1 **Abstract.** Recently, several Lagrangian microphysical models have been developed which use a
2 large number of (computational) particles to represent a cloud. In particular, the collision process
3 leading to coalescence of cloud droplets or aggregation of ice crystals is implemented differently
4 in the various models. Three existing implementations are reviewed and extended, and their perfor-
5 mance is evaluated by a comparison with well established analytical and bin model solutions. In this
6 first step of rigorous evaluation, box model simulations with collection/aggregation being the only
7 process considered have been performed for the three well-known kernels of Golovin, Long and
8 Hall.

9 Besides numerical parameters like the time step and the number of simulation particles (SIPs)
10 used, the details of how the initial SIP ensemble is created from a prescribed analytically defined
11 size distribution is crucial for the performance of the algorithms. Using a constant weight tech-
12 nique as done in previous studies greatly underestimates the quality of the algorithms. Using better
13 initialisation techniques considerably reduces the number of required SIPs to obtain realistic re-
14 sults. From the box model results recommendations for the collection/aggregation implementation
15 in higher dimensional model setups are derived. Suitable algorithms are equally relevant to treating
16 the warm-rain process and aggregation in cirrus.

17 1 Introduction

18 The collection of cloud droplets or the aggregation of ice crystals is an important process in liquid
19 and ice clouds. By changing the size, number, and in the case of ice the shape of hydrometeors,
20 collection and aggregation affect the microphysical behaviour of clouds and thereby their role in the
21 climate system.

22 The warm rain process (i.e. the production of precipitation in clouds in the absence of ice) de-
23 pends essentially on the collision and subsequent coalescence of cloud droplets. At its initial stage,

24 however, condensational growth governs the activation of aerosols and the following growth of cloud
25 droplets, which might initiate the collection process if they become sufficiently large. Then, collec-
26 tion produces drizzle or raindrops, which are able to precipitate from the cloud, affecting lifetime
27 and organisation of clouds (e.g. Albrecht, 1989; Xue et al., 2008).

28 In ice clouds, sedimentation, deposition growth and in particular radiative properties depend on
29 the ice crystals' habits (Sölch and Kärcher, 2011, and references therein). Ice aggregates scatter
30 more strongly shortwave radiation than pure ice crystals of the same mass. Recent simulation results
31 suggest that contrail-cirrus and natural cirrus can be strongly interwoven. In the mixing area with
32 ice crystals of both origins being present, a prominent bimodal spectrum occurs and enhances the
33 probability of collisions (Unterstrasser et al., 2016).

34 The temporal change of the droplet number distribution by the collision and subsequent coales-
35 cence of droplets (or any other particles) is described by the stochastic collection equation (SCE),
36 also known as kinetic collection equation, coagulation equation, Smoluchowski or population bal-
37 ance equation (e.g. Wang et al., 2007). It yields:

$$\frac{\partial f_m(m, t)}{\partial t} = \frac{1}{2} \int_0^m K(m', m - m') f_m(m', t) f_m(m - m', t) dm' - \int_0^\infty K(m, m') f_m(m, t) f_m(m', t) dm', \quad (1)$$

39 where $f_m(m)dm$ is the number concentration within an infinitesimal interval around the mass m .
40 The first term (gain term) accounts for the coalescence of two smaller droplets forming a new
41 droplet with mass m , the second term (loss term) accounts for the coalescence of m -droplets with
42 any other droplets forming a larger droplet. The collection kernel $K(m, m')$ describes the rate
43 by which a m -droplet- m' -droplet-collection occurs. Due to the symmetry of the collection kernel
44 ($K(m, m') = K(m', m)$) the first term of the right-hand side can also be written as $\int_0^{m/2} K(m', m -$
45 $m') f_m(m', t) f_m(m - m', t) dm'$.

46 For several kernel functions (mostly of polynomial form) analytic solutions exist for specific initial
47 distributions (Golovin, 1963; Berry, 1967; Scott, 1968). The Golovin kernel (sum of masses) is given
48 by

$$49 \quad K(m, m') = b(m + m'). \quad (2)$$

50 Solutions for more realistic kernels (Long, 1974; Hall, 1980; Wang et al., 2006) and arbitrary initial
51 distribution can be obtained with various numerical methods mainly using a bin representation of the
52 droplet size distribution (Berry and Reinhardt, 1974; Tzivion et al., 1987; Bott, 1998; Simmel et al.,
53 2002; Wang et al., 2007). The hydrodynamic kernel is defined as

$$54 \quad K(r, r') = \pi(r + r')^2 |w_{sed}(r) - w_{sed}(r')| E_c(r, r'), \quad (3)$$

55 based on the radius r and the sedimentation velocity w_{sed} . Parametrisations of the collection ef-
56 ficiency E_c are given, e.g. by Long (1974) or Hall (1980). In the above formula, the differen-
57 tial sedimentation is the driver of collections. No same-size collisions can occur, i.e. $K(r, r) = 0$.
58 More sophisticated expressions for $K(r, r')$ have been derived to include turbulence enhancement
59 of the collisional growth, which also allow same-size collisions ($K(r, r) > 0$) (e.g. Ayala et al., 2008;
60 Grabowski and Wang, 2013; Chen et al., 2016).

61 Solving (1) demands simplifications in the representation of the droplet spectrum for which sev-
62 eral numerical models have been developed. Spectral-bin models (e.g. Khain et al., 2000) represent
63 the spectrum by dividing it into several intervals, so-called bins. This approach enables the predic-
64 tion of the temporal development of the droplet number concentration in each bin by using finite
65 differences or more sophisticated numerical techniques (e.g. Bott, 1998). The accuracy of these
66 models is primarily determined by the number of used bins (usually on the order of 100), which
67 makes them computationally challenging and prohibits their use in day-to-day applications like nu-
68 merical weather prediction. Less challenging but less accurate, cloud microphysical bulk models
69 compute the temporal change of integral quantities of the droplet spectrum (e.g. Kessler, 1969;
70 Khairoutdinov and Kogan, 2000; Seifert and Beheng, 2001). These are usually equations for the
71 temporal evolution of bulk mass (so-called one-moment schemes), and additionally number con-
72 centration (two-moment schemes) or radar reflectivity (three-moment schemes), which describe the
73 change of the entities of cloud droplets and rain drops (in the case of warm clouds). The separation
74 radius between cloud droplets and rain drops depends on the details of the bulk scheme, but generally
75 cloud droplets (up to 20 to 40 μm in radius) are assumed to have negligible sedimentation fall veloci-
76 ties, while larger drops, frequently subsumed as rain drops, have significant sedimentation velocities
77 to cause collision/coalescence. The interactions of cloud and rain drops are therefore described in
78 terms of self-collection (coalescence of cloud (rain) drops resulting in cloud (rain) drops), autocon-
79 version (coalescence of cloud droplets resulting in rain drops) and accretion (collection of cloud
80 droplets by rain drops). A third alternative for computing cloud microphysics has been developed
81 in the recent years: Lagrangian cloud models (LCMs). These models represent cloud microphysics
82 on the basis of individual particles. Similar to spectral-bin models, LCMs enable the detailed rep-
83 resentation of droplet spectra but inherently avoid spurious numerical diffusion in condensational
84 and collisional growth usually affecting the results of spectral-bin models (Andrejczuk et al., 2010;
85 Arabas and Shima, 2013).

86 To our knowledge, five fully coupled LCMs for warm clouds exist, which are described in Andrejczuk et al.
87 (2008); Shima et al. (2009); Riechelmann et al. (2012); Arabas et al. (2015) and Naumann and Seifert
88 (2015) and have been extended or applied in various problems (e.g. Andrejczuk et al., 2010; Arabas and Shima,
89 2013; Lee et al., 2014; Hoffmann et al., 2015). For ice clouds, three models exist (Paoli et al., 2004;
90 Shirgaonkar and Lele, 2006; Sölch and Kärcher, 2010) which have been applied to natural cirrus
91 (Sölch and Kärcher, 2011) and, in particular, to contrails (e. g. Paoli et al., 2013; Unterstrasser, 2014;

92 Unterstrasser and Görsch, 2014). In the context of ice clouds and warm clouds, different names
93 are used for processes that are similar, in particular in terms of their numerical treatment (depo-
94 sition/sublimation vs. condensation/evaporation, collection vs. aggregation). Conceptually similar
95 are particle based approaches in aerosol physics (Riemer et al., 2009; Maisels et al., 2004) which
96 account for coagulation of aerosols (DeVille et al., 2011; Kolodko and Sabelfeld, 2003).

97 So far, no consistent terminology has been used in the latter publications. Various names have
98 been used for the same things by various authors. We point out that super droplet, computational
99 droplet and simulation particle (SIP) all have the same meaning and refer to a bunch of identical
100 real cloud droplets (or ice crystals). The number of real droplets represented in a SIP is denoted
101 as weighting factor or multiplicity. Moreover, Lagrangian approaches in cloud physics have been
102 named Lagrangian Cloud Model (LCM), super droplet method (SDM) or particle based method. In
103 this paper, we use the terms SIP, weighting factor ν_{sim} and LCM. Here droplet refers to either real
104 droplets or ice crystals.

105 Usually, only the liquid water or the ice of a cloud are described with a Lagrangian representation,
106 whereas all other physical quantities (like velocity, temperature and water vapour concentration) are
107 described in Eulerian space (see also discussion in Hoffmann, 2016). SIPs have discrete positions
108 $\mathbf{x}_p = (x_p, y_p, z_p)$ within a grid box. The position is regularly updated obeying the transport equation
109 $\partial \mathbf{x}_p / \partial t = \mathbf{u}$. Microphysical processes like sedimentation and droplet growth are treated individually
110 for each SIP. Interpolation methods can be used to evaluate the Eulerian fields at the specific SIP
111 positions. This implicitly assumes that all ν_{sim} droplets of the SIPs are located at the same position.
112 On the other hand, the droplets of a SIP are assumed to be well-mixed in the grid box in LCM
113 treatment of collection and sometimes condensation. Then, the number concentration represented
114 by a single SIP, e. g., is given by $\nu_{sim} / \Delta V$, where ΔV is the volume of the grid box.

