolated latitudinal half degree bins with monthly resolution (filename-code: '\_0p5degreeLatXmonth'), with means  
 610 for each latitudinal band provided at the center of the box, i.e. -89.75, -89.25, ... 89.25, 89.75. The area-weighted  
 611 mean over 15-degree latitudinal bands is the same as the files under (1).
- 612 III. Global and hemispheric means with monthly resolution (filename-code '\_GMNHSmeanXmonth').
- 613 IV. Global and hemispheric means with annual resolution (filename-code '\_GMNHSmeanXyear')

614 Given that climate effects will vary whether global, annual-mean or seasonally varying latitudinally-resolved surface  
 615 mixing ratios are prescribed, modelling groups are asked to document which data set(s) they choose.

616 The CMIP6 recommendation for the **picontrol** experiment are to use the 1850 greenhouse gas mixing ratios with annual  
 617 means as provided in Table 5 (CO<sub>2</sub> annual-mean mixing ratios of 284.32 ppmv, CH<sub>4</sub> mixing ratios of 808.25 ppbv and  
 618 N<sub>2</sub>O mixing ratios of 273.02 ppbv). Other gases are covered, depending on the choice of the modelling group by either  
 619 following Option 1, Option 2, or Option 3, or an equivalently suited method that aggregates the radiative effect of the  
 620 remaining 40 GHGs or a large fraction thereof.

621 The **abrupt4x** experiment should keep all greenhouse gas mixing ratios unchanged from the picontrol run except for the  
 622 CO<sub>2</sub> mixing ratios, which should be increased instantaneously in year 1 (=1850) of the experiment to four times the 1850  
 623 value, namely to 1137.27 ppmv (Table 6).

624 The **1pctCO2** experiment should also keep all greenhouse gas mixing ratios unchanged from the picontrol run except for  
 625 CO<sub>2</sub> mixing ratios. Starting in year 1 of the experiment, CO<sub>2</sub> mixing ratios should increase by 1% per annum, reaching  
 626 slightly over doubled CO<sub>2</sub> mixing ratios in year 70 (or 1920, if the startyear is set to 1850) with 570.56 ppmv and 1,264.76  
 627 ppmv in year 150 (or year 2000) (Table 4).

628 As with the abrupt4x and 1pctCO2 scenarios, the **historical** experiment should diverge from the picontrol run. Greenhouse  
 629 gases should then follow the historical observations as derived in this study, reaching e.g. CO<sub>2</sub> mixing ratios of 397.55  
 630 ppmv in 2014, and CH<sub>4</sub> and N<sub>2</sub>O mixing ratios of 1831.47 ppbv and 326.99 ppbv, respectively. Modelling groups should  
 631 document which spatial and temporal resolution (see above) of the provided data they use, as the climate effect will likely  
 632 be different with different resolutions.

633 The future concentration pathways, the so-called 'SSP-RCP' scenarios, considered under ScenarioMIP (O'Neill et al.  
 634 2016) are planned to provide the same data formats and spatio-temporal resolutions. The methodological approach to  
 635 derive and adapt both seasonality and latitudinal gradients in this study was designed such that a future extrapolation will  
 636 be possible.

#### 637 4.1 The vertical dimension

638 The purpose of our reconstructions is to provide radiative forcing for climate models. This radiative forcing depends on  
 639 the vertical as well as horizontal distribution of a gas' mixing ratio. Our reconstructions describe only surface  
 640 concentrations and modelers need some method for calculating the three-dimensional distribution. If the model is capable  
 641 of calculating tracer transport we recommend using this study's surface reconstruction as a mixing ratio lower boundary  
 642 condition for the tracer transport. If this is not possible then we propose a simple equation to reflect the relaxation of  
 643 horizontal gradients with height and the upward propagation of mixing ratio changes from the surface.

644 In case of CO<sub>2</sub>, there are no sinks in the middle and upper troposphere or stratosphere and only slight sources due to the  
 645 oxidization of CH<sub>4</sub> and carbon monoxide (CO). Evidence from Earth System Models (Figure 7) indicates an almost well-  
 646 mixed tropospheric column in the tropics and little or partly reversed vertical gradient in the southern troposphere, while  
 647 the annual-mean gradient in the northern hemisphere is – depending on the season – variable. The annual average vertical  
 648 gradient in the northern hemisphere is decreasing in all CMIP5 ESM models analysed here (Figure 7).

649 In order to enable the implementation surface mixing ratios in models that do not have an inherent transport model to  
 650 capture vertical gradients, we offer here simplified parameterizations as default options. While an assumption about a  
 651 well-mixed atmospheric vertical column seem a justifiable simplification, these simple vertical extensions could increase  
 652 the realism, vertical heating structure and overall climatic effect. Specifically, modelling teams could use the following  
 653 approximation to extend surface mixing ratio fields (at the 1000hPa level) towards higher tropospheric and stratospheric  
 654 levels. First, a bell-shaped mixing ratio distribution is assumed at the 100hPa level for the higher latitudie tropopause and  
 655 tropical upper troposphere:

$$656 \quad C(l, 100hPa, t) = \bar{C}(global, 1000hPa, t) \dots + (\bar{C}(global, 1000hPa, t - 5yrs) - \bar{C}(global, 1000hPa, t)) * \frac{\sin(l)^2}{2}$$

657 (9)

658 With  $\bar{C}(global, 1000hPa, t)$  indicating global-average, annual-average mixing ratios at the surface 1000hPa level at time  
 659 t. Ideally, a smoothed mean-preserving monthly dataseries of these annual-average global averages is used to prevent step  
 660 changes from calendar month 12 to 1. Equivalently,  $\bar{C}(global, 1000hPa, t - 5yrs)$  indicates the global-average, annual-  
 661 average surface mixing ratio 5 years earlier. The  $\frac{\sin(l)^2}{2}$  factor depends on the latitude l and results in the bell-shaped  
 662 mixing ratio curve with concentrations at the tropical 100hPa level to be identical to the global average surface mixing  
 663 ratios, while the polar mixing ratios are effectively of a medium age (2.5 years in the case of linearly increasing  
 664 concentration history). Having defined this 100hPa concentration level, the tropospheric mixing ratios at latitude l and  
 665 pressure level p (with p>100hPa) can then be assumed as a simple linear interpolation between the surface mixing ratio  
 666 level at latitude l and the 100hPa level, so that:

$$667 \quad C(l, p, t) = C(l, 100hPa, t) + (C(l, 1000hPa, t) - C(l, 100hPa, t)) * \frac{(p-100hPa)}{(1000hPa-100hPa)} \quad (10)$$

668 Above 100hPa - i.e. in the tropical upper troposphere and stratosphere, the mixing ratio is a simple linear interpolation  
 669 between the 100hPa level and the top-of-the atmosphere 1hPa level that is assumed to have a median age of air of 5 years,  
 670 so that for p<100hPa:

$$671 \quad C(l, p, t) = \bar{C}(global, 1000hPa, t - 5yrs) \dots + (C(l, 100hPa, t) - \bar{C}(global, 1000hPa, t - 5yrs)) \dots * \frac{(p-1hPa)}{(100hPa-1hPa)}$$

672 (11)

673 With  $\bar{C}(global, 1000hPa, t - 5yrs)$  being again the global-mean surface mixing ratio (1000hPa) 5 years ago and  
 674  $C(l, 100hPa, t)$  the latitudinally-dependent mixing ratio at the 100hPa level.

675 This equation captures the general form of the vertical CO<sub>2</sub> mixing ratio gradient observed in CMIP5 ESM models – with  
 676 the 100hPa being an approximate division line of the vertical CO<sub>2</sub> gradient in all CMIP5 models (see bold red line in

677 Figure 7). The annual-average vertical gradient in the northern hemisphere will be somewhat reducing the effect of the  
 678 strong surface latitudinal gradient. The idealized shaped of the above parameterization for an hypothetical flat surface  
 679 mixing ratio of 100 ppmv is shown in Figure 8b. Assuming linearly increasing surface mixing ratios from a south pole  
 680 minimum towards a 3 ppmv higher north pole maximum will – under this simplified parameterization - result in an almost  
 681 zero vertical tropospheric gradient in the southern hemisphere (Figure 8a).

682 For non-CO<sub>2</sub> gases, we here suggest a scheme adapted from the CESM model current parameterization – in case that  
 683 models do not have their own vertical extrapolation methods. These parameterisations assumed a simplified vertically  
 684 well-mixed troposphere and define a tropopause height as:

$$685 \quad p_{tropopause}(l) = 250hPa - 150hPa * \cos(l)^2 \quad (12)$$

686 With  $p_{tropopause}(l)$  being the tropopause height in hPa, depending on the latitude  $l$ . Thus, below the tropopause, the zonal  
 687 mean mixing ratios are assumed to be well-mixed vertically, so that:

$$688 \quad C(l, p, t) = C(l, 1000hPa, t) \text{ for } p > p_{tropopause}$$

689 The stratospheric mixing ratio can then modelled for  $p < p_{tropopause}$  as:

$$690 \quad C(l, p, t) = \bar{C}(global, 1000hPa, \bar{t} - 1yrs) * \left( \frac{p}{p_{tropopause}(l)} \right)^s \quad (13)$$

691 with  $\bar{C}(global, 1000hPa, \bar{t})$  being the global mean and annual-mean surface mixing ratio of the previous year,  
 692  $p/p_{tropopause}(l)$  being the ratio of the pressure at level  $p$  and the tropopause pressure at that latitude and  $s$  being a gas-  
 693 dependent scaling factor (Table 11).

694 As mentioned above, this simple vertical extrapolation option of the provided surface data is only to be regarded as a  
 695 simplified fall-back option in case that there are no model-intrinsic parameterizations available or active tracer transport  
 696 part of the model. While this study provides the main step from global-mean and annual-mean mixing ratio histories  
 697 towards zonally and monthly resolved ones, future research will be needed to provide more robust 4-D fields of mixing  
 698 ratios.

## 699 5 Discussion

700 We compare our results with a number of other data products. First, a comparison with the previous CMIP5 recommendation  
701 for historical GHG mixing ratios is provided (5.1). Then we analyse and compare our CMIP6 recommendations to what the  
702 Earth System Models from the previous CMIP5 intercomparison produced in terms of CO<sub>2</sub> mixing ratio fields in the emission-  
703 driven runs (5.2). Thirdly, we compare our data sets to the other global-mean, hemispheric and latitudinally-resolved data sets,  
704 namely the NOAA Marine Boundary Layer product and the WDCGG time series (5.3).

### 705 5.1 Comparison to CMIP5 input datasets.

706 For the CMIP5 inter-comparison, greenhouse gas mixing ratios were specified for historical times until 2005, followed by  
707 RCPs and their extensions until 2300. The recommendations for GHG mixing ratios were global and annual mean time series  
708 (Meinshausen et al. 2011b), not including a seasonal cycle or latitudinal gradient. Those historical time series were composite  
709 products of existing ice core and instrumental data annual means (see references in Meinshausen et al. 2011). Global, annual-  
710 mean CO<sub>2</sub> mixing ratios over 1975 to 2005 were very close (<0.7 ppmv different) to our current recommendations for CMIP6.  
711 The CMIP5 time series did not show the slight maximum in CO<sub>2</sub> mixing ratios around 1973 (difference 1.2 ppmv), and was  
712 generally lower between 1940 and 1956 at about the time of the World War II, when CO<sub>2</sub> mixing ratios briefly plateaued  
713 (differences between 1.0 and 2.3 ppmv) (Figure 9). While the CMIP5 historical greenhouse gases were an ad-hoc extension to  
714 the RCP pathways, our CMIP6 recommendation advanced the integration of historical data by accounting for latitudinal  
715 gradients (ice core data in CMIP5 has not been adjusted for the latitudinal gradients) and by taking into account a large array  
716 of additional data beyond a single network average for more recent times.

717 Recommended global-mean CH<sub>4</sub> mixing ratios for CMIP5 were generally lower than derived here, up to 50 ppbv around 1910  
718 and between 25-30 ppbv more recently (2000-2005). The primary reason is that the CMIP5 data did not take into account the  
719 strong latitudinal gradient of CH<sub>4</sub> mixing ratios. In terms of N<sub>2</sub>O mixing ratios, the CMIP5 historical timeseries did not capture  
720 some higher frequency variability, which caused the CMIP6 recommendation for the piconrol 1850 global-mean mixing ratio  
721 being lower by around 2.5 ppbv, and N<sub>2</sub>O mixing ratios in the 1910s being higher by up to 2.3 ppbv (Figure 9).

722 Overall, CMIP5 and CMIP6 recommendations are relatively similar. The 1850 piconrol values at the time of CMIP5 were  
723 slightly higher for CO<sub>2</sub> and N<sub>2</sub>O (0.14% or 0.4 ppmv and 0.87% or 2.4 ppbv, respectively), countered to some degree by  
724 slightly lower values for CH<sub>4</sub> (2.18% or 17.3 ppbv). This is equivalent to a small net change in base year radiative forcing of  
725 0.0065 W/m<sup>2</sup>, when applying linear radiative efficiencies of IPCC AR5 (Appendix 8.A in IPCC WG1 AR5).

### 726 5.2 Comparison to CMIP5 ESM CO<sub>2</sub> mixing ratio fields.

727 Several Earth System models during CMIP5 used prescribed CO<sub>2</sub> emissions instead of CO<sub>2</sub> mixing ratios and derived CO<sub>2</sub>  
728 mixing ratio fields endogenously. For the year 1875, we see that models vary greatly, with some showing reverse latitudinal  
729 gradients with higher mixing ratios in the south (e.g. CanESM2), almost no gradient (CESM1-BCC), a local maximum in the  
730 tropics with lower poleward mixing ratios (MIROC-ESM) and very heterogeneous fields with high mixing ratios over the  
731 tropical rainforests (NorESM1-ME) (see Figure 10). Similarly, for 1990 (Figure 11), the fields are dissimilar, with some models  
732 exhibiting very strong north-south gradients (MPI-ESM-LR), while others show little gradients (CanESM2), although all  
733 models indicate an increase of northern hemispheric mixing ratios compared to the global mean between 1875 and 1990 (Figure  
734 12).

735 Though not as strong as NorESM1-ME, most models show a slight tropical maximum in the latitudinal gradient (exceptions  
736 are CanESM2, MIROC-ESM) both during 1875 and 1990 (Figure 12). The high-latitude southern mixing ratio deviations from  
737 the global-mean in the 1875 time slices have different signs across the models, with some indicating clearly lower mixing  
738 ratios (BNU-ESM, MPI-ESM-LR, NorESM1-ME) and others suggesting slightly positive mixing ratios (CanESM2, MIROC-  
739 ESM in 1875). The average of three CMIP5 ESMs with full CO<sub>2</sub> data coverage at the surface 1000 hPa level and approximately  
740 correct global mean CO<sub>2</sub> mixing ratio values (CanESM2, MPI-ESM-LR, and NorESM1-ESM) shows a latitudinal gradient for  
741 1990 comparable to the observed one derived in this study (Figure 2b). In light of this evidence, we assumed constant mixing  
742 ratios with latitude for pre-industrial times.

743 In general, all ESMs show climatological seasonal cycles of CO<sub>2</sub> mixing ratios similar to the seasonality derived in this study  
744 (Figure 2a). The climatological 1861-1890 average mixing ratios across the models clearly exhibits higher seasonality in the  
745 northern hemisphere, especially above 40°N. While the seasonality in some models is weaker, especially CESM1-BCC, others  
746 show variations of up to ±10 ppmv (MPI-ESM-LR). In addition, the latter model exhibits as a southern hemisphere seasonality  
747 larger than other models and what we observe. As expected from our analysis of observational data, this seasonality strengthens  
748 up to 1990 across all models (Figure 14). The latitudinal spread of the northern hemisphere minimum extends southwards  
749 towards the equator in August, September and October as we observe (Figure 2a), with the exception of the BNU-ESM model  
750 (Figure 14), which indicates a northward propagation of the minimum summer mixing ratio values.

751 Overall, the basic features of the latitudinal gradient and seasonal cycle are represented in the ESMs as seen in the observational  
752 data. However, the variation across the models is substantial. This difference of several ppmv in the latitudinal gradient or  
753 seasonal cycles will lead to follow-on differences in the climate response observed in those models.

754 As common input for the CMIP5 concentration-driven experiments, all models were provided with the same historical global  
755 and annual mean CO<sub>2</sub> mixing ratios. Some models had the capability to nudge internally-generated CO<sub>2</sub> mixing ratio fields to  
756 match the prescribed annual and global mean CO<sub>2</sub> mixing ratios. Nevertheless, the differences in those internally-generated  
757 fields can be substantial as our analysis from CMIP5 shows and different from the observations. While the internally-generated  
758 CO<sub>2</sub> mixing ratio fields are a better match to observations compared to globally uniform annual-mean values, the question  
759 arises as to how important those differences are for cross-model comparisons and detection and attribution studies. Differences  
760 between model output and observational diagnostics are influenced by the quality of the prescribed input data, and input data  
761 have been prescribed in different ways across models. For future model inter-comparisons, it seems preferable that any  
762 concentration-driven runs would use the same starting point. Of course, the longer-term aspiration has to be that emission-  
763 driven ESMs reliably reproduce observational mixing ratio patterns. For CMIP6, modelling groups are requested to document  
764 their choice of concentration input data, specifically in relation to the chosen temporal and spatial resolutions.

### 765 5.3 Comparison of global-means to NOAA marine boundary layer products and WDCGG

766 The primary observational data product with coverage across all latitudes are the marine boundary layer or GLOBALVIEW  
767 fields (NOAA 2013, NOAA ESRL GMD 2014c) produced by NOAA based on the Cooperative Global Air Sampling Network  
768 (Conway et al. 1994, Dlugokencky et al. 1994b, Trolier et al. 1996) for CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O (available at  
769 <http://www.esrl.noaa.gov/gmd/ccgg/mbl/mbl.html>, with N<sub>2</sub>O data pers. comm. Pieter Tans). The aggregation method used to  
770 produce this data set is to first fit parametric functions to the weekly data of each station, thereby providing a gap-filling  
771 method. In a next step, the procedure fits smooth weekly latitudinal distributions to the various station data points (Tans et al.

772 1989). These latitudinal distributions are then combined into a 2-D field of latitude versus time, comparable to this study's  
773 data product. The time period for which these NOAA MBL data products is 1979 to 2014 for CO<sub>2</sub>, 1983 to 2014 for CH<sub>4</sub> and  
774 2001 to 2014 for N<sub>2</sub>O.

775 The four main methodological differences between the NOAA MBL data product and ours are (1) the NOAA data product has  
776 a higher resolution in time (weekly instead of monthly) and latitudes, (2) the NOAA MBL data product includes only a subset  
777 of the NOAA network data (sites within the marine boundary layer), while this study mixes both NOAA and AGAGE network  
778 data in the case of CH<sub>4</sub> and N<sub>2</sub>O, (3) this study characterizes the global fields by lower rank representations (EOFs) of annual  
779 mean latitudinal gradients and seasonality, while the NOAA product derives latitudinal gradients (and seasonality thereby only  
780 implicitly) directly from the observations at each time step. In other words, the main smoothing/regularization step in our study  
781 happens at a later level in the analysis, and (4) this study is extended by ice core and firn data, regressions and extra-  
782 /interpolation to span the full time period between year 0 and 2014. In other words, this study seamlessly merges in situ  
783 observational, air archive, ice and firn data to generate a comprehensive data product.

784 For several applications, the NOAA data product has clear advantages. However, with the task to produce a continuous data  
785 product beyond the instrumental observations, this study had to choose a method that was readily extendable. Hence, this study  
786 chooses the characterization of global fields into global-means, latitudinal gradients and seasonality. This implies a high degree  
787 of regularizations by relying on EOFs and corresponding scores. By regression, these EOF scores for latitudinal gradients or  
788 seasonality changes can be easily extended to cover the full time period of interest. Hence, our method allows an estimate of  
789 global-means even if there is a single data point (such as a Law Dome ice core record for a specific year), under the assumption  
790 that latitudinal gradients and seasonality are captured by the derived EOFs and regressed EOF scores.

791 Global-average time series of monthly greenhouse gas mixing ratios are also provided by the World Data Center for  
792 Greenhouse Gases (WDCGG) (Tsutsumi 2009). The WDCGG product uses similar smoothing techniques as the NOAA  
793 product, but include, like this study, a broader set of measurement stations, both in terms of regional coverage (including  
794 continental stations) and different networks that use different calibration scales, sampling, gas handling etc.

795 We compare the results of this study and NOAA MBL and WDCGG products for the time periods covered by the latter.  
796 Overall, our monthly hemispheric averages of CO<sub>2</sub> closely match the NOAA product. The NOAA product suggests a slightly  
797 faster increase of northern hemispheric mixing ratios in the latter months of each calendar year (cf. thick and thin orange lines  
798 in Figure 15a). Specifically, this difference results from the mid-latitude northern hemispheric bands from about 1995 onwards  
799 (with monthly-average differences of up to 4 ppmv) where our study is higher than the NOAA product. This could be because  
800 this study does not screen out land stations closer to the pollution sources, as the NOAA marine-boundary-layer product does.

801 Likewise, the WDCGG includes a broader set of stations and matches very closely with our global-mean time series, with our  
802 study being very close to WDCGG or in between NOAA MBL and WDCGG (Figure 15a). Given that the difference between  
803 the NOAA study and our study has a strong seasonality, the nature of those pollution sources and how they become mixed in  
804 the atmosphere, if these effects contribute to the differences, could be a combination of fossil fuel related and (more seasonally-  
805 varying) biospheric sources (Figure 16c). The southern hemispheric means of our study and NOAA MBL are very closely  
806 matched (cf. thick and thin blue lines in Figure 15a). Consequently, the global-mean mixing ratios from NOAA MBL and our  
807 study are closely matched, although again our data suggests NH autumn mixing ratios rising slightly faster than the NOAA  
808 MBL product, reflecting the northern hemispheric difference (cf. thick and thin black lines in Figure 15a).

809 For CH<sub>4</sub>, the differences between this study and the NOAA MBL data are more systematic and stronger (~10 ppbv), with  
810 generally higher surface CH<sub>4</sub> mixing ratios implied by this study (Figure 15b). Again, this study's global mean matches closely  
811 the WDCGG or sits in between the NOAA MBL and the WDCGG data products. There are some differences in the seasonality  
812 compared to the NOAA MBL product though. The seasonal variation is similarly shaped between our study and NOAA MBL  
813 for the southern hemisphere, although there seems to be a slight phase-shift of about a month with the NOAA MBL product  
814 in the southern hemisphere assuming a slightly earlier increase and decrease and slightly higher amplitude (Figure 15b). This  
815 phase-shift of the southern hemisphere together with sometimes lower peak northern hemispheric mixing ratios in the NOAA  
816 MBL product suggests global-mean NOAA MBL CH<sub>4</sub> mixing ratio that show a double peak within any year, while our data  
817 assimilation and the WDCGG product suggests a smoother single-peak oscillation of global-mean CH<sub>4</sub> mixing ratios (Figure  
818 15b). This peak results from the mid northern latitudes, where in the summer months, our study suggests up to 40 or 50 ppbv  
819 higher mixing ratios (Figure 17c).

820 For N<sub>2</sub>O, the WDCGG global-mean and our data match very closely, with our implicit smoothing due to our lower rank  
821 representation of seasonal cycles and latitudinal means resulting in a smoother global mean compared to WDCGG (Figure  
822 15c). Similarly, the draft data product of the NOAA MBL indicates almost identical mixing ratios to our concentration fields  
823 over the available time period from 2001 to 2014, with maximal differences being 0.8 ppbv (Figure 18).

824 In summary, our dataset closely matches the global-means of WDCGG in many years, but provides a complete 2-D field of  
825 mixing ratios. In comparison to the NOAA MBL products, there is one more systematic difference. Our CMIP6 GHG mixing  
826 ratio fields are meant to represent the mean monthly state of the latitudinally-averaged surface atmosphere, including land and  
827 polluted areas, i.e. not confined to areas with background mixing ratios (see Section 6 limitations). This is a key difference to  
828 the NOAA Marine Boundary Layer product, which is a consistent background mixing ratio product, resulting in slightly lower  
829 global-mean mixing ratio estimates.

#### 830 **5.4 Comparison to mid-troposphere CO<sub>2</sub> mixing ratios by NASA Aqua satellite**

831 Since its launch in 2002, the Aqua satellite and its infrared sounder provides an additional independent data product to estimate  
832 tropospheric CO<sub>2</sub> mixing ratios. Rather than at ground level, this sensor provides an estimate of tropospheric mixing ratios  
833 with a maximum sensitivity around 7km height, i.e. in the mid-troposphere. In the tropics and the parts of the southern  
834 hemisphere that are covered by the Aqua satellite product, the agreement between our data and the AIRS level 3 data (available  
835 at: [ftp://acdisc.gsfc.nasa.gov/ftp/data/s4pa/Aqua\\_AIRS\\_Level3/AIRX3C2M.005/](ftp://acdisc.gsfc.nasa.gov/ftp/data/s4pa/Aqua_AIRS_Level3/AIRX3C2M.005/)) is encouraging, although the overall  
836 gradient is lower in line with 3-D atmospheric transport model results (Olsen and Randerson 2004). In the northern hemisphere,  
837 the difference in the phase and amplitude of the seasonal cycle is most apparent, with satellite data showing a later onset of the  
838 autumn mixing ratio increase by about 4 months while the drawdown of mixing ratios seems closer in phase between mid-  
839 troposphere and surface mixing ratios (Figure 15a). Overall the amplitude is less than half of the surface hemispheric mean  
840 amplitude, leading to seasonally higher winter and lower summer mixing ratios of our surface data product in the northern  
841 hemisphere by up to 10 ppmv (Figure 16e).

842 This systematic difference between ground-level and mid-atmosphere mixing ratios, supported by 3-D transport modelling  
843 studies (Olsen and Randerson 2004), has ramifications for the implementation of vertical mixing ratio profiles in climate  
844 models. Without taking into account the dampened seasonal cycle and latitudinal gradient in the mid and higher troposphere,  
845 the models could overestimate the variations in the radiative effects, if our latitudinally and monthly resolved surface mixing

846 ratio fields are prescribed. On the other hand, if global- annual mean values are prescribed, the radiative forcing effect  
847 variations over latitudes and within a year will obviously be underestimated.

#### 848 **5.5 Comparison to other literature studies.**

849 Our greenhouse gas derivations over the recent instrumental periods are based on the AGAGE and NOAA station-by-station  
850 data and we extended our 2-D mixing ratio field results back in time by using e.g. global-mean estimates of previous studies'  
851 estimates (Methods). The AGAGE and NOAA networks themselves publish global-mean results, and WMO as well as other  
852 literature studies produce composite long-term global-mean and/or hemispheric mixing ratio estimates. Thus, while often not  
853 entirely independent, as the studies use the same original data sources or we rely on some studies' previous derivations, we  
854 here provide a comparison to a selection of the literature. Specifically, in addition to the comparisons with NOAA marine  
855 boundary layer, WDCGG and NASA Aqua satellite data, we discuss some instances where our results show substantial  
856 differences compared to earlier studies that have derived hemispheric or global means from instrumental data (Montzka et al.  
857 2014, Rigby et al. 2014), from firn data (Butler et al. 1999, Trudinger et al. 2016) or are themselves composites of multiple  
858 data sources (Martinerie et al. 2009, Velders et al. 2014, WMO 2014). The comparisons are shown in the panels f, g, and h of  
859 the factsheets for each gas (Figure 2, Figure 4, Figure 5, and Figure 23 to Figure 62).