115 Lists of used symbols and abbreviation are given in Tables 1 and 2.

116 2 Description of the various collection/aggregation implementations

117 We use the terminology of Berry (1967), where $f_{\ln r}$ and $g_{\ln r}$ denote the number and mass density
118 function with respect to the logarithm of droplet radius $\ln r$. The relations $g_{\ln r}(r) = m f_{\ln r}(r)$ and
119 $f_{\ln r}(r) = 3m f_m(m)$ hold. The latter designates the number density function with respect to mass
120 and obeys the transformation property of distributions: $f_y(y)dy = f_x(x(y))dx$. For consistency with
121 previous studies, $g_{\ln r}$ is used for plotting purposes, whereas f_m and g_m are more relevant in the
122 following analytical derivations.

123 The moments of order k of the mass distribution f_m (= number density function with respect to
124 mass) are defined as:

$$125 \lambda_k(t) = \int m^k f_m(m, t) dm. \quad (4)$$

Table 1. List of symbols.

Symbol	Value/Unit	Meaning
f_m, \tilde{f}_m	$\text{kg}^{-1} \text{m}^{-3}, 1$	(normalised) droplet number concentration per mass interval
$g_m, g_{\ln r}$	$\text{m}^{-3}, \text{kg m}^{-3}$	droplet mass concentration per mass interval/per logarithmic radius interval
m, m'	kg	mass of a single real droplet
m_{bb}	kg	bin boundaries of the bin grid
$\bar{m} = \lambda_1/\lambda_0 = \mathcal{N}/\mathcal{M}$	kg	mean mass of all droplets
$n_{bin,l}$	1	droplet number in bin l
r, r'	m	droplet radius
r_{tb}	m	threshold radius in $\nu_{random,lb}$ -init
$r_{critmin}$	m	lower cut-off radius in singleSIP-init
w_{sed}	m s^{-1}	sedimentation velocity
$DNC = \lambda_0$	m^{-3}	droplet number concentration
E_c	1	collection/aggregation efficiency
K	$\text{m}^3 \text{s}^{-1}$	collection/aggregation kernel
$LWC = \lambda_1$	kg m^{-3}	droplet mass concentration, liquid water content
$M_{bin,l}$	kg	total droplet mass in bin l
N_{SIP}	1	number of SIPs
N_{BIN}	1	number of bins
$\alpha_{low}, \alpha_{med}, \alpha_{high}$	1	parameters of the ν_{random} -init method.
Δt	s	time step
ΔV	m^3	grid box volume
η	1	parameter in RMA algorithm and singleSIP-init method
κ	1	number of bins per mass decade
λ_k	$\text{kg}^k \text{m}^{-3}$	moments of the order k
μ	kg	single droplet mass of a SIP
$\nu_{critmax}$	1	maximum number of droplets represented by a SIP
$\nu_{critmin}$	1	minimum number of droplets represented by a SIP
ν	1	number of droplets represented by a SIP
ξ	1	splitting parameter of AON algorithm
$\chi = \mu \nu, \tilde{\chi} = \chi/\mathcal{M}$	kg, 1	total droplet mass of a SIP
$\mathcal{N} = \lambda_0 \Delta V$	1	total droplet number
$\mathcal{M} = \lambda_1 \Delta V$	kg	total droplet mass
$\mathcal{Z} = \lambda_2 \Delta V$	kg^2	second moment of droplet mass distribution (radar reflectivity)

Table 2. List of abbreviations.

AON	All-Or-Nothing algorithm	AIM	Average Impact algorithm
DSD	droplet size distribution	LCM	Lagrangian Cloud Model
PDF	probability density function	RMA	Remapping algorithm
SIP	simulation particle		

126 The low order moments represent the number concentration ($DNC = \lambda_0$) and the mass concentra-
 127 tion ($LWC = \lambda_1$). The analogous extensive properties $\lambda_k(t) \Delta V$ are the total droplet number \mathcal{N} ,
 128 total droplet mass \mathcal{M} and radar reflectivity ($\mathcal{Z} = \lambda_2 \Delta V$). For a given SIP ensemble, the moments
 129 can be simply computed by

$$130 \quad \lambda_{k,SIP}(t) = \left(\sum_{i=0}^{N_{SIP}} \nu_i \mu_i^k \right) / \Delta V, \quad (5)$$

131 where μ_i is the single droplet mass of SIP i and N_{SIP} is the number of SIPs inside a grid box. For
 132 reasons of consistency with Wang et al. (2007), we translate the SIP ensemble into a mass distribu-
 133 tion g_m in bin representation and then compute the moments with the formula

$$134 \quad \lambda_{k,BIN}(t) = \sum_{i=0}^{N_{BIN}} g_m(m_i, t) (\bar{m}_{bb,l})^{k-1} \frac{\ln 10}{3 \kappa} \quad (6)$$

135 (cf. with their equation 48).

136 The initialisation is successful for a given parameter set, if the moments of the SIP ensemble
 137 $\lambda_{k,SIP}$ are close to the analytical values $\lambda_{k,anal}$. For an exponential distribution (as used in this
 138 study), the probability density function (PDF) reads as

$$139 \quad f_m(m) = \frac{\mathcal{N}}{\Delta V \bar{m}} \exp\left(-\frac{m}{\bar{m}}\right), \quad (7)$$

140 the moments are given analytically by

$$141 \quad \lambda_{k,anal}(t) = (k-1)! \mathcal{N} \bar{m}^k / \Delta V, \quad (8)$$

142 where $k!$ is the faculty of k and $\bar{m} = \mathcal{M}/\mathcal{N}$ the mean mass (Rade and Westergren, 2000).

143 Throughout this study, the initial parameters of the droplet size distribution (DSD) are $DNC_0 =$
 144 $2.97 \times 10^8 \text{ m}^{-3}$ and $LWC_0 = 10^{-3} \text{ kg m}^{-3}$ (implying a mean radius of $9.3 \mu\text{m}$) as in Wang et al.
 145 (2007). The higher moments are $\lambda_{2,anal} = 6.74 \times 10^{-15} \text{ kg}^2 \text{ m}^{-3}$ and $\lambda_{3,anal} = 6.81 \times 10^{-26} \text{ kg}^3 \text{ m}^{-3}$.

146 2.1 Initialisation

147 In our test cases, all microphysical processes except collection are neglected and an exponential DSD
 148 is initialised. In the results section, we will demonstrate that the outcome of the various collection
 149 algorithms critically depends on how this initial, analytically defined, continuous DSD is translated
 150 into a discrete ensemble of SIPs. Hence, the SIP initialisation is described in some detail.

151 2.1.1 SingleSIP-init and MultiSIP-init

152 First, the mass distribution is discretized on a logarithmic scale. The boundaries of bin l are given
153 by $m_{bb,l} = m_{low} 10^{l/\kappa}$ and $m_{bb,l+1}$, where m_{low} is the minimum droplet mass considered. The
154 bin centre is computed using the arithmetic mean $\bar{m}_{bb,l} = 0.5(m_{bb,l+1} + m_{bb,l})$. The bin size is
155 $\Delta m_{bb,l} = (m_{bb,l+1} - m_{bb,l})$. The mass increases tenfold every κ bins. Several previous studies used
156 the parameter s with $m_{bb,l+1}/m_{bb,l} = 2^{1/s}$ to characterise the bin resolution. The parameters s and
157 κ are related via $s = \kappa \log_{10}(2) \approx 0.3\kappa$.

158 For each bin, the droplet number is approximated by $\nu_b = f_m(\bar{m}_{bb,l}) \Delta m_{bb,l} \Delta V$ and one SIP with
159 weighting factor $\nu_{sim} = \nu_b$ and droplet mass $\mu_{sim} = \bar{m}_{bb,l}$ is created, if ν_b is greater than a lower
160 cut-off threshold $\nu_{critmin}$. No SIP is created, if $\nu_b < \nu_{critmin}$. Moreover, no SIPs are created from
161 bins with radius $r < r_{critmin}$. We will refer to this as deterministic singleSIP-init. In its probabilistic
162 version, the mass μ_{sim} is randomly chosen within each bin l and $\nu_{sim} = f_m(\mu_{sim}) \Delta m_{bb,l} \Delta V$ is
163 adapted accordingly. By default, $r_{critmin} = 0.6 \mu\text{m}$ and $\nu_{critmin} = \eta \times \nu_{max}$, which is determined
164 from the maximal weighting factor within the entire SIP ensemble ν_{max} and the prescribed ratio
165 of the minimal to the maximal weighting factor $\eta = 10^{-9}$. For larger $r_{critmin}$ it is advantageous to
166 initialise one additional "residual" SIP that contains the sum of all neglected contributions.

167 Following Unterstrasser and Sölch (2014, see their Appendix A), we introduce the multiSIP-init
168 technique. It is similar to singleSIP-init technique, except that we additionally introduce an upper
169 threshold $\nu_{critmax}$. If $\nu_b > \nu_{critmax}$ is fulfilled for a specific bin, then this bin is divided into $\kappa_{sub} =$
170 $\lceil \nu_b / \nu_{critmax} \rceil$ sub-bins and a SIP is created for each sub-bin. The multiSIP-init technique gives a
171 good trade-off between resolving low concentrations at the DSD tails and high concentrations of the
172 most abundant droplet masses.

173 So far, we introduced initialisation techniques with a strict lower threshold $\nu_{critmin}$ with no SIPs
174 created in bins with $\nu_b < \nu_{critmin}$. We can relax this condition by introducing—what we call—
175 a *weak* threshold. This means, that in such low contribution bin (with $\nu_b < \nu_{critmin}$) we create a
176 SIP with the probability $p_{create} = \nu_b / \nu_{critmin}$ and weighting factor $\nu_{sim} = \nu_{critmin}$. Having many
177 realisations of initial SIP ensembles, the expectation value of the droplet number represented by
178 such SIPs, $\nu_{critmin} \cdot p_{create} + 0 \cdot (1 - p_{create})$, equals the analytically prescribed value ν_b . Using a
179 strict threshold the droplet number would be simply 0 in those low contribution bins. In a related
180 problem, such a probabilistic approach has been shown to strongly leverage the sensitivity of ice
181 crystal nucleation on the numerical parameter $\nu_{critmin}$. This led to a substantial reduction of the
182 number of SIPs that are required for converging simulation results (Unterstrasser and Sölch, 2014).