860 Martinerie et al. (2009) provided high latitude northern hemisphere data for atmospheric mixing ratios, used by (and made  
861 available in the supplement of) Buizert et al. (2012). For CO<sub>2</sub>, the Martinerie data set has, as expected for the high northern  
862 latitudes, a very strong seasonal cycle, stronger than our northern hemispheric cycle (Figure 2f, g, and h). The long-term mixing  
863 ratio trend over time in the Martinerie CO<sub>2</sub> record seems similar to the global CMIP5 data set which in turn was based on  
864 previous Law Dome data, indicating a slight local maximum in 1890 and lower 1940s plateau (cf. Figure 2g and Figure 9).

865 For CH<sub>4</sub>, the Martinerie et al. record shows a comparable, yet again stronger, seasonality. The annual means are very  
866 comparable to our derivation (compare the high latitude red circles, indicating annual-mean station averages of our analysis  
867 and Martinerie et al. data as shown in Figure 4f), although there are some steps in annual means in the Martinerie et al. data  
868 set around 1956 and 1975, which are not present in our dataset (Figure 4f). For earlier times, i.e. between 1860 to 1920s, the  
869 Martinerie annual mean is closer to our global-mean, not the high-latitude estimates, as our study assumes a large latitudinal  
870 gradient based on the NEEM and Law Dome data differences (Methods) (Figure 4g).

871 For CCl<sub>4</sub>, the Martinerie data show a lower increase from 1955 to the late 1960s and strong increase around 1970. The firn  
872 data by Butler et al. (1999) suggests an earlier start of atmospheric mixing ratio increases around 1890, and then slightly lower  
873 levels over 1960 to 1990 compared to the WMO (2014), Velders et al. (2014) timeseries to which we nudge our 2-D fields.  
874 The findings by Sturrock et al. (2002) suggest an onset of atmospheric mixing ratios around 1920 (Figure 5f therein). The  
875 NOAA global mean that is available from 1992 onwards (Montzka et al. (1999) updated at  
876 <http://www.esrl.noaa.gov/gmd/hats/combined/CCl4.html>) and indicates initially slightly higher global mean estimates than our  
877 derivation, which is for the instrumental period based on 6 AGAGE and 13 NOAA HATS stations (Figure 23f, g, h).

878 For CFC-11 (Figure 24g), the NOAA Montzka reconstruction of the global-mean is slightly higher (1 pptv) than ours, which  
879 is almost identical to the WMO (2014) and Velders data (2014). Those differences presumably result from differences in  
880 station coverage, different calibration scales and air sampling and analysis techniques between the networks. The seasonalities  
881 show comparable amplitudes, as they do for CFC-12 (Figure 25h). With CFC-115, our study follows the historical shape of  
882 the WMO (2014) record, with Velders (2014) being slightly lower (~0.5 pptv) (Figure 28f).

883 For  $\text{CH}_2\text{Cl}_2$ , the in situ instrumental record we use only reaches back to 1994, although the Cape Grim air archive record goes  
884 back to 1978. From 1994 to 2003, the northern latitude measurements imply a mixing ratio reduction from 40 to 30 pptv,  
885 whereas the southern hemispheric measurements are almost flat during that time. Similarly, the southern hemispheric firm  
886 reconstructions (Trudinger et al. 2004) indicate an almost flat southern hemispheric evolution from 1997 onwards (Figure 29f).  
887 We note however that there are substantial uncertainties in the pre-1995 mixing ratios, as e.g. Koppmavn (1993) reported 18  
888 pptv and 36 pptv average mixing ratios for the southern hemispheric and northern hemispheric measurements from a 1989  
889 Atlantic transect ship measurement campaign (not shown in the figure). This could imply a global average value of  
890 approximately 27 pptv in 1989, instead of the 20 pptv assumed in this study – although different calibration scales might  
891 contribute to this difference. Recent seasonality and increases of  $\text{CH}_2\text{Cl}_2$  are closely matching other time series, such as the  
892 AGAGE monthly global means from the Medusa instruments (Figure 29f), although there is a slight offset in the absolute  
893 level, possibly caused by our study not sorting out data points from so-called pollution events in the case of  $\text{CH}_2\text{Cl}_2$ .

894 For  $\text{CH}_3\text{Br}$ , our CMIP6 recommendations match very closely the NOAA (Montzka et al. (2003) updated on  
895 <ftp://ftp.cmdl.noaa.gov/hats/methylhalides/ch3br/flasks>) and AGAGE global means (2014) after 1995. Before then, the Butler  
896 (1999) global-mean firm reconstruction coincides closely with our southern-hemispheric mean. The 2004 firm reconstruction  
897 by Trudinger (2004) is close to the southern hemispheric mean, but shows somewhat more variation than the smooth  
898 exponential increase assumed by this study, WMO (2014) and Velders et al. (2014).

899 For  $\text{CH}_3\text{CCl}_3$ , the overall agreement between the different (although not independent) studies considered here is excellent, for  
900 example the high northern latitude data in Martinerie et al. (2009) in the south pole firm data reconstruction (Montzka et al.  
901 2010), approximately in line also with the findings by Sturrock et al. (2002).

902 The atmospheric mixing ratios of  $\text{CH}_3\text{Cl}$  show a strong seasonal cycle, as is to be expected from the short lifetime due to the  
903 OH-related sink. As in the case of methyl bromide ( $\text{CH}_3\text{Br}$ ), the pre-instrumental period before 1995 implies a number of  
904 uncertainties. Here, we follow again the WMO (2014) and Velders et al. (2014) reconstruction that are in line with shape of  
905 the Butler et al. firm reconstructions. However, we note that the more recent Trudinger et al. (2004) reconstruction indicates  
906 both a significantly lower mixing ratio for southern latitudes in the 1970s and a smoother increase compared to the more sudden  
907 rise of mixing ratios around 1940 as implied in this study (Figure 32g).

908 As briefly discussed in section 3.4, the  $\text{CHCl}_3$  history in this study relies on the Worton et al. (2006), reconstruction, whose  
909 shape is similar to Trudinger et al. (2004), although the latter indicates lower global mean mixing ratios and not the  
910 diminishing latitudinal gradient suggested by Worton et al. (2006). The implied pre-industrial value of around 6 pptv should  
911 be investigated in the future (Figure 33).

912 For Halon-1211, the recent study by Vollmer et al. (2016) and also the earlier study by Sturrock et al. (2002) (not shown)  
913 suggest slightly higher initial mixing ratios (around 1975 to 1988) compared to the initially-lower and then larger exponential  
914 increase we assumed by following Velders (2014). After 1990 the southern hemispheric reconstruction by the Bristol and  
915 CSIRO models (Vollmer et al. 2016) are slightly lower and hence the latitudinal gradient slightly larger than what we derived  
916 from the AGAGE and NOAA station data, but the differences are small (Figure 34f). Similarly, the very early mixing ratio  
917 increases of the Halon-1301 between 1970 and 1978 are higher in the Vollmer (2016) study, and again the more recent years  
918 from 2007 onwards (Figure 35h) are higher in Vollmer. In those latter years, our aggregation of AGAGE and NOAA station

919 data however suggests slightly lower mixing ratios, although the absolute difference (0.05 pptv) is within the measurement  
920 uncertainty and the overall agreement is very good.

921 Halon-2402 is likely the most obvious example, where a shifting measurement spatial coverage density can lead to small jumps  
922 in latitudinal gradients or global means (Figure 36f and h). The overall mixing ratios are very small and the early agreement  
923 between the WMO (2014) time series and the Vollmer et al. (2016) findings is very good. In 2009, when data coverage  
924 increased, the latitudinal gradient is suggested to suddenly decrease, which is likely an artefact of the assimilation procedure  
925 that is only able to cope with time-varying data coverage to a certain degree (Methods). However, overall, the implied shifts  
926 of 0.02 pptv are negligible in the larger picture, and certainly negligible for radiative forcing, as the shift in Southern  
927 hemispheric radiative forcing is equivalent to only about 0.000003 W/m<sup>2</sup> (Figure 36h).

928 For HCFC-142b our derived global-mean is in the middle of the AGAGE and NOAA network averages, despite our study  
929 including those data points that are subject to ‘pollution’ events in the case of HCFC-142b, with large positive outliers (Figure  
930 39f), similar as in the case of HFC-134a (Figure 53f). Pollution events might however be contributing to the difference between  
931 our HFC-152a global-means and the two independently derived network global means for AGAGE and NOAA, which largely  
932 exclude pollution events by e.g. using statistical methods (O’Doherty et al. 2001) (see Figure 55f). Two more issues can be  
933 observed with HCFC-142b data. Firstly, our end of 2014 mixing ratios are somewhat uncertain and this case possibly wrongly  
934 decreasing, which results from the smooth annual mean representation and our assimilation procedure. The differences are  
935 again very small and negligible in radiative forcing terms, but a smooth connection will have to be designed for the adjacent  
936 datasets representing SSP-RCP scenarios. Secondly, since 2010, our estimates for the HCFCs, namely HCFC-22 (Figure 37f),  
937 HCFC-141b (Figure 38f) and HCFC-142b (Figure 39f) indicate smaller increases than implied by Velders et al. (2016). As the  
938 early study by Sturrock et al. (2002), our study represents the slow onset of HFC-142b mixing ratios in between 1960 and  
939 1990 as shown in WMO (2014) and Velders et al. (2014).

940 For the three main PFCs, i.e. CF<sub>4</sub> (Figure 48), C<sub>2</sub>F<sub>6</sub> (Figure 40), and C<sub>3</sub>F<sub>8</sub> (Figure 41), we find a similar and good agreement  
941 of the main studies. The Trudinger et al. (2016) time series are slightly below those suggested by Mühle et al. (2010b) (~0.5  
942 pptv, ~0.1 pptv, ~0.01 pptv, respectively), but the overall agreement again is very good. The outliers are the previously  
943 recommended CMIP5 mixing ratios (Meinshausen et al. 2011b) for these gases, which were at the time not yet based on either  
944 the Trudinger et al. (2016) or Mühle et al. (2010b) studies. As mentioned above, the mixing ratios of the lesser important PFCs,  
945 C<sub>4</sub>F<sub>10</sub> (Figure 42), C<sub>5</sub>F<sub>12</sub> (Figure 43), C<sub>6</sub>F<sub>14</sub> (Figure 44), C<sub>7</sub>F<sub>16</sub> (Figure 45) and C<sub>8</sub>F<sub>18</sub> (Figure 46) are based on the Ivy et al.  
946 (2012) reconstructions, with reversing latitudinal gradients in the case of C<sub>6</sub>F<sub>14</sub>, C<sub>7</sub>F<sub>16</sub>, and C<sub>8</sub>F<sub>18</sub>, which are unexplained so far  
947 and require further confirmation. Our historical c-C<sub>4</sub>F<sub>8</sub> mixing ratios are based on the study by Oram et al. (2012) with assumed  
948 conversions of the Cape Grim measurements to northern hemispheric and global-averages.

949 For HFC-43-10mee, we based our trajectory on the NH and SH estimates of Arnold et al. (2014) with relatively small latitudinal  
950 gradient and hemispheric means being informed by the recently available observations since 2010 from the AGAGE Medusa  
951 instruments (Figure 51f). Note that the difference for HFC-365mfc data (Figure 59) between the station data and those  
952 published in Montzka (2014) reflects a difference that now vanished after a correction to the NOAA calibration scale since the  
953 publication of the Montzka et al. (2014) study. All studies are now in relatively close alignment with the shown AGAGE  
954 network average, the Vollmer et al. (2011) study and our derivation (which is slightly lower, <0.1ppt). The air archive and  
955 AGAGE network analysis by Vollmer et al. (2011) investigated in addition the HFCs HFCs-236fa, HFC-227ea, and HFC-

956 245fa. Those results are closely aligned with the ones constructed here on the basis of the WMO AGAGE network average  
957 estimates (Figure 57, Figure 56, Figure 58).

958 Similar to our study, there are also studies that assimilate a wide range of gases with latitudinal and seasonal variation. For  
959 example, the AGAGE network assimilation with a 12-box model and optimization approach to reconcile emissions and mixing  
960 ratios (Rigby et al. 2011, Rigby et al. 2013) produces 4 semi-hemispheric concentration timeseries with 3 vertical levels (Rigby  
961 et al. 2014). Those studies based on AGAGE data are more comprehensive than this one, as both emissions and concentrations  
962 as well as lifetimes are optimized and reconciled. In our case, we only assimilate AGAGE and NOAA observations to derive  
963 atmospheric mole fractions in 15 degree latitudinal bands (methods).

## 964 **6 Limitations**

965 Even though the presented dataset of historical surface greenhouse gas concentrations is – to our knowledge - more  
966 comprehensive than other composite datasets before, there are a number of key limitations.

967 First of all, the dataset was assimilated from a number of sources in order to provide a common starting point for global climate  
968 models. Thus, for example, the data was not designed to perform as a starting point for inversion studies, which estimate  
969 emissions, or studies of biogeochemical processes. Those studies tend to require pure observations, rather than partly  
970 interpolated composite products. This warning in terms of our data use is especially important for the fine-grid interpolation  
971 we present. The 0.5-degree mean-preserving smooth interpolation should not be misinterpreted to actually portray  
972 measurement information at such a fine scale.

973 Secondly, the purpose of forcing climate models correctly would best be accomplished by vertically resolved latitudinal and  
974 longitudinal fields, which (in the case of CO<sub>2</sub>) even include a diurnal cycle. Our latitudinally and monthly resolved dataset  
975 offers climate models already an option to capture some key variability compared to the global and annual mean CMIP5  
976 concentration recommendation (Meinshausen et al. 2011b). However, a correct implementation of this additional monthly and  
977 latitudinal variability is also dependent on an appropriate propagation of the surface signal throughout the troposphere and  
978 stratosphere. For example, some studies (Olsen and Randerson 2004) find that column CO<sub>2</sub> is found to only exhibit roughly  
979 half of the latitudinal gradient and seasonal variation compared to the surface mixing ratios. In the CESM1 model (Hurrell et  
980 al. 2013) with prescribed surface greenhouse gas concentrations, the vertical propagation of CO<sub>2</sub> mixing ratio is assumed to  
981 be constant. In the case of the other greenhouse gases (CH<sub>4</sub>, N<sub>2</sub>O and CFCs) a constant mixing ratio in the troposphere and a  
982 decrease of mixing ratio in the stratosphere is assumed in CESM1. In particular, the scale heights in the stratosphere of these  
983 trace gases depend on latitude, which produces a more realistic stratospheric distribution. We recommend vertical extensions  
984 to our surface mixing ratio reconstructions only in the case that the model has no intrinsic transport model or extension  
985 parameterisation. Furthermore, we do not include the longitudinal variation. Again, in particular for CO<sub>2</sub>, this longitudinal  
986 variation might be systematic given the land/ocean contrast. For example, the MPI-ESM-LR model indicates systematically  
987 higher surface CO<sub>2</sub> mixing ratio over land, which in turn would have a radiative effect (cf. Figure 14).

988 Thirdly, our assimilation procedure is a rather simple one and does not attempt to offset potential biases due to day and night-  
989 time sampling biases for CO<sub>2</sub> in the case of some flask measurements, or whether including pollution events would bias the  
990 latitudinal averages towards higher than current average values. In a world with continuing point sources, screening out

991 pollution effects might cause proposed averages to lag slightly behind the true average mixing ratio. The question is whether  
992 the correlation between sampling locations and source locations will inherently bias the average mixing ratios towards higher-  
993 than true average values in our assimilation for species, where we include pollution events. For most substances we do not find  
994 any systematic difference between the network averages from AGAGE or NOAA, although there are some species (e.g. HFC-  
995 152a, see Figure 55) for which our higher mixing ratio reconstructions could in part be explained by this different method.

996 The opposite might also be the case, i.e. that despite including some pollution events, there could still be an inherent  
997 underestimation of true zonal means. That is because the NOAA and AGAGE sampling stations we are sourcing our raw data  
998 from tend to be biased to remote/clean-air/well mixed conditions and this will have implications for our latitudinal gradient  
999 and seasonal cycle. Where there are continental sites they are often at altitude, and when flasks are sampled they are generally  
1000 for mid-afternoon when mixing is largest. Hence the fitted latitudinal gradient for CO<sub>2</sub> at least might be closer to the NOAA  
1001 marine boundary layer product than to a true zonal mean. Also the seasonal cycle will be more representative of marine  
1002 conditions than continental ones (where a diurnal rectifier could potentially dampen or offset seasonally low mixing ratios in  
1003 summer in the case of CO<sub>2</sub>). This bias towards remote measurements tends to increase the further back in time we go.

1004 Another limitation of our study is related to the different calibration scales of atmospheric gas measurements. In our data  
1005 assimilation method with no scale conversion between the SIO and NOAA scales of the AGAGE and NOAA networks  
1006 (Methods), a time-varying difference between the scales or time-varying coverage from one network to another can lead to  
1007 spurious trends in the derived mixing ratios. We argue that our “middle of the road” data assimilation method across the two  
1008 networks is however one justifiable, yet not the only viable assimilation method. The reasons for our chosen approach are a)  
1009 uncertainties in absolute mole fractions estimates are small compared to other uncertainties that would affect the radiative  
1010 forcing in climate models, b) alternative “pure” scale data assimilation could only deal with the trend uncertainty, not with the  
1011 uncertainty arising for absolute mole fraction values (assuming that both the SIO and NOAA scales are equally sound), c) we  
1012 intend to be “network”-neutral and d) a single “in-between” mixing ratio estimate is likely the most appropriate for the primary  
1013 application purpose (historical simulations of climate models) of the provided data. However, future researchers are  
1014 encouraged to work directly with the principal investigators of the two networks to devise data assimilation methods that would  
1015 be better suited for alternative applications, such as uncertainty estimates of inverse emissions etc. A clear limitation of our  
1016 data produce is hence our implicit “in between” scale, with time-varying influences from measurements under the one or other  
1017 network. Thus, differences to “pure” SIO or NOAA scale will partly arise from this “scale” issue.

1018 Another important limitation of our study is that we do not provide uncertainty estimates. This is primary related to the fact  
1019 that the purpose of this study was to provide a consolidated dataset for climate model experiments. Those models experiments  
1020 can only be performed a limited number of times given today’s computational resources. The experimental protocol hence  
1021 does not foresee an ability to vary greenhouse gas mixing ratios within its uncertainties, given that many aspects of climate  
1022 models are affected by more substantial uncertainties, such as aerosols. The original AGAGE and NOAA (sometimes monthly  
1023 averaged) sampling data points shown in the Factsheets (see panels f, g, and h) can however provide an indication of  
1024 uncertainties and the spread in observations.

1025 Note that our choice of predictor for the CO<sub>2</sub> seasonality change (namely the product of CO<sub>2</sub> mixing ratio and global-mean  
1026 temperature deviation since pre-industrial) is subjective and using only CO<sub>2</sub> mixing ratio or temperature would have yielded

1027 in a larger seasonality difference between current and pre-industrial times. Further research will be necessary to obtain an  
1028 optimal proxy for pre-observational CO<sub>2</sub> seasonality changes.

1029 Similarly, our common explanatory variable for regressions of latitudinal gradients, i.e. global emissions, is an approximation.  
1030 Ideally, the time-changing latitudinal distribution of emissions would be taken into account in those backward extensions of  
1031 the latitudinal gradient over time.

1032

1033 **7 Conclusion**

1034 Glacial and interglacial cycles are driven by Milankovich cycles. Ice core measurements over the past 800k years reveal how  
1035 atmospheric greenhouse gas mixing ratios of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O varied in turn, indicating various feedback mechanisms. With  
1036 the arrival of homo sapiens, initially deforestation and agriculture, and then the onset of the fossil-fuel driven industrial  
1037 revolution, the atmospheric composition changed. Unprecedented over this time of the ice core record, CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O  
1038 mixing ratios shot upwards, with CO<sub>2</sub> reaching a historical mark of 400 ppmv in 2015. Recently, synthetic greenhouse gases  
1039 arising from refrigerants, solvents, insulation appliances and even gas-cushioned shoe soles added to the warming effect, the  
1040 radiative forcing. As the IPCC AR5 found, the most likely warming contribution from these greenhouse gases is now higher  
1041 than the observed warming (Figure TS.10 in IPCC AR5 (IPCC 2013)). That means that without the human activities that happen  
1042 to cool the planet, namely the aerosols we emit, observed warming would have been even greater than what has already been  
1043 experienced.

1044 In this study, we compile a set of greenhouse gas histories over the last 2000 years – based on numerous efforts by the scientific  
1045 community to retrieve firm samples and ice cores in the most remote places on Earth, unlock their secrets by analyzing the  
1046 enclosed air and by investing in a large network of in-situ and flask measurement stations across the planet. Our understanding  
1047 of past climate change is vital to develop scenarios of the future and design humanities' response strategies in terms of  
1048 mitigation and adaptation. Without the ongoing efforts to retrieve and monitor the composition of the planet's atmosphere,  
1049 sometimes at risk (Lewis 2016), the future ahead of us remains shrouded in many uncertainties.

1050 In this dataset, we attempted to provide a solid base for the next generation of climate and earth system models to further our  
1051 understanding of past and future climate changes. Providing seasonal and latitudinal differences of the radiative forcing that  
1052 drives the climate change across the globe, we can hope for an even more appropriate comparison between models and past  
1053 land-ocean, regional land and oceanic temperature observations. Ignoring these seasonal and latitudinal differences can lead  
1054 to different calculated climate impacts of GHG emissions. Thus, accurately including this variability is a necessary condition  
1055 to accurately comparing model calculations and observations and to understanding the reasons for the differences. Those  
1056 agreements and disagreements between what models and past observations tell us, will then allow us to calibrate our  
1057 understanding of the earth system, its non-linearities and its many feedback cycles, the human influences and natural  
1058 variabilities – in jargon called 'detection and attribution'. We have been engaging in a unique experiment with our climate. In  
1059 order to achieve the limits we set forth in the Paris Agreement of how much further we push the planetary system out of the  
1060 boundaries it has been in for thousands of years (up to 2°C and 1.5°C, respectively) and in order to cope with the climate  
1061 change committed to already, the next generation of climate models will be vital. This study into the main past driver of human-  
1062 induced climate change intends to provide the basis for this further examination of a tremendous challenge we find ourselves  
1063 in.

1064

1065 **8 Code Availability**

1066 The matlab and R code that was used to assimilate the raw data is available from the authors on request.

1067 **9 Data Availability**

1068 A supplementary data table is available with global and annual mean mole fractions. The complete dataset with latitudinally  
1069 and monthly resolved data in netcdf format is available via <https://pcmdi.llnl.gov/search/input4mips/>. Additional data formats,  
1070 i.e. CSV, XLS, MATLAB .mat files of the same data are also available via [www.climatecollege.unimelb.edu.au/cmip6](http://www.climatecollege.unimelb.edu.au/cmip6). The  
1071 respective raw data used in this study is available from the original referenced data providers on request.

1072 **10 Acknowledgements**

1073 The authors would first and foremost like to thank the large community of scientists, research assistants and measurement  
1074 technicians that were involved collecting the firm, ice core and atmospheric in-situ and flask measurements across the world.  
1075 The primary networks AGAGE and the Cooperative Air Sampling Network managed by NOAA deserve the most credit,  
1076 including all its individual researchers and the networks' policy to make the raw data available to the broader scientific  
1077 community. In particular, we thank the following researchers for invaluable efforts to collect, screen and make available NOAA  
1078 network data: Ed Dlugokencky, Pieter Tans, David Nance, Bradley Hall, Geoff Dutton, James Elkins, Debra Mondeel. We  
1079 also like to thank the Editor O. Morgenstern for helpful suggestions.

1080 Furthermore, we thank the ESM CMIP5 modelling groups who contributed to the 5th Climate Model Intercomparison project  
1081 and whose data we analyzed.

1082 Attributions: MM designed the study. EV wrote most of the data analysis and read-in routines together with MM. KL analysed  
1083 the CMIP5 ESM models and produced related figures. Other figures and the factsheets were produced by MM. AN provided  
1084 an initial literature overview. All authors wrote, commented on and/or discussed the manuscript based on a first draft by MM.  
1085 NM designed the mean-preserving interpolation routines. Multiple authors provided vital data.

 1096 **Methods.**

Gas	Time period	Main data source	Global and annual-mean $C_{global}$	Seasonality $S_{i,m}$	Seasonality Change $\Delta S_{i,m}$	Latitudinal gradient $\hat{L}$
CO <sub>2</sub>	1984-2013/2014	NOAA ESRL Carbon Cycle Cooperative Global Air Sampling Network, 1968-2014. Version: 2015-08-03, monthly station averages (NOAA ESRL GMD 2014c, NOAA ESRL GMD 2014b, NOAA ESRL GMD 2014a, Dlugokencky 2015b)	Calculated based on observational data source (section 2.1.3).	Mean over 1984-2013 period.	Leading EOF of residuals from observation	Two leadings EOF and their scores derived from residuals from observations. (2014: optimized to match observational data).
	Before 1984	Law Dome (Etheridge et al. 1998c, MacFarling Meure et al. 2006, Rubino et al. 2013)	Optimized to match smoothed median approximation of Law Dome record	Kept constant as above	regressed against product of CO <sub>2</sub> mixing ratio and surface air temperature change since pre-industrial	The score for EOF1 is regressed against global annual fossil fuel & industry emissions (Boden et al. 2013). Score for EOF2 linearly returned to zero in 1850.
CH <sub>4</sub>	1985 to 2013/2014	AGAGE monthly station means, incl. pollution events ('.mop') (Cunnold et al. 2002) & NOAA ESRL monthly station data (Dlugokencky 2015a)	Calculated based on observational data source (section 2.1.3).	Mean over 1985-2013 period. Applied as relative seasonality	Assumed zero	Two leadings EOF and their scores derived from residuals from observations. (2014: optimized to match observational data).
	Before 1985	Law Dome (Etheridge et al. 1998b, MacFarling Meure et al. 2006) & NEEM (Rhodes et al. 2013)	Optimized to match smoothed Law Dome record & NEEM firn data			The score for EOF1 is regressed against global annual fossil fuel & industry emissions (Gütschow et al. 2016). Score for EOF2 kept constant before in situ instrumental period.
N <sub>2</sub> O	1990 to 2013/2014	AGAGE monthly station means, incl. pollution events (Prinn et al. 1990) & Combined Nitrous Oxide data (monthly station averages) from the NOAA/ESRL Global Monitoring Division.	Calculated based on observational data source (section 2.1.3).	Mean over 1990-2013 period. Applied as relative seasonality	Assumed zero	Two leadings EOF and their scores derived from residuals from observations. (2014: optimized to match observational data).
	Before 1990	Law Dome (MacFarling Meure et al. 2006)	Optimized to match smoothed Law Dome record.			The score for EOF1 is regressed against global annual fossil fuel & industry emissions (Gütschow et al. 2016). Score for EOF2 kept constant before in situ instrumental period.