183 Using the probabilistic version and a weak lower threshold is particularly important if different
184 realisations of SIP ensembles of the same analytic DSD should be created. The number of SIPs
185 N_{SIP} depends on κ , $\nu_{critmin}$, $\nu_{critmax}$ and the parameters of the prescribed distribution.

186 Moreover, the singleSIP-init is used in a hybrid version, where different κ -values are used in
187 specified radius ranges.

188 **2.1.2 ν_{const} -init and ν_{draw} -init**

189 The accumulated PDF $F(m)$ is given by $\int_0^m \tilde{f}_m(m') dm'$ with the normalised PDF $\tilde{f}_m = f_m/\lambda_0$.
 190 First, the size N_{SIP} of the SIP ensemble that should approximate the initial DSD is specified. For
 191 each SIP, its mass μ_i is reasonably picked by

$$192 \quad \mu_i = F^{-1}(\text{rand()}),$$

193 where $\text{rand}()$ generates uniformly distributed random numbers $\in [0, 1]$. In case of the ν_{const} -init,
 194 the weighting factors of all SIPs are equally $\nu_i = \nu_{const} = \mathcal{N}/N_{SIP}$. This init method reproduces
 195 SIP ensembles similar to the ones in Shima et al. (2009) or Hoffmann et al. (2015). As a variety of
 196 the ν_{const} -init method, the weighting factors ν_i in the ν_{draw} -init method are simply perturbed by
 197 $\nu_i = 2\text{rand}() \nu_{const}$.

198 For the case of an exponential distribution, the following holds for the SIPs $i = 1, N_{SIP}$:

$$199 \quad \mu_i = -\bar{m} \log(\text{rand()}).$$

200 In the literature, this approach is known as inverse transform sampling. A proof of correctness can
 201 be found in classical textbooks, e.g. Devroye (1986, their section II.2).

202 **2.1.3 ν_{random} -init**

203 The third approach allows specifying the spectrum of weighting factors that should be covered by
 204 the SIP ensemble. Similar to the ν_{draw} -init method, the weighting factors are randomly determined.
 205 Whereas the latter method produced a SIP ensemble with weighting factors uniformly distributed
 206 in ν , the ν_{random} -init produces weighting factors uniformly distributed in $\log(\nu)$ and covering the
 207 range $[\mathcal{N} 10^{\alpha_{low}}, \mathcal{N} 10^{\alpha_{high}}]$. The eventual number of SIPs depends most sensitively on the param-
 208 eter α_{high} , which controls how big the portion of a single SIP can be.

209 SIPs with weighting factors $\nu_i = \mathcal{N} 10^{(\alpha_{low} + (\alpha_{high} - \alpha_{low}) \cdot \text{rand}())}$ are created, until $\sum_{j=1}^{N_{SIP}} \nu_j$ ex-
 210 ceeds \mathcal{N} . The weighting factor of the last SIP is corrected such that $\sum_{j=1}^{N_{SIP}} \nu_j = \mathcal{N}$ holds. Now the
 211 mass μ_i of each SIP is determined by the following technique: The first SIP represents the smallest
 212 droplets and covers the mass interval $[0, m_1]$, whereas the last SIP represents the largest droplets in
 213 the interval $[m_{N_{SIP}-1}, \infty]$. The SIPs i in between cover the adjacent mass intervals $[m_{i-1}, m_i]$. The
 214 boundaries are implicitly determined by $\int_0^{m_i} f_m(m') dm' \Delta V = \sum_{j=1}^i \nu_j$. The total mass contained
 215 in each SIP is given by $\chi_i = \int_{m_{i-1}}^{m_i} f_m(m') m' dm' \Delta V$ and the single droplet mass by $\mu_i = \chi_i/\nu_i$.

216 For the case of an exponential distribution, the following holds for the interval boundaries and the
 217 SIPs $i = 1, N_{SIP}$:

$$218 \quad m_i = -\bar{m} \log \left(\mathcal{N} - \sum_{j=0}^i \nu_j \right)$$

219 and

$$220 \quad \mu_i = \left(\frac{m_{i-1} - \bar{m}}{\exp(m_{i-1}/\bar{m})} - \frac{m_i - \bar{m}}{\exp(m_i/\bar{m})} \right) \frac{\mathcal{N}}{\nu_i}.$$

221 The above formulas must be carefully implemented such that numerical cancellation errors are kept
 222 tolerable.

223 Experimenting with the SIP-init procedure, several optimisations have been incorporated. First,
 224 the ν -spectrum is split into two intervals $[\mathcal{N} 10^{\alpha_{low}}, \mathcal{N} 10^{\alpha_{med}}]$ and $[\mathcal{N} 10^{\alpha_{med}}, \mathcal{N} 10^{\alpha_{high}}]$. We
 225 alternately pick random values from the two intervals. Without this correction, it happened that
 226 several consecutive SIPs with small weights and hence nearly identical droplet masses are created,
 227 which increases the SIP number without any benefits.

228 Going through the list of SIPs, the droplet masses increase and hence the individual SIPs contain
 229 gradually increasing fractions of the total grid box mass. This can lead to a rather coarse repre-
 230 sentation of the right tail of the DSD. Two options to improve this have been implemented. In the
 231 $\nu_{random,rs}$ -option, the ν_i -values are reduced by some factor, that increases, as $\sum_{j=1}^i \nu_j$ approaches
 232 \mathcal{N} . In the $\nu_{random,lb}$ -option, ν -values are randomly picked up to a certain radius threshold r_{lb} . Above
 233 this threshold, SIPs are created with the singleSIP-method used on a linear bin.

234 2.1.4 Comparison

235 Figure 1 shows the weighting factors and other properties of the initial SIP ensemble, which may
 236 affect the performance of the algorithms. Each column shows one class of initialisation techniques.
 237 For a certain realisation, the first row shows the weighting factors ν_i of all SIPs as a function of their
 238 represented droplet radius r_i . Each dot shows the (ν_i, r_i) -pair of one SIP. For the singleSIP-init, the
 239 dots are uniformly distributed along the horizontal axis, as one SIP is created from each bin (with
 240 exponentially increasing bin sizes). The according ν -values relate directly to the prescribed DSD.
 241 The higher $f_m \Delta m$, the more droplets are represented in a SIP. No SIPs smaller than $r_{critmin} =$
 242 $0.6 \mu\text{m}$ are initialised and the ν -values range over nine orders of magnitude consistent with $\eta =$
 243 10^{-9} . The MultiSIP-init introduces an upper bound of $\nu_{critmax} = 2 \cdot 10^6$ for ν . This threshold is
 244 effective over a certain radius range where the SIPs have lower ν -values compared to the singleSIP-
 245 init and are also more densely distributed along the horizontal axis. For the ν_{const} -init, all SIPs use
 246 $\nu = \nu_{const}$, whereas for the ν_{draw} -init the ν -values scatter around this value. For ν_{const} and ν_{draw} ,
 247 the ν -values are chosen independently of the given DSD contrary to the latter techniques. However,
 248 for both techniques, the density of the dots along the r -axis is correlated to $f_m \Delta m$.

249 The ν_{random} -init technique randomly picks ν -values which are distributed over a larger range
 250 compared to the ν_{draw} -init. In fact, they are uniformly distributed in $\log(\nu)$. The range of possi-
 251 ble ν -values can be adjusted and is chosen similar to the singleSIP/multiSIP by setting $\alpha_{high} =$
 252 $-2, \alpha_{med} = -3$ and $\alpha_{low} = -7$. One possible advantage compared to the singleSIP-approach could
 253 be that the occurrence of certain ν -values is not limited to a certain radius range. In the singleSIP-

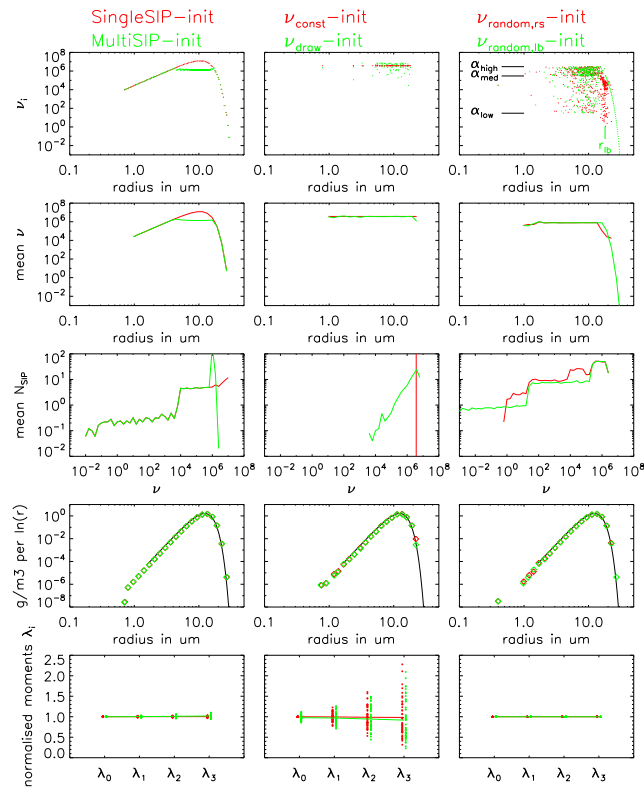

Figure 1. Characteristics of the various SIP initialisation methods (as given on top of each panel): Weighting factors $\nu_i(r_i)$ of an initial SIP ensemble, the mean weighting factors $\bar{\nu}(r)$, the occurrence frequency of the ν_i -values and the resulting mass density distributions $g_{\ln r}$ are displayed (Row 1 to 4). Row 1 displays data of a single realisation, whereas rows 2 to 4 show averages over 50 SIP ensembles. The bottom row shows the moments $\lambda_0, \lambda_1, \lambda_2$ and λ_3 normalised by the respective analytical value. Every symbol depicts the value of a single realisation. The nearly horizontal line connects the mean values over all realisations. In the displayed examples, $\kappa = 20$ in the singleSIP-init, $\kappa = 20, \nu_{critmax} \approx 2 \cdot 10^6$ in the multiSIP-init, $N_{SIP} = 80$ in the ν_{const}, ν_{draw} -init and $(\alpha_{high}, \alpha_{med}, \alpha_{low}) = (10^{-2}, 10^{-3}, 10^{-7})$ in the ν_{random} -inits (see black bars in top right panel). The vertical bar depicts the threshold radius r_{ib} .