Dataset	Reference / URL	Stations / Location	Used for	Description / Filtering
NOAA ESRL GMD Surface Flask data.	(Komhyr et al. 1983, Komhyr et al. 1985, Thoning 1987, Conway et al. 1988, Tans et al. 1989, Thoning et al. 1989, Tans et al. 1990a, Tans et al. 1990b, Conway et al. 1994, Thoning et al. 1995, Zhao and Tans 2006)	81 stations of the surface flask network <sup>a</sup> : ABP, ALT, AMS, AOC, ASC, ASK, AVI, AZR, BAL, BHD, BKT, BME, BMW, BRW, BSC, CBA, CGO, CHR, CIB, CMO, CPT, CRZ, DRP, DSI, EIC, GMI, GOZ, HBA, HPB, HSU, HUN, ICE, IZO, KCO, KEY, KUM, KZD, KZM, LEF, LLB, LLN, LMP, MBC, MEX, MHD, MID, MKN, MLO, NAT, NMB, NWR, OPW, OXK, PAL, PAO, POC, PSA, PTA, RPB, SCS, SDZ, SEY, SGI, SGP, SHM, SMO, SPO, STC, STM, SUM, SYO, TAP, THD, TIK, USH, UTA, UUM, WIS, WLG, WPC, ZEP	Observational period estimation of global mean, latitudinal gradient seasonality and seasonality change over 1984-2013. Optimization of global mean and latitudinal gradient in 2014 and before 1984.	This study used monthly average data that uses all sample points, which have an 'accepted' flag, i.e. initial two dots ('.*') in the three digit flag.
NOAA ESRL GMD Surface Flask data.	(NOAA ESRL GMD 2014c, NOAA ESRL GMD 2014b, NOAA ESRL GMD 2014a)	BRW, MLO, SMO		
Law Dome	(Etheridge et al. 1996, Etheridge et al. 1998c, Rubino et al. 2013) (MacFarling Meure et al., 2006)	Law Dome ice core	Used as input for piecewise 3rd-degree polynomial smoothing over remainder of years 0 to 1966.

Dataset	Reference / URL	Stations / Location	Used for	Description / Filtering
NOAA ESRL GMD Surface Flask data.	(Steele et al. 1987, Lang 1990b, Lang 1990a, Steele 1991, Lang 1992, Steele et al. 1992, Dlugokencky et al. 1994a, Dlugokencky et al. 1994c, Dlugokencky et al. 1998, Dlugokencky et al. 2001, Dlugokencky et al. 2005, Dlugokencky et al. 2009, Dlugokencky 2015a)	87 stations of the surface flask network <sup>a</sup> : ABP, ALT, AMS, AMT, AOC, ASC, ASK, AVI, AZR, BAL, BHD, BKT, BME, BMW, BRW, BSC, CBA, CGO, CHR, CIB, CMO, CPT, CRZ, DRP, DSI, EIC, GMI, GOZ, HBA, HPB, HSU, HUN, ICE, ITN, IZO, KCO, KEY, KPA, KUM, KZD, KZM, LEF, LLB, LLN, LMP, MBC, MCM, MEX, MHD, MID, MKN, MLO, NAT, NMB, NWR, NZL, OPW, OXK, PAL, PAO, POC, PSA, PTA, RPB, SCS, SDZ, SEY, SGI, SGP, SHM, SIO, SMO, SPO, STM, SUM, SYO, TAP, THD, TIK, USH, UTA, UUM, WIS, WKT, WLG, WPC, ZEP	Observational period estimation of global mean, latitudinal gradient seasonality and seasonality change over 1984-2013. Optimization of global mean and latitudinal gradient in 2014 and before 1984.	This study used monthly station averages that include all sample points, which have a 'accepted' flag, i.e. initial two dots ('.*') in the three digit flag.
AGAGE GC-MD	(Prinn et al. 2000b)	AGAGE GC-MD network <sup>b</sup> : CGO, MHD, RPB, SMO, THD		The monthly station averages that include pollution events ('.mop' file endings in case of AGAGE) were used.
Law Dome	(Etheridge et al. 1998a, MacFarling Meure et al. 2006)	Law Dome ice core at -66.73-degree south.	Long-term high-latitude southern hemisphere reference point with piecewise 3rd-degree polynomial smoothing over years 155 to 1974.	
EPICA Dronning Maud Land Ice Core	(Barbante et al. 2006, Capron et al. 2010)	Dronning Maud Land Ice Core	Used as input for piecewise 3rd-degree polynomial smoothing over remainder of years 0 to 153.	
NEEM Greenland	(Dahl-Jensen et al. 2013, Rhodes et al. 2013)	NEEM ice core Greenland data	Used for optimisation of global mean and latitudinal gradient score of EOF1 over timescale from year 0 to 1984, with linear interpolation of score 1 in between available NEEM datapoints. (section 2.1.4)

1131

1132 **Table 9 - Raw data used for N<sub>2</sub>O surface mixing ratio field derivation**

Dataset	Reference / URL	Stations / Location	Used for	Description / Filtering
NOAA ESRL GMD Surface Flask data.	Combined N <sub>2</sub> O data from the NOAA/ESRL Global Monitoring Division, (ftp://ftp.cmdl.noaa.gov/hats/n2o/combined/HATS_global_N2O.txt, file date: Wed, Aug 19, 2015 2:40:55 PM)	13 stations of the NOAA HATS global <sup>a</sup> : alt, brw, cgo, kum, mhd, mlo, nwr, psa, smo, spo, sum, tdf, thd	Observational period estimation of global mean, latitudinal gradient seasonality and seasonality change over 1990-2013. Optimization of global mean and latitudinal gradient in 2014.	This study uses station averages, which include all sample points, which have an 'accepted' flag, i.e. initial two dots ('.*') in the three digit flag. ('.mop' file endings in case of AGAGE)
AGAGE GC-MD	(Prinn et al. 1990, Prinn et al. 2000b)	AGAGE GC-MD network <sup>b</sup> : CGO, MHD, RPB, SMO, THD		
Law Dome	(MacFarling Meure et al. 2006)	Law Dome ice core at -66.73 degree south.	Long-term high-latitude southern hemisphere reference point with piecewise 3rd-degree polynomial smoothing over years 155 to 1974.	
NEEM Greenland	(Dahl-Jensen et al. 2013, Rhodes et al. 2013)	NEEM firn Greenland data	Used for comparison only as latitudinal gradient estimated as very small and constant and assumed constant before observational period	
Gap			At this stage, sparse data availability in the period 1968 to 1986 suggests against optimisations of global-means with annual datapoints, which is why an interpolation between 1968 (starting from smoothed Law Dome record) to 1986 (ending with optimized global mean to fit observational data) is assumed.

1160 **Figure 1 - Atmospheric CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O mixing ratios over different time-scales, from 800 thousand years ago until today (panel**  
 1161 **a, c, e), from Year 0 A.D. to today (panel b, d, f). The shown data is for CO<sub>2</sub>: Mauna Loa data by Keeling et al. (Keeling et al. 1976);**  
 1162 **the Law Dome ice record (Etheridge et al. 1998c, MacFarling Meure et al. 2006, Rubino et al. 2013); NOAA ESRL station data**  
 1163 **(NOAA 2013, NOAA ESRL GMD 2014c, NOAA ESRL GMD 2014b, NOAA ESRL GMD 2014a); the EPICA composite data (Lüthi**  
 1164 **et al. 2008, Bereiter et al. 2015) and the WAIS data (Bauska et al. 2015). For CH<sub>4</sub>, the shown data is the Law Dome data (Etheridge**  
 1165 **et al. 1998b, MacFarling Meure et al. 2006), the instrumental data from the NOAA and AGAGE networks (see Table 8), NEM ice**  
 1166 **core measurements (Rhodes et al. 2013) and the EPICA composite (Barbante et al. 2006) In case of N<sub>2</sub>O, the shown data is the**  
 1167 **Law Dome record (MacFarling Meure et al. 2006), the Talos Dome record (Schilt et al. 2010b), the GISP2 record (Sowers et al.**  
 1168 **2003) and the EPICA record (Fluckiger et al. 2002, Spahni et al. 2005, Schilt et al. 2010a) [The figure will be updated to reflect**  
 1169 **references in legend and to include CH<sub>4</sub> data over the last 800,000 years based on data by Loulergue (2008)].**

1170

1171

1172

1173 **Figure 2 - Overview of historical CO<sub>2</sub> mixing ratios.** Panel a.1, the average seasonality of CO<sub>2</sub> over the observational period, a.2, the  
 1174 change of seasonality over time. a.3, the observationally derived and extended EOF score of the seasonality change. The first EOF1's  
 1175 score is almost linearly increasing over the time of instrumental data from 1984 to 2014. b, the latitudinal variation of mixing ratios  
 1176 (dashed lines), shown for example years from 1500 to 2014, including (for comparison) the average of three CMIP5 ES  
 1177 models (solid lines). c, the first and second EOF of latitudinal variation. The second EOF exhibits a strong signal around middle northern  
 1178 latitudes d, the EOF scores derived from the observational data (dots) and regression (dashed line) as well as the ultimately used  
 1179 EOF score (solid line). The second EOF's score indicates that the mid-latitude northern spike was only a recent phenomenon and

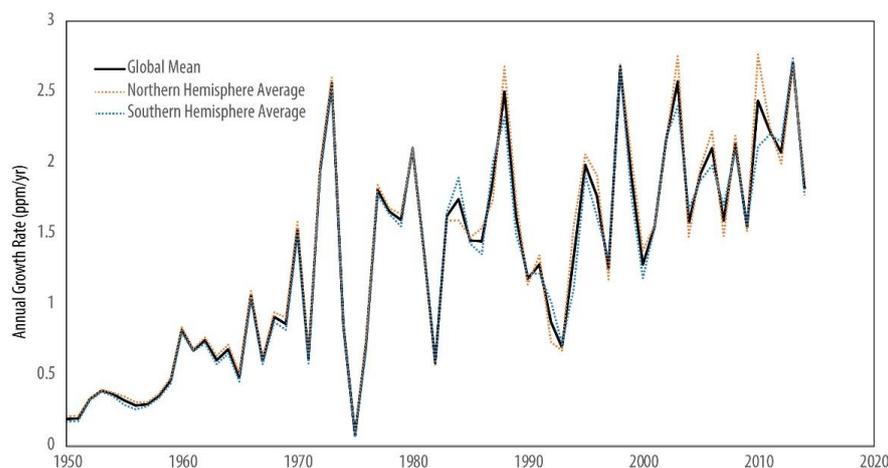

1180 the score is here assumed to linearly converge to zero. The first EOF's score is more linearly increasing, and regressed against global  
 1181 fossil emissions. e, the resulting latitudinal-monthly mixing ratio field, here shown between 1950 and 2014. f, global and hemispheric  
 1182 means of the derived mixing ratio field over the same time period 1950 to 2014 in comparison to monthly station data (grey dots),  
 1183 latitudinal average station data (colored circles), and various literature studies (see legend). g, same as panel f, except for time period  
 1184 1750 to 2014. h, same as panel f but for time period 2005 to 2010.

1185

1186

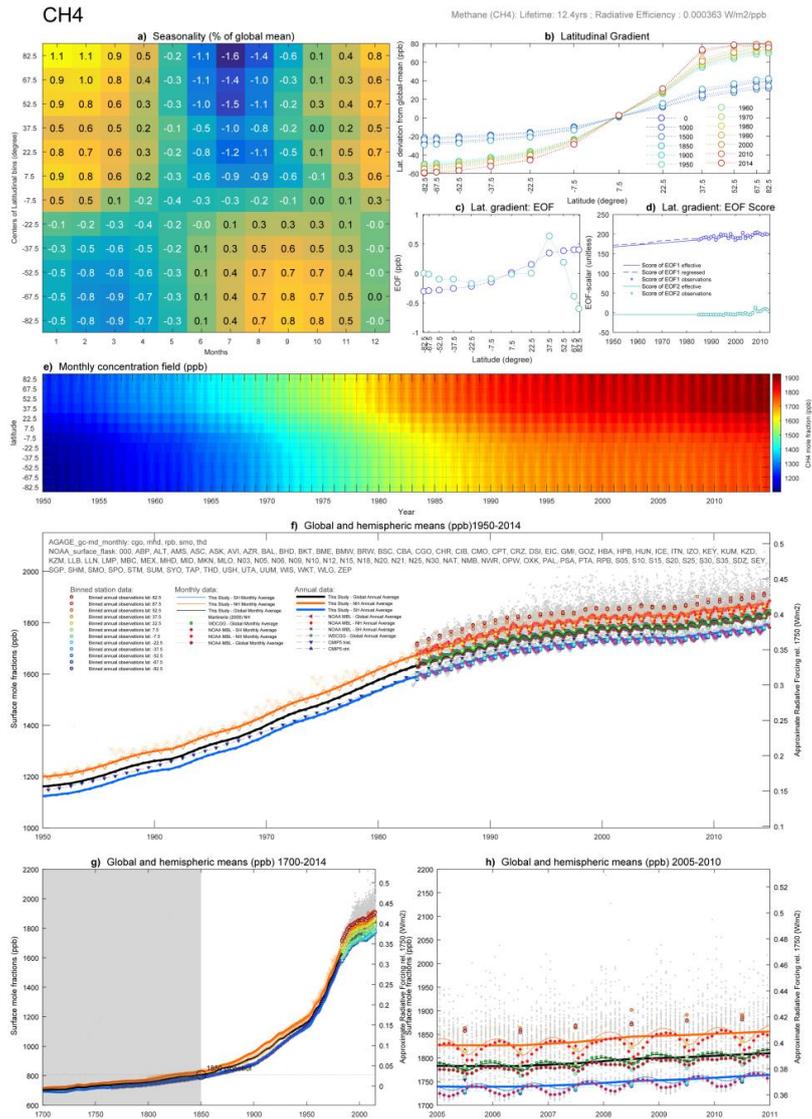

1187

1188

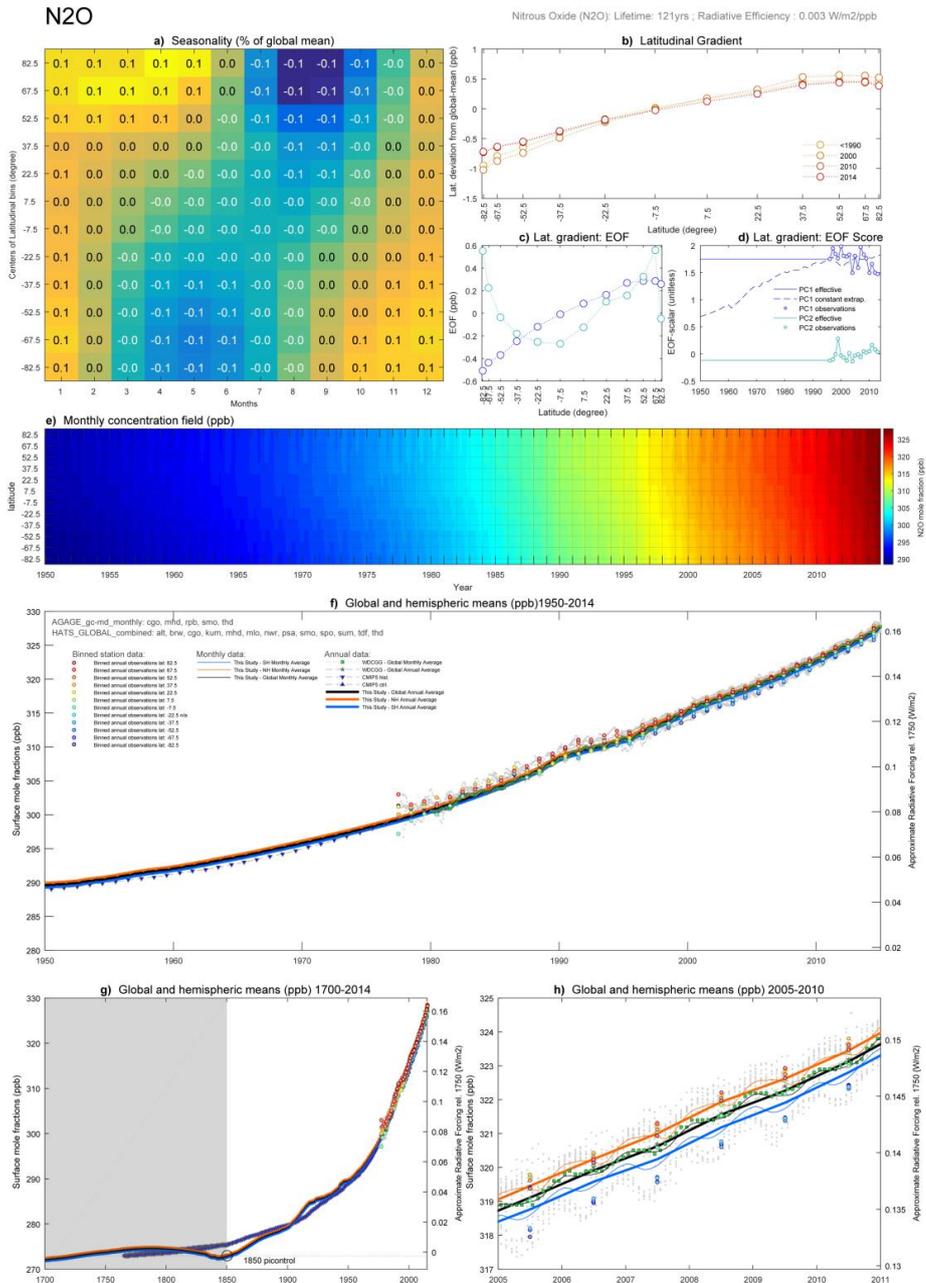

1189

1190 **Figure 3 - Annual Growth Rate of CO<sub>2</sub> mixing ratios for global-mean, northern hemispheric average and southern hemispheric**  
 1191 **average mixing ratios. Before 1960, the smooth growth rate results from interpolated global mean values. After 1960, the growth**  
 1192 **rates are diagnosed from the surface station data, as shown in Figure 2f. Noticeable are fluctuations of the annual growth rate around**  
 1193 **1973, 1981, and 1992.**

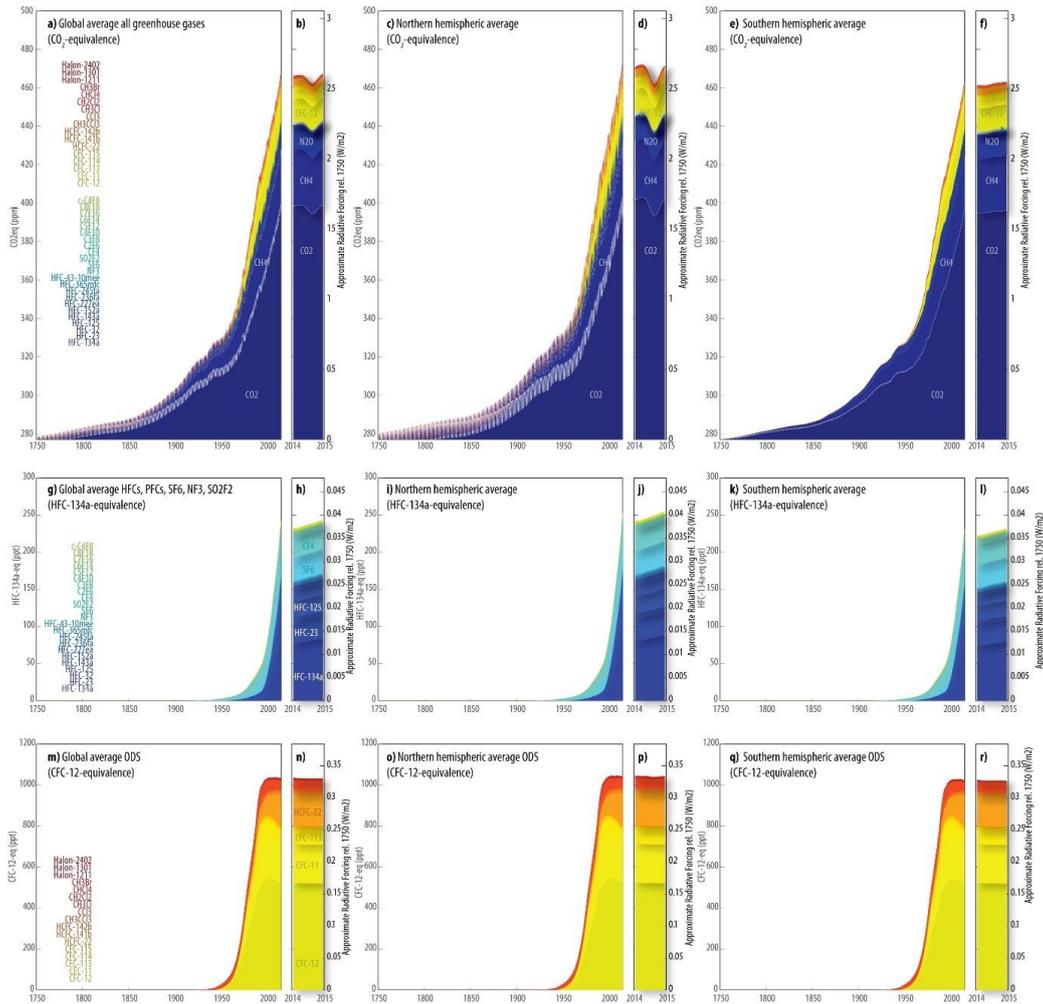

1194

1195 **Figure 4 - Overview of historical CH<sub>4</sub> mixing ratios.** Panel a.1, the relative seasonality of CH<sub>4</sub> over the observational period. b, the  
 1196 latitudinal variation of mixing ratios (dashed lines), shown for example years. c, the first and second EOF of latitudinal variation. d,  
 1197 the EOF scores derived from the observational data (dots) and regression against global emissions (dashed line) as well as the  
 1198 ultimately used EOF score (solid line). e, the resulting latitudinal-monthly mixing ratio field, here shown between 1950 and 2014. f,  
 1199 global and hemispheric means of the derived mixing ratio field over the same time period 1950 to 2014 in comparison to monthly  
 1200 station data (grey dots), latitudinal average station data (colored circles), and various literature studies (see legend). g, same as panel  
 1201 f, except for time period 1700 to 2014. h, same as panel f but for time period 2005 to 2010.

1202

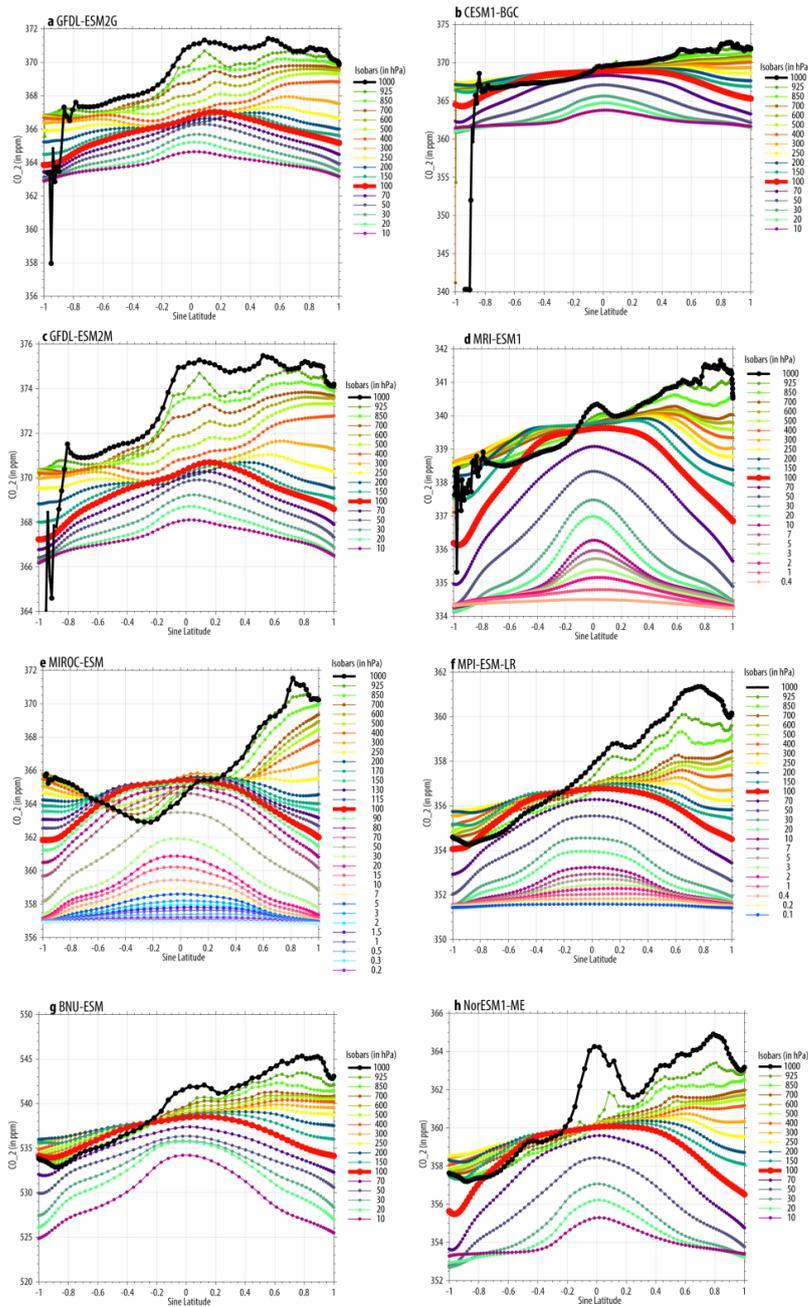

1203 **Figure 5 - Overview over historical N<sub>2</sub>O mixing ratios. As Figure 4, but for N<sub>2</sub>O.**

1204

1205 **Figure 6 – Historical GHG mixing ratios from 1750 to 2014 as global-mean average (right panels) northern hemispheric average**  
 1206 **(middle panels) and southern hemispheric averages (right panels). The top row comprises all greenhouse gases, the middle row**  
 1207 **comprises HFCs, PFCs, SF6, NF3 and SO2F2. The lower row comprises all ozone depleting substances, expressed as equivalent**  
 1208 **CFC-12eq mixing ratios. In the narrow boxes, the last data year from 15 Jan 2014 to 15 Dec 2015 is shown, indicating the intra-**  
 1209 **annual trend (top row), increasing gradient (middle row) or relatively flat mixing ratio levels (lower row). [NOTE, the lower two**  
 1210 **rows of this figure need a slight update in regard to their left hand axes, as equivalent mixing ratios are positive due to some**  
 1211 **gases with natural background mixing ratios].**