254 init, the smallest ν -values occur only at the left and right tail of the DSD, whereas in the ν_{random} -
255 approach the smallest ν -values (down to $\mathcal{N} 10^{\alpha_{low}}$) can appear over the whole radius range. The
256 horizontal bars in the plot indicate the values of α_{low} , α_{med} and α_{high} and the vertical bar the
257 threshold radius r_{lb} .

258 The second row shows average ν -value of all SIPs in a certain size bin. All init techniques are
259 probabilistic and the average is taken over 50 independent realisations of SIP ensembles. Not sur-
260 prisingly, the average ν of the ν_{draw} -method is identical to ν_{const} . Moreover, also for the ν_{random} -
261 init the average ν -value is constant over a large radius range. Only in the right tail, the ν -values drop
262 as intended. The third row shows the occurrence frequency of weighting factors.

263 To display DSDs represented by a SIP ensemble, a SIP ensemble must be converted back into
264 a bin representation. For this, we establish a grid with resolution $\kappa_{plot} = 4$, count each SIP in its
265 respective bin, i.e. SIP i with $m_{bb,l} < \mu_i \leq m_{bb,l+1}$ contributes to bin l via $M_{bin,l} = M_{bin,l} + \mu_i \times \nu_i$
266 and $n_{bin,l} = n_{bin,l} + \nu_i$. We note that all displayed DSDs in this study will use $\kappa = 4$, irrespective of
267 the κ -value chosen in the initialisation. The fourth row shows such DSDs, again as an average over
268 50 SIP ensemble realisations. We find that any init technique is, in general, successful in producing
269 a meaningful SIP ensemble as the "back"-translated DSD matches the originally prescribed DSD
270 (black). Hence, the moments $\lambda_{k,SIP}$ match the analytical values $\lambda_{k,anal}$ for $0 \leq k \leq 3$, as shown in
271 the fifth row. Nevertheless for the ν_{const} - and ν_{draw} -init, the spread between individual realisations
272 can be large and they deviate substantially from the analytical reference. The singleSIP/multiSIP and
273 ν_{random} , on the other hand, guarantee that each individual realisation is close to the reference.

274 2.2 Description of Hypothetical algorithm

275 First, we present a hypothetical algorithm for the treatment of collection/aggregation in an LCM,
276 which would probably yield excellent results. However is prohibitively expensive in terms of com-
277 puting power and memory, as N_{SIP} increases drastically over time until the state is reached where
278 each SIP represents exactly one real droplet. Nevertheless, the presentation of this algorithm is useful
279 for introducing several concepts which will partly occur in the subsequently described "real-world"
280 algorithms.

281 Whereas condensation/deposition and sedimentation may be computed using interpolated quanti-
282 ties which implicitly assumes that all droplets of a SIPs are located at the same point, the numerical
283 treatment of collection usually assumes that the droplets of a SIP are spatially uniformly distributed,
284 i.e. well-mixed within the grid box. An approach, where the vertical SIP position is retained in the
285 collection algorithm and larger droplets overtaking smaller droplets is explicitly modelled, is de-
286 scribed in Sölch and Kärcher (2010), is not treated here.

287 Following Gillespie (1972) and Shima et al. (2009), the probability P_{ij} that one droplet with mass
288 m_i collides with one droplet with mass m_j inside a small volume δV within a short time interval δt

289 is given by:

$$290 \quad P_{ij} = K_{ij} \delta t \delta V^{-1}, \quad (9)$$

291 where $K_{ij} = K(m_i, m_j)$.

292 For SIPs i and j containing ν_i and ν_j real droplets in a grid box with volume ΔV , on average
 293 $\nu_{coll} = P_{ij} \nu_i \nu_j$ collections between droplets from SIP i and SIP j occur. The average rate of such
 294 $i - j$ -collections ($i \neq j$) to occur is:

$$295 \quad \frac{\partial \nu_{coll}(i, j)}{\partial t} = \nu_i K_{ij} \nu_j \Delta V^{-1} =: \nu_i o_{ij} =: O_{ij}. \quad (10)$$

296 So-called self-collections, collisions of the droplets belonging to the same SIP ($i = j$), are described
 297 by:

$$298 \quad \frac{\partial \nu_{coll}(i, i)}{\partial t} = 2 \cdot \left(\frac{\nu_i}{2} K_{ii} \frac{\nu_i}{2} \Delta V^{-1} \right) = \frac{1}{2} \nu_i K_{ii} \nu_i \Delta V^{-1} =: \nu_i o_{ii} =: O_{ii}, \quad (11)$$

299 assuming that the SIP is split into two portions, each containing one half of the droplets of the original
 300 SIP. The factor of 2 originates from the collections of each half, which have to be added to gain the
 301 total number of self-collections for SIP i . Accordingly, the diagonal elements of the matrices o_{ij} and
 302 O_{ij} differ from the off-diagonal elements by an additional factor of 0.5. In terms of concentrations
 303 (represented by SIPs in a grid box with volume ΔV), we can write

$$304 \quad \frac{\partial n_{coll}(i, j)}{\partial t} = K_{ij} n_i n_j \quad (12)$$

305 for collections between different SIPs and

$$306 \quad \frac{\partial n_{coll}(i, i)}{\partial t} = \frac{1}{2} K_{ii} n_i^2 \quad (13)$$

307 for self-collections.

308 In the hypothetical algorithm, the weighting factor of SIP i is reduced due to collections with all
 309 other SIPs and self-collections and reads as

$$310 \quad \frac{\partial \nu_i}{\partial t} = - \sum_{j=1}^{N_{SIP}} \frac{\partial \nu_{coll}(i, j)}{\partial t} = - \sum_{j=1}^{N_{SIP}} O_{ij}. \quad (14)$$

311 The droplet mass μ_i in SIP i is unchanged.

312 For each $i - j$ -combination, a new SIP k is generated:

$$313 \quad \frac{\partial \nu_k}{\partial t} = O_{ij} \quad \text{and} \quad \mu_k = \mu_i + \mu_j \quad (15)$$

314 To avoid double counting only combinations with $i \geq j$ are considered.

315 The rate equations for the weighting factors can be numerically solved by a simple Euler forward
 316 step: The weighting factor of existing SIPs is reduced by

$$317 \quad \nu_i^\Delta := \left(\sum_{j=1}^{N_{SIP}} O_{ij} \right) \Delta t \quad (16)$$

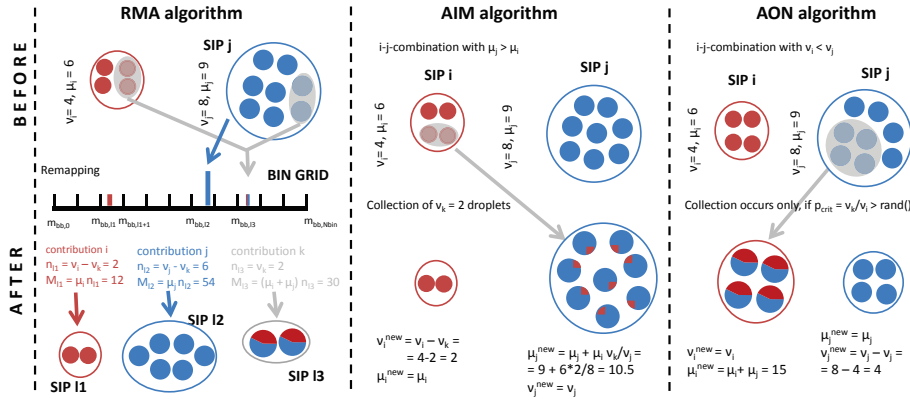

Figure 2. Treatment of a collection between two SIPs in the Remapping Algorithm (RMA), Average Impact Algorithm (AIM) and All-Or-Nothing Algorithm (AON).

318 leading to

$$319 \quad \nu_i^* = \nu_i - \nu_i^\Delta, \quad (17)$$

320 or, equivalently,

$$321 \quad \nu_i^* = \nu_i \left(1 - \Delta t \sum_{j=1}^{N_{SIP}} o_{ij} \right). \quad (18)$$

322 For new SIPs k we have

$$323 \quad \nu_k = 0 + O_{ij} \cdot \Delta t. \quad (19)$$

324 Per construction the algorithm is mass-conserving subject to rounding errors.

325 In each time step, $N_{SIP,add} = N_{SIP} (N_{SIP} - 1) / 2$ new SIPs are produced and the new number
 326 of SIPs is $N_{SIP}^* = N_{SIP} + N_{SIP,add}$. After nt time steps, the number of SIPs would be of order
 327 $(N_{SIP,0})^{nt}$ which is not feasible.

328 In the following subsections, algorithms are presented that include various approaches to keep the
 329 number of SIPs in an acceptable range.

330 In the following the various algorithms are described and pseudo-code of the implementations
 331 is given. For the sake of readability, the pseudo-code examples show easy-to-understand imple-
 332 mentations. The actual codes of the algorithms are, however, optimised in terms of computational
 333 efficiency.