1226  
 1227  
 1228

**Figure 10 - Annual mean CO<sub>2</sub> mixing ratios in 8 CMIP5 ESM models in the year 1875. The CMIP5 recommended value was 288.7 ppmv for 1875. Two more models with higher average CO<sub>2</sub> mixing ratios, namely BNU-ESM and FIO-ESM, are shown in Figure 63 and Figure 64.**

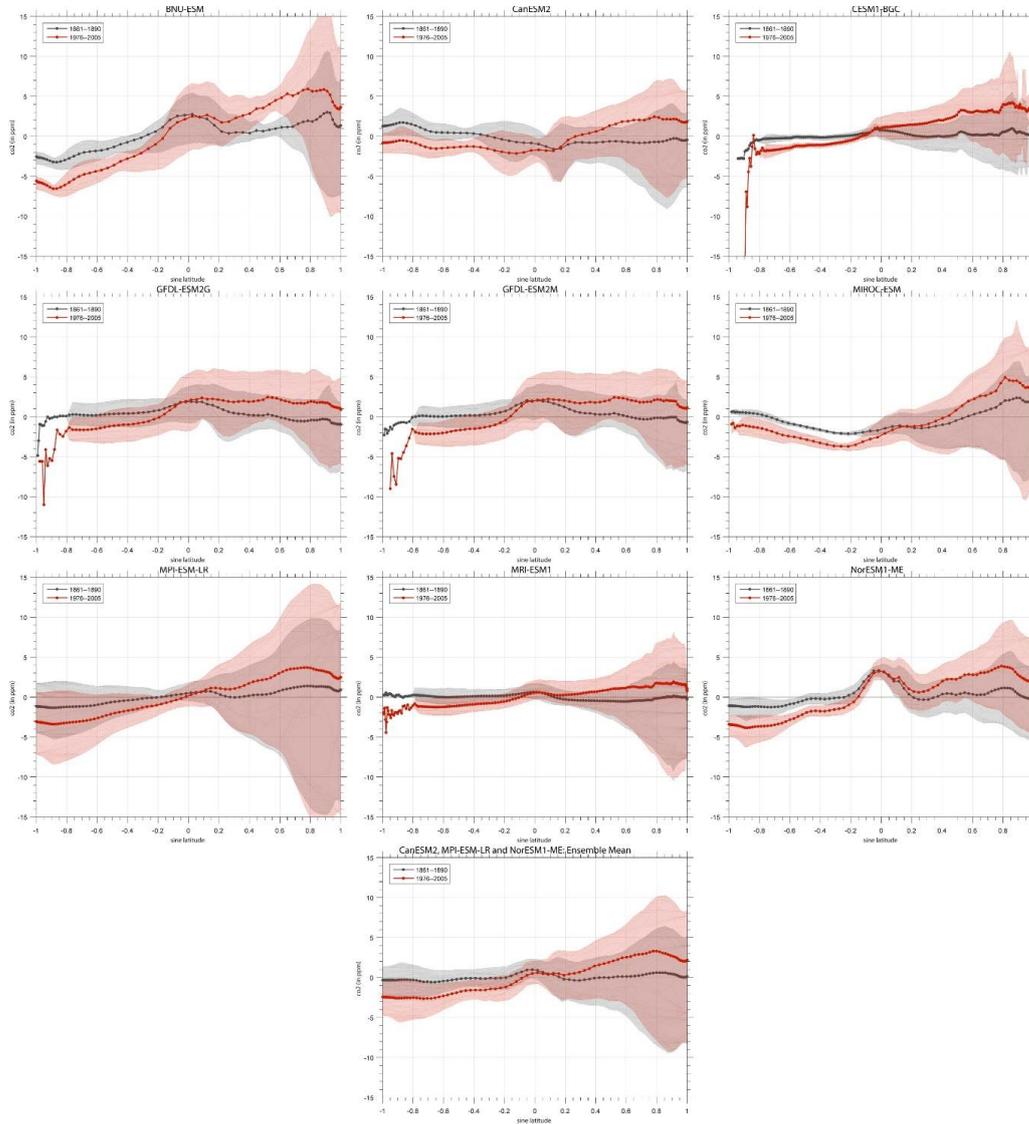

1229

1230  
 1231

**Figure 11 - Annual mean CO<sub>2</sub> mixing ratios in 8 CMIP5 ESM models in the year 1990. The CMIP5 recommended value was 353.885 ppmv for 1990 in the historical experiment.**

1232

1233

1234

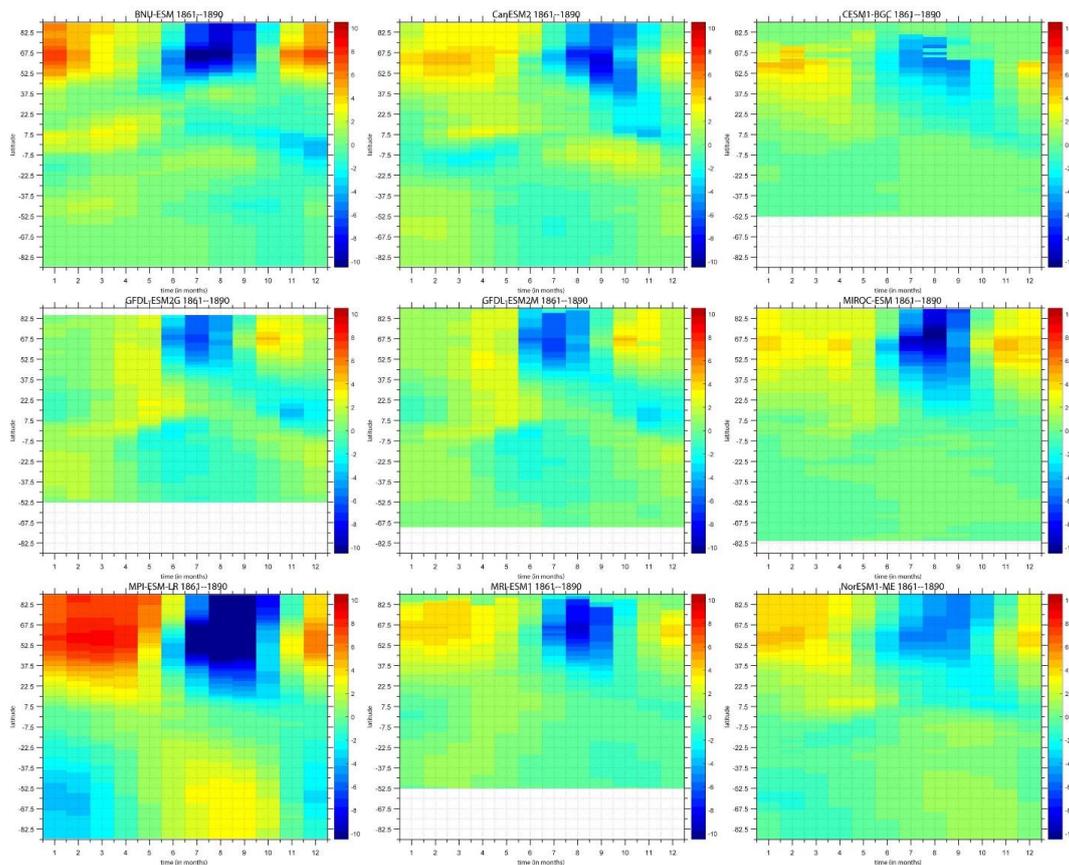

1235

1236

1237

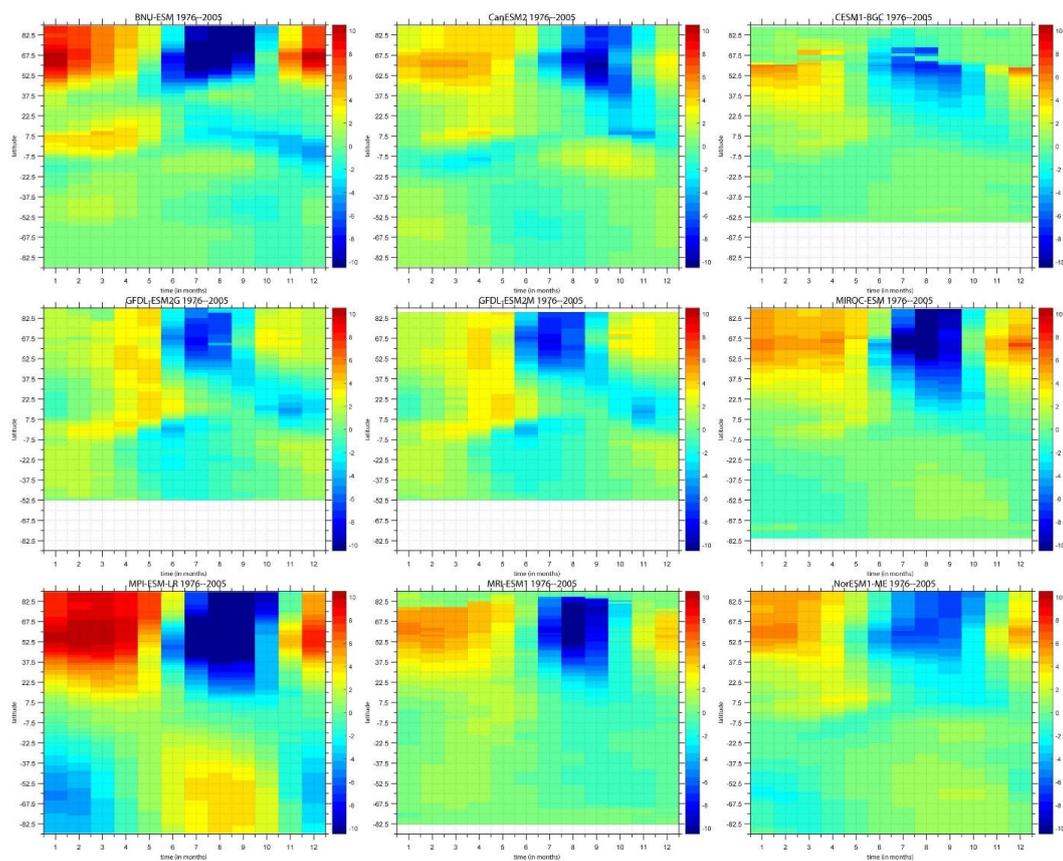

**Figure 12 - Latitudinal gradient of surface atmospheric CO<sub>2</sub> mixing ratios exhibited in 9 considered CMIP5 ESM models for both the preindustrial period (grey lines) and recent period 1976-2005 (red lines). The bold dotted lines indicate the annual means. The 12 finer lines represent the individual 12 monthly averages over the respective 30 year periods. The lowest panel shows an ensemble mean for three CMIP5 ESMs, namely CanESM2, MPI-ESM-LR and NorESM1-ME.**

1238

1239

1240 **Figure 13 – Climatological seasonal cycle of CO<sub>2</sub> mixing ratios in 9 CMIP5 ESM models for the historical experiment's 30-year**  
1241 **period 1861-1890.**

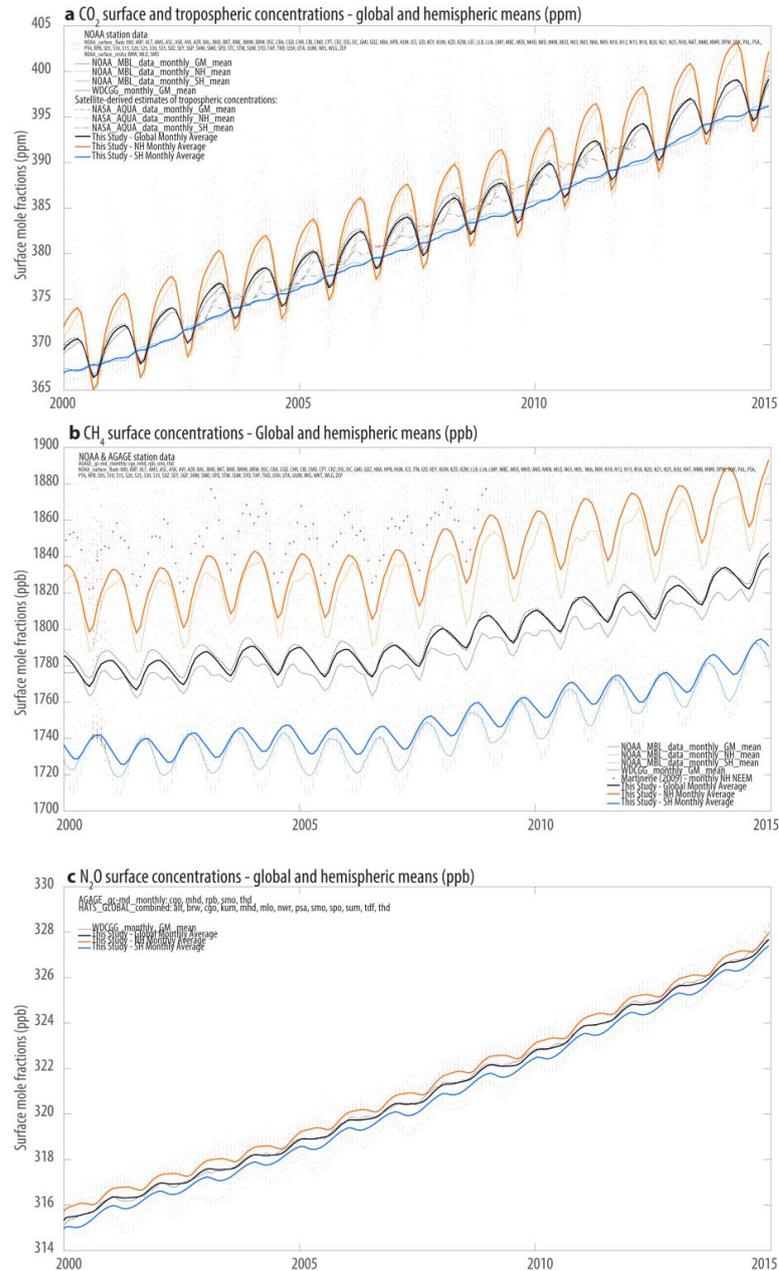

1242

1243

1244

**Figure 14 – Climatological seasonal cycle of CO<sub>2</sub> mixing ratios in 9 CMIP5 ESM models for the historical experiment's 30-year period 1976-2005.**