334 2.3 Description of the Remapping (RMA) algorithm

Algorithm 1 Pseudo-code of the Remapping algorithm

```

1: INIT BLOCK
2: Given: Ensemble of SIPs; Specify:  $\kappa, \eta, \Delta t$ 
3: for  $l = 1$  to  $l_{max}$  do {Create temporary bin}
4:      $m_{bin,l} = m_{bin,low} 10^{l/\kappa}$ 
5: end for
6: TIME ITERATION
7: while  $t < T_{sim}$  do
8:     LOSS BLOCK {Compute reduced bin contribution of existing SIPs}
9:     for  $i = 1$  to  $N_{SIP}$  do
10:        Calculate  $\nu_i^*$  according to Eq. 18
11:        Select bin  $l$  with  $m_{bb,l} < \mu_i \leq m_{bb,l+1}$ 
12:         $n_{bin,l} = n_{bin,l} + \nu_i^*$ 
13:         $M_{bin,l} = M_{bin,l} + \nu_i^* \cdot \mu_i$ 
14:    end for
15:    GAIN BLOCK {Compute bin contribution of coalescing droplets}
16:    for all  $i < j \leq N_{SIP}$  do
17:         $k++$ 
18:        Compute  $\nu_k$  according to Eq. 19
19:         $\mu_k = \mu_i + \mu_j$ 
20:        Select bin  $l$  with  $m_{bb,l} < \mu_k \leq m_{bb,l+1}$ 
21:         $n_{bin,l} = n_{bin,l} + \nu_k$ 
22:         $M_{bin,l} = M_{bin,l} + \nu_k \cdot \mu_k$ 
23:    end for
24:    CREATE BLOCK {Replace SIPs}
25:    Delete all SIPs
26:    for all  $l$  with  $M_{bin,l} > M_{critmin} = \eta \lambda_1$  do {use  $M_{critmin}$  as a weak threshold value}
27:         $i++$ 
28:        Generate SIP  $i$  with  $\nu_i^{new} = n_{bin,l}$  and  $\mu_i = M_{bin,l} / \nu_{bin,l}$ 
29:    end for
30:     $N_{SIP} = ii$ 
31:     $t = t + \Delta t$ 
32: end while
33: EXTENSIONS
34: Self-collections for a kernel with  $K(m, m) \neq 0$  can be easily incorporating in the algorithm by changing
    the condition in line 16 to  $i \leq j \leq N_{SIP}$ .

```

335 First, the remapping algorithm is described as its concept follows closely the hypothetical algo-
 336 rithm introduced in the latter section. The RMA algorithm is based on ideas of Andrejczuk et al.
 337 (2010). We call their approach ‘remapping algorithm’ as N_{SIP} is kept reasonably low by switch-
 338 ing between a SIP representation and a bin representation in every time step. A temporary bin grid
 339 with a pre-defined κ is established which stores the total number $n_{bin,*}$ and total mass $M_{bin,*}$ of all
 340 contributions belonging to a specific bin. The bin boundaries are given by $m_{bb,*}$.

341 Instead of creating a new SIP k (with number ν_k obtained by Eq. 15 and mass $\mu_k = \mu_i + \mu_j$)
 342 from each $i - j$ -combination, the according contribution is stored on a temporary bin grid. More
 343 explicitly, this means that the droplet number $n_{bin,l}$ of bin l with $m_{bb,l} < \mu_k \leq m_{bb,l+1}$ is increased
 344 by ν_k . Similarly, the total mass $M_{bin,l}$ of that bin is increased by $\mu_k \nu_k$. Similarly, the reduced
 345 contributions ν_i^* from the existing SIPs with droplet mass μ_i are added to their respective bins.

346 Figure 2 illustrates how a collection process between two SIPs is treated in RMA. In this example,
 347 $\nu_k = 2$ droplets are produced by collection which have a droplet mass of $\mu_k = \mu_i + \mu_j = 15$. Instead
 348 of creating a new SIP k (as in the hypothetical algorithm), the contribution k is recorded in the bin
 349 grid. The droplet number n in bin $l3$ is increased by $\nu_k = 2$ and the according total mass M_{l3} by
 350 $\nu_k \mu_k = 30$. The remaining contribution of SIP i falls into bin $l1$ and n_{l1} and M_{l1} are increased by
 351 $\nu_i^* = \nu_i - \nu_k = 2$ and $\mu_i \nu_i^* = 12$, respectively. The operation for SIP j is analogous.

352 At the end of each time step after treating all possible $i - j$ -combinations, a SIP ensemble is
 353 created from the bin data with $\nu_i = n_{bin,l}$ and $\mu_i = M_{bin,l}/n_{bin,l}$.

354 Optionally, a lower threshold $\nu_{min,RMA}$ can be introduced, such that SIP i is created only if
 355 $n_{bin,l} > \nu_{min,RMA}$ holds. However, this may destroy the property of mass conservation which can
 356 be remedied by the following.

357 We pick up the concept of a weak threshold introduced earlier and adjust it such that on av-
 358 erage the total mass is conserved (instead of total number as before). We introduce the thresh-
 359 old $M_{critmin} = \eta \lambda_1$. E.g. η is set to 10^{-10} , which implies that each SIP contains at least 10^{-10}
 360 of the total mass in a grid box. If $M_{bin,l} > M_{critmin}$, a SIP is created representing $\nu_i = n_{bin,l}$
 361 drops with single mass $\mu_i = M_{bin,l}/n_{bin,l}$. If $M_{bin,l} < M_{critmin}$, a SIP is created with probability
 362 $p_{create} = M_{bin,l}/M_{critmin}$. In this case the SIP represents $\nu_i = M_{critmin}/\mu_i$ droplets with single
 363 mass $\mu_i = M_{bin,l}/n_{bin,l}$. Pseudo-code of the algorithm is given in algorithm 1.

364 Time steps typically used in previous collection/aggregation tests are around $\Delta t = 0.1$ to 10 s
 365 depending inter alia on the used kernel. From Eq. 18 follows that the time step in RMA must satisfy

$$366 \quad \Delta t < \sum_{j=1}^{N_{SIP}} o_{ij}. \quad (20)$$

367 Otherwise, negative ν -values can occur which would inevitably lead to a crash of the simulation. In
 368 mature clouds, the Long and Hall kernel attain large values which required tiny time steps of 10^{-4} s
 369 and smaller in the first test simulations. To be of any practical relevance, RMA had to be modified
 370 in order to be able to run simulations with suitable time steps.

371 Hence, several extensions to RMA allowing larger time steps are discussed in the following.

372 1. *Default version:* Use the algorithm as outlined in Algorithm 1 (i.e. do not change anything).
373 Negative ν_i^* -values obtained by Eq. 17 are acceptable, as long as $n_{bin,l}$, from which the SIPs
374 are created at the end of the time iteration, is non-negative for all l . This means that an existing
375 SIP i (which falls into bin l) can lose more droplets (ν_i^Δ) than it actually possesses (ν_i) as long
376 as the gain in bin l (from all suitable SIP combinations) compensates this deficit. We will later
377 see that this approach works well for the Golovin kernel, however fails for the Long and Hall
378 kernel.

379 2. *Clipping:* Simply ignore bins with negative $n_{bin,l}$ and do not create SIPs from those bins.
380 This approach destroys the property of mass conservation and is not pursued here.

381 3. *Adaptive time stepping:* Instead of reducing the general time step, only the treatment of SIPs
382 with $\nu_i^* < 0$ is sub-cycled. For each such SIP i , Eq. 17 is iterated $\tilde{\eta}_i$ times with time step
383 $\Delta t_{SIP} = \Delta t / \tilde{\eta}_i$. Note that even though the computation of Eq. 17 and O_{ij} involves the ν -
384 evaluation of all SIPs, only ν_i is updated in the subcycling steps and not the whole system of
385 fully coupled equations is solved for a smaller time step. For sufficiently large $\tilde{\eta}_i$, $\nu_{i,subcycl}^*$ is
386 positive, as $\nu_{i,subcycl}^\Delta < \nu_i$ as desired. Basically, we now assume that all collections involving
387 SIP i are equally reduced by a factor of $\eta_i = \nu_{i,subcycl}^\Delta / \nu_i^\Delta$ compared to the default time step.
388 In the GAIN block of the algorithm (as termed in Alg. 1), all computations use the default
389 time step and no sub-cycling is applied. To be consistent with the reduction in the LOSS
390 block, Eq. 19 is replaced by $\nu_k = \eta_i O_{ij} \Delta t$.

391 4. *Reduction limiter* The effect of an adaptively reduced time step can be reached with simpler
392 and cheaper means. We introduce a threshold parameter $0 < \tilde{\gamma} < 1.0$ similar to the approach in
393 Andrejczuk et al. (2012). Again, we focus on SIPs with $\nu_i^* < 0$ and simply set the new weight
394 of SIP i to $\nu_{i,RedLim}^* = \tilde{\gamma} \nu_i$. As above, all contributions involving SIP i have to be re-scaled,
395 now with $\gamma_i = (\nu_i - \nu_{i,RedLim}^*) / \nu_i^\Delta$.

396 5. *Update on the fly* Another option to eliminate negative ν_i -values is to do an "update on the
397 fly". In this case, the algorithm is not separated in a LOSS and GAIN block. Instead, the $i - j$ -
398 combinations are processed one after another. After each collection process, as exemplified
399 in Fig. 2, the weighting factors ν_i and ν_j of the two involved SIPs are reduced by ν_k , i.e. the
400 number of droplets that were collected. Subsequent evaluations of Eq. 19 then use updated ν -
401 values. Compared to the default version, it now matters in which order the $i - j$ -combinations
402 are processed, e.g. if you deal first with combinations of the smallest SIPs or of the largest
403 SIPs.

404 2.4 Description of Average Impact (AIM) algorithm

Algorithm 2 Pseudo-code of the average impact algorithm

```

1: INIT BLOCK + SIP SORTING
2: Given: Ensemble of SIPs; Specify:  $\Delta t$ 
3: TIME ITERATION
4: while  $t < T_{\text{sim}}$  do
5:     {Sort SIPs by droplet mass}
6:     Apply (adaptive) sorting algorithm, such that  $\mu_j \geq \mu_i$  for  $j > i$ 
7:     {Compute total mass  $\chi_i$  of each SIP}
8:      $\chi_i = \nu_i \mu_i$ 
9:     for  $i = 1$  to  $N_{\text{SIP}}$  do
10:        {Compute reduction of weighting factor due to number loss to all larger SIPs}
11:         $\nu_i^{\text{new}} = \nu_i \left(1 - \Delta t \sum_{j=i+1}^{N_{\text{SIP}}} o_{ij}\right)$ 
12:        {Compute mass transfer; mass gain from all smaller SIPs and mass loss to all larger SIPs}
13:         $\chi_i^{\text{new}} = \chi_i - \chi_i \Delta t \sum_{j=i+1}^{N_{\text{SIP}}} o_{ij} + \sum_{j=1}^{i-1} \chi_j o_{ij} \Delta t$ 
14:    end for
15:     $\nu_i = \nu_i^{\text{new}}$ 
16:     $\mu_i = \chi_i^{\text{new}} / \nu_i^{\text{new}}$ 
17:     $t = t + \Delta t$ 
18: end while
19: EXTENSIONS
20: {Self-collections for a kernel with  $K_{ii} \neq 0$  can be incorporated simply by adding the term  $-0.5 \Delta t o_{ii}$ 
    inside the bracket on the r.h.s. of line 11 (see also Eq. (23) in the text)}
    
```

405 The average impact algorithm by Riechelmann et al. (2012) and further developed in Maronga et al.
 406 (2015) predicts the temporal change of the weighting factor, ν_i , and the total mass of all droplets
 407 represented by each SIP, $\chi_i = \nu_i \mu_i$. In this algorithm, two fundamental interactions of droplets are
 408 considered (see also Fig. 7 in Maronga et al., 2015). First, the coalescence of two SIPs of different
 409 size. It is assumed that the larger SIP collects a certain amount of the droplets represented by the
 410 smaller SIP, which is then equally distributed among the droplets of the larger SIP. As a consequence,
 411 the total mass and the weighting factor of the smaller SIP decrease, while the total mass of the larger
 412 SIP increases accordingly. Fig. 2 illustrates how a collection between two SIPs is treated. SIP j is
 413 assumed to represent larger droplets than SIP i , i.e. $\mu_j > \mu_i$. As in the RMA example before, we
 414 say that $\nu_k = 2$ droplets are collected. Then SIP i loses two droplets to SIP j , i.e. ν_i is reduced by 2
 415 and a mass of $\mu_i \nu_k$ is transferred to SIP j where it is distributed among the existing $\nu_j = 8$ droplets.
 416 Unlike to RMA, where droplets with mass $\mu_j + \mu_i = 15$ are produced, AIM predicts a droplet mass
 417 of $\mu_j + \mu_i \nu_k / \nu_i = 10.5$ in SIP j . Usually, $\nu_k / \nu_i \ll 1$ and hence the name "average impact" for this
 418 algorithm.

Figure 3. top: (r_i, ν_i) -evolution of selected SIPs. The black line shows the initial distribution. Each coloured line connects the data points that depict the (r_i, ν_i) -pair of an individual SIP every 200s.
 bottom: Ratios $r_i(t = 3600\text{s})/r_i(t = 0\text{s})$ (red curve) and $\nu_i(t = 0\text{s})/\nu_i(t = 3600\text{s})$ (black curve) for all SIPs as a function their initial radius $r_i(t = 0\text{s})$.
 An example simulation with Long kernel, singleSIP-init, $\Delta t = 10\text{s}$, $\kappa = 40$ and $N_{SIP} = 197$ is displayed.

419 Moreover, same-size collisions are considered in each SIP. This decreases the weighting factor of
 420 each SIP but not its total mass. Accordingly, the radius of the SIP increases.

421 Both processes are represented in the following two equations which are solved for all colliding
 422 SIPs (assuming that $\mu_0 \leq \mu_1 \leq \dots \leq \mu_{N_{SIP}}$):

$$423 \quad \frac{d\nu_i}{dt} = -K_{ii} \frac{1}{2} \frac{\nu_i \nu_i}{\Delta V} - \sum_{j=i+1}^{N_{SIP}} K_{ij} \nu_i \nu_j \Delta V^{-1} \quad (21)$$

424 and

$$425 \quad \frac{d\chi_i}{dt} = \sum_{j=1}^{i-1} \mu_j K_{ij} \nu_i \nu_j \Delta V^{-1} - \mu_i \sum_{j=i+1}^{N_{SIP}} K_{ij} \nu_i \nu_j \Delta V^{-1}. \quad (22)$$

426 The first term on the right-hand-side of Eq. 21 describes the decrease of ν due to same-size col-
 427 lections, the second term the decrease of ν due to collection by larger SIPs. The first term on the
 428 right-hand-side of Eq. 22 describes the gain in total mass due to collections with smaller SIPs, while
 429 the second term describes the loss of total mass due to collection by larger SIPs.

430 Using a Euler forward method for time integration the above equations read as:

$$431 \quad \nu_i^{new} = \nu_i \left(1 - \sum_{j=i+1}^{N_{SIP}} o_{ij} \Delta t - 0.5 o_{ii} \Delta t \right) \quad (23)$$

432 and

$$433 \quad \chi_i^{new} = \chi_i \left(1 - \sum_{j=i+1}^{N_{SIP}} o_{ij} \Delta t \right) + \sum_{j=1}^{i-1} \chi_j o_{ij} \Delta t. \quad (24)$$

434 Finally, the mass μ_i of each SIP is updated: $\mu_i^{new} = \chi_i^{new} / \nu_i^{new}$.

435 Figure 2 illustrates how the AIM algorithm works for an example simulation with the Long kernel
 436 and singleSIP-init. The top panel shows the (r_i, ν_i) -evolution of selected SIPs. The black line shows
 437 the initial distribution. Each coloured line connects the data points that depict the (r_i, ν_i) -pair of an
 438 individual SIP every 200s. Clearly, ν_i of any SIP decreases over time, however the decrease is much
 439 smaller for the largest SIPs and becomes zero for the largest SIP. The majority of SIPs starting from
 440 the smallest radii show an opposite behaviour as their evolution is dominated by a strong ν_i -decrease
 441 at nearly constant r_i . In contrast, the evolution of the two largest SIPs is dominated by a strong r_i -
 442 increase for constant ν_i . The SIPs next to the largest SIPs undergo a transition; in the beginning, they
 443 primarily grow in size, towards the end the decrease of ν_i is dominant. The bottom panel shows the
 444 ratios $r_i(t = 3600\text{s}) / r_i(t = 0\text{s})$ (red curve) and $\nu_i(t = 0\text{s}) / \nu_i(t = 3600\text{s})$ (black curve) for all SIPs
 445 of the simulation. Both ratios are smooth functions of the initial r_i which is plotted on the x -axis.

446 By construction, the number of SIPs remains constant over the course of a simulation. Hence, the
 447 number of SIPs per radius or mass interval decreases, when the DSD broadens over time. In our
 448 example, the SIP resolution becomes coarser, particularly in the large droplet tail.

449 Negative values of ν_i^{new} and χ_i^{new} may occur. However, this case never occurred in our manifold
 450 tests of the algorithm. The behaviour appears more benign than in RMA. Moreover, we found that
 451 the algorithm preserved the initial size-sortedness of the SIP ensemble. However, for an arbitrary
 452 kernel function and initial SIP ensemble, this is not guaranteed and we recommend to use adaptive
 453 sorting algorithms that benefit from partially pre-sorted data sets (Estivill-Castro and Wood, 1992).
 454 Adaptive sorting is also advantageous, when AIM is employed in real world applications, where
 455 sedimentation, advection and condensation changes the SIP ensemble in each individual grid box.

456 2.5 Description of the All-Or-Nothing (AON) algorithm

457 The All-Or-Nothing (AON) algorithm is based on the ideas of Sölch and Kärcher (2010) and
 458 Shima et al. (2009). Fig. 2 illustrates how a collection between two SIPs is treated. SIP i is assumed
 459 to represent fewer droplets than SIP j , i.e. $\nu_i < \nu_j$. Each real droplet in SIP i collects one real droplet
 460 from SIP j . Hence, SIP i contains $\nu_i = 4$ droplets, now with mass $\mu_i + \mu_j = 15$. SIP j now contains
 461 $\nu_j - \nu_i = 8 - 4 = 4$ droplets with mass $\mu_j = 9$. Following Eq. 19, only $\nu_k = 2$ pairs of droplets would,
 462 however, merge in reality. The idea behind this probabilistic AON algorithm is that such a collection
 463 event is realised only under certain circumstances in the model, namely such that the expectation
 464 values of collection events in the model and in the real world are the same. This is achieved if a
 465 collection event occurs with probability $p_{crit} = \nu_k / \nu_i$ in the model. Then, the average number of

Figure 4. As in Fig. 3, for the AON algorithm.

466 collections in the model,

$$467 \quad \bar{\nu}_k = p_{crit} \nu_i = (\nu_k / \nu_i) \nu_i,$$

468 is equal to ν_k as in the real world. A collection event between two SIPs occurs, if $p_{crit} > \text{rand}()$. The
 469 function $\text{rand}()$ provides uniformly distributed random numbers $\in [0, 1]$.

470 Noticeably, no operation on the SIPs is performed if $p_{crit} < \text{rand}()$.

471 The treatment of the special case $\nu_k / \nu_i > 1$ needs some clarification. This case is regularly en-
 472 countered when the singleSIP-init is used, where SIPs with large droplets and small ν_i collect small
 473 droplets from a SIP with large ν_j . The large difference in droplet masses μ lead to large kernel
 474 values and high ν_k with $\nu_i < \nu_k < \nu_j$. By the way, the case of ν_k being even larger than ν_j is not
 475 considered, as it occurs only with unrealistically large time steps. If $p_{crit} > 1$, we allow multiple
 476 collections, as each droplet in SIP i is allowed to collect more than one droplet from SIP j . In total,
 477 SIP i collects ν_k droplets from SIP j and distributes them on ν_i droplets. A total mass of $\nu_k \mu_j$ is
 478 transferred from SIP j to SIP i and the droplet mass in SIPs i becomes $\mu_i^{new} = (\nu_i \mu_i + \nu_k \mu_j) / \nu_i$.
 479 The number of droplets in SIP j is reduced by ν_k and $\nu_j^{new} = \nu_j - \nu_k$. Sticking to the example in
 480 Fig. 2 and assuming $\nu_k = 5$, each of the $\nu_i = 4$ droplets would collect $\nu_k / \nu_i = 1.25$ droplets. The
 481 properties of SIP i and SIP j are then: $\nu_i = 4$, $\mu_i = 17.25$, $\nu_j = 3$ and $\mu_j = 9$.

482 Another special case appears if both SIPs have the same weighting factor which regularly occurs
 483 when the ν_{const} -init is used. After a collection event, SIP j would carry $\nu_j - \nu_i = 0$ droplets, whereas
 484 SIP i would still represent ν_i droplets. In this case, half of the droplets from SIP i are moved to
 485 SIP j and both SIPs carry $\nu_j^{new} = \nu_i^{new} = 0.5 \nu_i$ droplets with mass $\mu_i + \mu_j$. Without this correction,

486 zero- ν SIPs would accumulate over time and reduce the effective number of SIPs causing a poorer
487 sampling. Instead of this equal splitting, one can also assign unequal shares $\xi \nu_i$ and $(1 - \xi) \nu_i$ to the
488 two SIPs (with ξ being some random number).