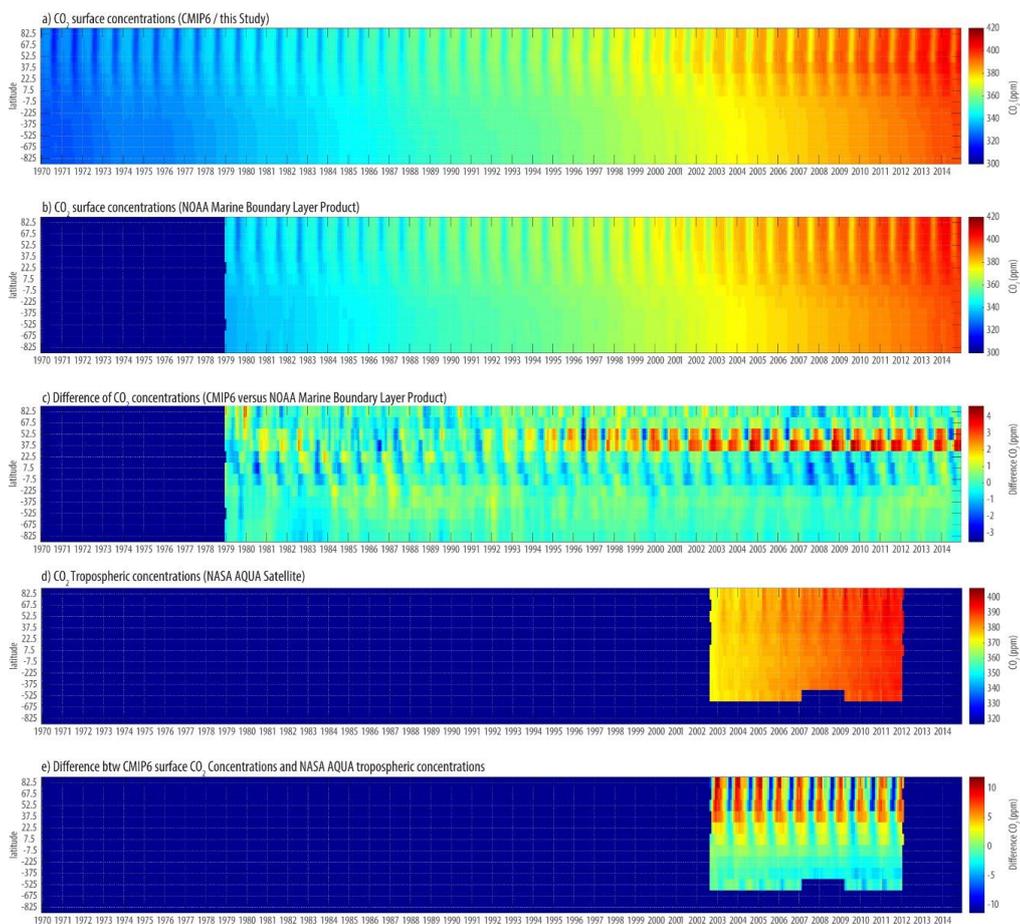

1245

1246

1247 **Figure 15 - Comparison of global-mean, and hemispheric monthly average mixing ratios of CO<sub>2</sub> (panel a), CH<sub>4</sub> (panel b) and N<sub>2</sub>O**  
 1248 **(panel c) between the CMIP6 surface mole fractions (this study), the NOAA Marine Layer Boundary products, the World Data**  
 1249 **Centre of Greenhouse gases (WDCGG) products and the NASA AQUA satellite data of tropospheric CO<sub>2</sub> mixing ratios. For**  
 1250 **comparison, individual (monthly average) NOAA and AGAGE station data across all latitudes is shown in the background (grey**  
 1251 **dots).**

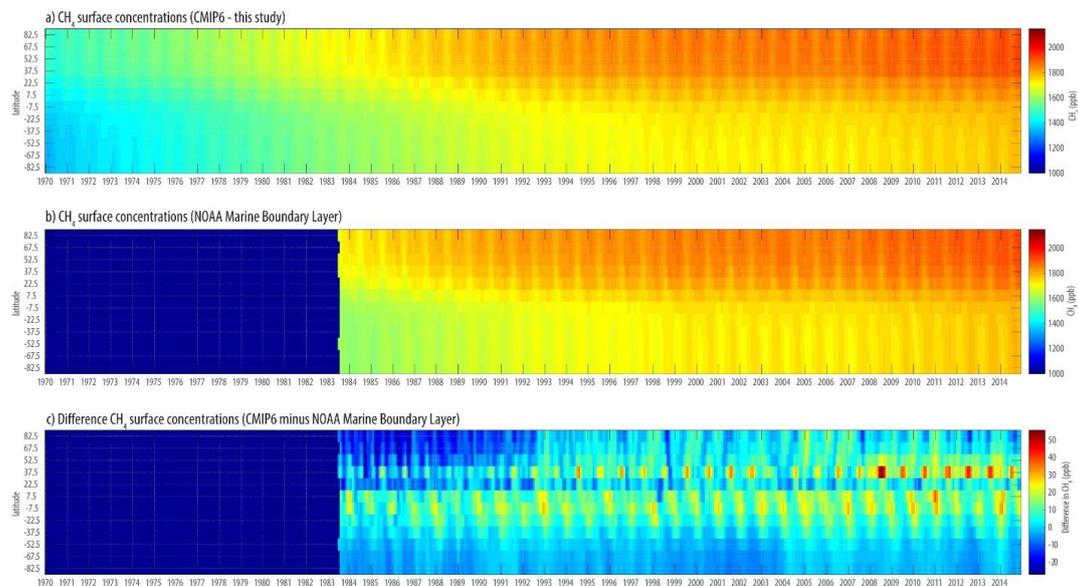

1252

1253

1254 **Figure 16 - Comparison of the CMIP6 historical CO<sub>2</sub> emissions (panel a) with the NOAA Marine Boundary Layer MBL product**  
1255 **from 1979 to 2014 (panel b). Differences indicate that a seasonal higher CO<sub>2</sub> mixing ratio is implied by the CMIP6 data of up to 5**  
1256 **ppmv in mid-latitude northern bands, whereas some monthly tropical CO<sub>2</sub> mixing ratios tend to be slightly lower in the CMIP6**  
1257 **product compared to NOAA MBL (panel c).**

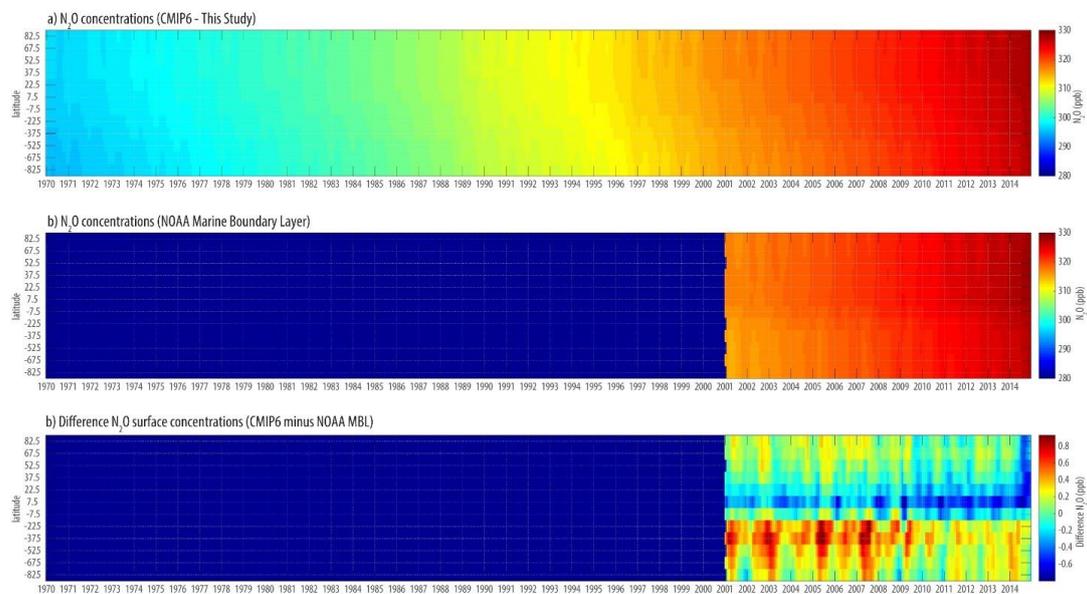

1258

1259

1260 **Figure 17 - Comparison of the surface CH<sub>4</sub> monthly mean mixing ratios between CMIP6 (panel a), the NOAA Marine Boundary**  
1261 **Layer product (panel b) and the difference (panel c). Since around 1992, there are seasonal differences in the mid northern latitudes**  
1262 **with the CMIP6 data being up to 50ppb higher than the NOAA MBL product. Similarly, higher mixing ratios are apparent in the**  
1263 **areas of tropical southern and lower latitude southern areas, presumably due to differences of data over land areas.**

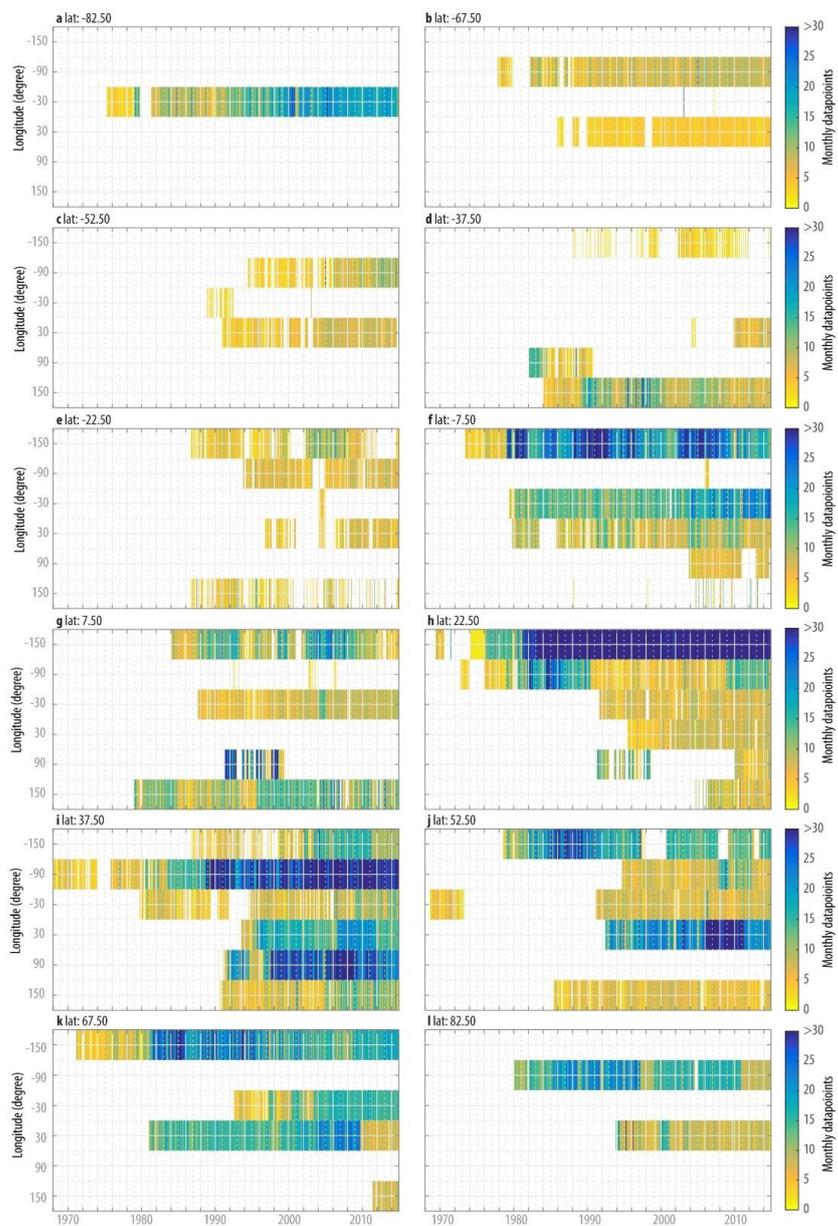

1264

1265

1266 **Figure 18 - The comparison between latitudinal and monthly N<sub>2</sub>O mixing ratios to the NOAA Marine Boundary Layer product**  
1267 **(panel b). The differences (panel c) show that the CMIP6 historical GHG mixing ratios are slightly higher in the southern hemisphere**  
1268 **(-0.5ppb) and slightly lower in the tropics (+0.5ppb), as the stronger latitudinal gradient from tropics to southern latitudes is not**  
1269 **reproduces in CMIP6 data. Note: Data submitted by Pieter Tans, pers. Communication.**