489 Moreover, self-collections can be considered for kernels with $K_{ii} > 0$. If $2 p_{crit} > \text{rand}()$, self-
490 collections occur between the droplets in a SIP (note the factor 2 due to symmetry reasons). Then
491 every two droplets within a SIP coalesce, implying $\nu_i = \nu_i/2$ and $\mu_i = 2 \mu_i$.

492 So far, we explained how a single $i - j$ -combination is treated in AON. In every time step, the full
493 algorithm simply checks each $i - j$ -combination for a possible collection event. To avoid double-
494 counting only combinations with $i < j$ and self-collections with $i = j$ are considered. Pseudo-code
495 of the algorithm is given in Algorithm 3. The SIP properties are updated on the fly. If a certain SIP is
496 involved in a collection event in the model and changes its properties, all subsequent combinations
497 with this SIP take into account the updated SIP properties. Similar to the update on the fly version
498 of RMA, results may depend on the order in which the $i - j$ -combinations are processed.

499 For most $i - j$ -combinations, p_{crit} is small and usually only a limited number of collection events
500 occurs in the model and AON may suffer from an insufficient sampling of the droplet space. Ac-
501 tual collections are a rare event in this algorithm. In our standard setup, $< 1\%$ of all possible col-
502 lections occur in the model until rain is initiated by very few lucky SIPs (similar to lucky drops,
503 e.g. Kostinski and Shaw (2005)). Indeed, Shima et al. (2009) reported convergence of AON only
504 for tremendously many SIPs (on the order of 10^5 to 10^6 in a box). We will later see that conver-
505 gence is possible with as few as $O(10^2)$ SIPs, if the SIPs are suitably initialised. Hence, it will
506 be demonstrated that AON is a viable option in 2D/3D cloud simulations, as already implied in
507 Arabas and Shima (2013).

508 As for AIM in Fig. 3, Fig. 4 (top) shows the (r_i, ν_i) -evolution of selected SIPs for AON. The
509 picture looks more chaotic than for AIM, as each individual SIP has its own independent history due
510 to the probabilistic nature of AON. For the initially smallest SIP, only ν_i changes for most of the
511 time, as only collections occur where the partner SIPs have smaller weighting factors ν . Towards
512 the end, the still very small SIP is at least once involved in a collection with a very large SIP that
513 has a larger ν . Hence, r_i of this SIP increases substantially. In contrast to the smallest SIP, other
514 initially small SIPs i with similar properties are never part of a collection with $\nu_i < \nu_j$. Hence, their
515 radii r_i remain small over the total period and ν_i is the only property that changes. The bottom panel
516 summarises the overall changes in ν_i (black) and r_i (red) for all SIPs of the simulation. Unlike to
517 AIM, where only the initially largest SIPs grow, SIPs from both ends of the spectrum grow in AON.
518 Those SIPs have small ν -values in common and in each collection their mass is updated to $m_i + m_j$.
519 The SIPs with initially large ν -values lie in the radius range $[2 \mu\text{m}, 15 \mu\text{m}]$ and keep their initial radii
520 (at least in the singleSIP-init used here). The reductions in ν_i scatter around $\sim 10^3$ for most SIPs and
521 fall off to 1 for the largest SIPs.

522 For the generation of the random numbers, the well-proven (L'Ecuyer and Simard, 2007) Mersenne
 523 Twister algorithm by Matsumoto and Nishimura (1998) is used. AON simulations may be accel-
 524 erated if random numbers are computed once a priori. However, this requires saving millions of
 525 random numbers for every realisation. An AON simulation with 1000 time steps and 200 SIPs im-
 526 plying 200×100 combinations, e.g. processes $2 \cdot 10^7$ random numbers. Using random numbers with
 527 a smaller cycle length deteriorated the simulation results in several tests and is not recommended.

528 The current implementation differs slightly from the version in Shima et al. (2009). Due to an
 529 unfavourable SIP initialisation similar to the ν_{const} -technique, Shima et al. (2009) deal with large
 530 N_{SIP} -values in their simulations, where it becomes prohibitive to evaluate all $N_{SIP}(N_{SIP} - 1)$
 531 SIP-combinations. Hence, they resort to $\lfloor N_{SIP}/2 \rfloor$ randomly picked $i - j$ -combinations, where each
 532 SIP appears exactly in one pair (if N_{SIP} is odd, one SIP is ignored). As only a subset of all possible
 533 combinations are numerically evaluated, the extent of collisions is underestimated. To compensate
 534 for this, the probability p_{crit} is up-scaled with a scaling factor $N_{SIP}(N_{SIP} - 1)/(2 \lfloor N_{SIP}/2 \rfloor)$ to
 535 guarantee an expectation value as desired.

536 Moreover, in Shima's formulation the weighting factors are considered to be integer numbers. In
 537 contrast, we use real numbers ν which can even attain values below 1.0. This has several computa-
 538 tional advantages: 1. better sampling of the DSD, in particular at the tails, 2. simpler AON imple-
 539 mentation with fewer arithmetic and rounding operations, and 3. more flexibility, e.g. SIP splitting
 540 with real-valued ξ in the case of identical weighting factors.

541 Sölch and Kärcher (2010) makes use of the vertical position of the SIPs and explicitly calculates
 542 whether or not a larger droplet overtakes a smaller droplet within a time step. This approach will be
 543 thoroughly analysed in a follow-up study.

544 In RMA and AIM SIPs with negative weights may be generated depending, e.g. on the condition
 545 $\Delta t \sum_{j=1}^{N_{SIP}} o_{ij} > 1$ in RMA. In AON, the latter condition implies that $\sum_{j=1} p_{crit,ij}$ of SIP i is greater
 546 than unity. Hence, this SIP is likely to be involved in several collections (for j with $p_{crit,ij} < 1$) or
 547 is involved in one or several multiple collections (for j with $p_{crit,ij} > 1$).

548 3 Box model results

549 In this section, box model simulations of the three algorithms introduced in the latter section are
 550 presented, starting with the results of the Remapping (RMA) Algorithm, then those of the Average
 551 Impact (AIM) and finally the All-or-Nothing (AON) algorithm. The results of each algorithm are
 552 tested for three different collection kernels (Golovin, Long and Hall). Simulations with the Golovin
 553 kernel are compared against the analytical solution given by Golovin (1963). Consistent with many
 554 previous studies we choose $b = 1.5 \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-1}$.

555 Simulations with the Long and Hall kernel are compared against high-resolution benchmark sim-
 556 ulations obtained by the spectral-bin model approaches of Wang et al. (2007) and Bott (1998). In all

Figure 5. Mass density distributions obtained by the RMA algorithm for the Golovin kernel from $t = 0$ to 60 min every 10 min (from black to cyan). The solid curves show the reference solution, the dotted curves the simulation result of the RMA algorithm. The parameter settings are probabilistic singleSIP-init with weak threshold, $\kappa = 60$, $\eta = 10^{-8}$ and $\Delta t = 1$ s. The following versions of the RMA algorithm are depicted (from left to right): regular version, version with reduction limiter, version with update on the fly (start with combinations of smallest/largest droplets).

557 simulations, collision/coalescence is the only process considered in order to enable a rigorous evalu-
 558 ation of the algorithms. The evaluation is based on the comparison of mass density distributions, and
 559 the temporal development of 0th, 2nd, and 3rd moment of the droplet distributions. The 1st moment
 560 is not shown since the mass is conserved in all algorithms per construction. As default, probabilistic
 561 SIP initialisation methods are used. For each parameter setting, simulations are performed for 50
 562 different realisations.

563 3.1 Performance of Remapping (RMA) Algorithm

564 Figure 5 compares DSDs of the RMA algorithm and the analytical reference solution for the Golovin
 565 kernel. Each panel displays DSDs from $t = 0$ to 60 min every 10 min. The left panel shows an ex-
 566 cellent agreement of RMA with the reference solution and proves at least a correct implementation.
 567 Figure 6 compares the temporal evolution of the moments. Moreover, the first row shows the number
 568 of SIPs used in RMA. Except for the case with a very coarse grid ($\kappa = 5$) with fewer than 40 SIPs
 569 in the end, the RMA results agree perfectly with the reference solution irrespective of the chosen κ
 570 (≥ 10) and minimum weak threshold η ranging from 10^{-5} to 10^{-8} . The number of non-zero bins
 571 increases as the DSD broadens over time. In the last step of the time iteration, SIPs are created from
 572 such bins. Hence, their number increases over time. Using a strict threshold, the total mass is not
 573 conserved (not shown); The larger η is, the more mass is lost. Hence, using a weak threshold or some
 574 other measure (e.g. creation of a residual SIP containing contributions of all neglected bins) to avoid
 575 this is highly recommended.

576 Next, RMA simulations with the Long kernel are discussed. As already mentioned, the default
 577 RMA version would require tiny time steps which would rule out RMA from any practical appli-
 578 cation. Both approaches introduced before, "Update on the fly" and "Reduction Limiter", succeed

Figure 6. SIP number and moments λ_0, λ_2 and λ_3 as a function of time obtained by the RMA algorithm for the Golovin kernel. The black curves show the moments of the reference solution. All other curves depict the RMA results. The default settings are: Probabilistic singleSIP-init with weak threshold and $\Delta t = 1$ s. Left column: regular version with $\kappa = 60, 20, 10, 5$ (brown, blue, green, red) and threshold $\eta = 10^{-5}, 10^{-6}, 10^{-7}, 10^{-8}$ (solid, dashed, dash-dotted, dotted). Middle column: as in left column, but version with reduction limiter. Right column: version with update on the fly, solid/dotted lines: start with combinations of smallest/largest droplets, colours as before.

Figure 7. Mass density distributions obtained by the RMA algorithm for the Long kernel from $t = 0$ to 60 min every 10 min (from black to cyan). The solid curves show the reference solution, the dotted curves the simulation result of the RMA algorithm with Reduction Limiter ($\tilde{\gamma} = 0.1$). The parameter settings are probabilistic singleSIP-init with weak threshold, $\eta = 10^{-8}$, $\Delta t = 0.1$ s and $\kappa = 4$ or 20 (as indicated on top).

579 in eliminating negative ν_i -values and in finishing the simulation within a reasonable time. However,
 580 the results are not as desired. Fig. 7 shows the DSDs for a simulation with Reduction Limiter, weak
 581 threshold $\eta = 10^{-8}$ and parameters $\kappa = 60$, $\Delta t = 0.1$ s and $\tilde{\gamma} = 0.1$. Whereas the algorithm is ca-
 582 pable of realistically reducing the number of the smaller droplets, it fails to predict the formation
 583 of the rain mode and strong oscillations appear in the intermediate radius range $[100 \mu\text{m}, 200 \mu\text{m}]$.
 584 We tested the algorithm with many parameter settings varying all of the aforementioned parameters,
 585 $\Delta t \in [0.1 \text{ s}, 1 \text{ s}]$, $\kappa \in [10, 60]$, $\tilde{\gamma} \in [0, 1]$ and $\eta \in [10^{-10}, 10^{-5}]$. Unfortunately, spurious oscillations
 586 occur in most cases. Integrating over the whole mass spectrum, those oscillations do not average out
 587 and, not surprisingly, the moments do not come close to the reference solution (not shown). Non-
 588 oscillating results are obtained only if an unreasonably low resolution is used and very few bins exist
 589 in the problematic radius range. However, in this case, the large droplet mode does not emerge and
 590 the moments are again far from the reference. Hence, our RMA implementation is not capable of
 591 producing reasonable results for the Long kernel.

592 It is not clear whether the oscillations are inherent to the original RMA algorithm or caused by the
 593 introduction of the reduction limiter. The latter might introduce discontinuities where instabilities
 594 could be triggered. The first option seems more probable, as the Golovin RMA simulations with
 595 Reduction limiter do not show any instability and gives a perfect agreement with the reference (see
 596 column 2 in Figs. 5 and 6). Similarly, Golovin RMA simulations with update on the fly are stable
 597 and close to the reference, however the results depend on the order in which the SIP combinations
 598 are processed (see column 3 (and 4) in Figs. 5 and 6). Again, Long simulations with an update on
 599 the fly version of RMA are unstable (not shown).

600 Andrejczuk et al. (2010) introduced and evaluated the RMA algorithm and applied it in a simula-
 601 tion of boundary layer stratocumulus. Our findings are seemingly in conflict with the conclusions of
 602 their evaluation exercises. What both studies have in common is a similar trend for a κ -variation. In

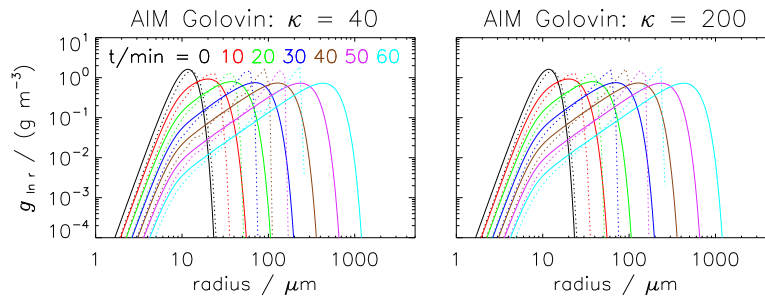

Figure 8. Mass density distributions obtained by the AIM algorithm for the Golovin kernel from $t = 0$ to 60 min every 10 min (from black to cyan). The solid curves show the reference solution, the dotted curves the simulation result of the AIM algorithm (ensemble average over 50 realisations). The parameter settings are: probabilistic singleSIP-init, $\nu_{critmin} = 10^{-9} \max(\nu_i)$, $\Delta t = 1$ s and $\kappa = 40$ (left) or $\kappa = 200$ (right).

603 their Fig. 13, simulations for κ ranging roughly from 4 to 30 are depicted. The simulations with many
604 bins show oscillations, whereas the coarsest simulation has no oscillations, but is clearly far from
605 the real solution (largest droplets around $40 \mu\text{m}$ compared to $500 \mu\text{m}$ in the reference simulation).
606 In their Fig. 14, they presented a detailed sensitivity test only for a $\kappa = 4$ simulation, which down-
607 plays the severity of the oscillation issue. Moreover, their simulations ran up to 2000 s compared to
608 3600 s in this study and many other studies (e.g. Bott, 1998; Wang et al., 2007). Hence, they missed
609 the regime where the effect of the oscillations is strongest. Despite our extensive tests we cannot
610 exclude that in Andrejczuk et al. (2010) an RMA implementation was used where oscillations are
611 less cumbersome; however, the study missed to demonstrate this for a conclusive test case and we
612 come to the conclusion that the evaluation exercises were incomplete and not suited to reveal the
613 deficiencies faced here.

614 RMA simulations with the Hall kernel are similarly corrupted by oscillations and do not produce
615 useful simulations either (not shown).

616 3.2 Performance of Average Impact (AIM) Algorithm

617 Fig. 8 displays DSDs obtained by AIM for the Golovin kernel. Compared to the reference, the
618 droplets pile up at too small radii and the algorithm is not capable of reproducing the continuous
619 shift to larger sizes, even if a fine grid with $\kappa = 200$ (right) instead of $\kappa = 40$ (left) is used. For both
620 κ -values, the increase of the higher moments proceeds at a too low rate (see Fig. 9), whereas the
621 decrease in droplet number matches the analytical evolution. AIM is a very robust algorithm in the
622 sense that the results are fairly insensitive to most numerical parameters as demonstrated for κ and
623 Δt in the left column of Fig. 9. Most simulations converge to—what we call—the best AIM solution,
624 which is, however, not the same as the correct solution. The results deteriorate slightly if the initial

Figure 9. SIP number and moments λ_0, λ_2 and λ_3 as a function of time obtained by the AIM algorithm for the Golovin kernel. The black curves show the moments of the reference solution. All other curves depict the AIM results (average over 50 realisations). The default settings are: Probabilistic singleSIP-init, $\kappa = 40$, $\nu_{critmin} = 10^{-9} \max(\nu_i)$ and $\Delta t = 1$ s. Left column: default simulation (red), larger time step ($\Delta t = 10$ s, blue) and more SIPs ($\kappa = 200$, brown). Right column: ν_{const} -init (red) and ν_{draw} -init (blue) with $N_{SIP} = 160$.

625 SIP ensemble is generated with the ν_{const} -init or ν_{draw} -init instead of with the singleSIP-init (right
 626 column of Fig. 9).

627 The algorithm performs, in general, better for the Long and Hall kernel as is detailed in the follow-
 628 ing. Fig. 10 displays DSDs obtained by AIM for the Long kernel. Generally, the results are in good
 629 agreement with the reference solution, as long as the SIP ensemble is initialised with the singleSIP-
 630 init method (left and middle column). Towards the end of the simulated period (magenta and cyan
 631 lines), the removal of small droplets is a bit underestimated and too many small droplets are present.
 632 For $t = 30$ and 40 min, the large droplet mode is too weak as not enough large droplets have formed.
 633 At that stage, the droplets grow rapidly by collection and the AIM results lag behind. Although the
 634 offset is less than five minutes, it might become crucial in simulations of short-lived clouds. Also

Figure 10. Mass density distributions obtained by the AIM algorithm for the Long kernel from $t = 0$ to 60 min every 10 min (from black to cyan). The solid curves show the reference solution, the dotted curves the simulation result of the AIM algorithm as an average over 50 realisations. The default settings are: Probabilistic singleSIP-init, $\kappa = 40$, $\nu_{critmin} = 10^{-9} \max(\nu_i)$, $\Delta t = 1$ s (column 1); Δt increased to 20 s (column 2); ν_{const} -init technique with $N_{SIP} = 160$ (column 3).

635 the evolution of the moments (see Fig. 11) confirms this, as the onset of the rapid changes at around
 636 $t = 30$ min is only slightly retarded if parameters are suitably chosen. Towards the end, the AIM re-
 637 sults get again very close to the reference solution. The left column of Fig. 11 shows the dependence
 638 on the time step. For time steps $\Delta t \leq 20$ s all results are similar to the best AIM solution which is
 639 close to the reference. Time steps of 50 s and more do not produce good enough results. Moreover,
 640 AIM is fairly insensitive to the choice of κ , $r_{critmin}$ and $\nu_{critmin}$ (see middle column). Simulations
 641 with κ ranging from 10 to 100 yield similar results. Only, for a very coarse resolution ($\kappa = 5$) with
 642 25 SIPs, the decrease in droplet number is too small. Increasing the lower cutoff radius $r_{critmin}$
 643 from $0.6 \mu\text{m}$ to $5 \mu\text{m}$, the $r < 5 \mu\text{m}$ -part of the DSD is represented by a single SIP and N_{SIP} is re-
 644 duced by 60%. The predicted moments are unaffected by this variation. Those small- r_i SIPs are not
 645 relevant for the AIM performance. They simply carry too small fractions of the total grid box mass
 646 to be important. Their status will not change over time as already illustrated in Fig. 3. Similarly, a
 647 variation of $\nu_{critmin}$ or the switch to a strict threshold $\nu_{critmin}$ has no effect.

648 Now we draw the attention to the importance of the SIP-init method. The right panel of Fig. 10
 649 shows the DSDs when the SIPs are initialised with the ν_{const} -init method. The algorithm completely
 650 fails and no droplets larger than $70 \mu\text{m}$ occur after 60 minutes. Consequently, the moments are far off
 651 from the reference solution (solid lines in the right column of Fig. 11). Switching to the ν_{draw} -init
 652 method (dotted lines) or using many more SIPs (up to 1600) improves the results, yet they are still
 653 useless. This clearly demonstrates how crucial the initial characteristics of the SIP ensemble are.
 654 Initialising the SIPs with an appropriate technique like the singleSIP-init, useful results are obtained
 655 with as few as 50 SIPs. Using the ν_{const} -init or ν_{draw} -init, on the other hand, solutions are still
 656 useless, even though the number of SIPs and the computation time are factor 30 and 900 higher.

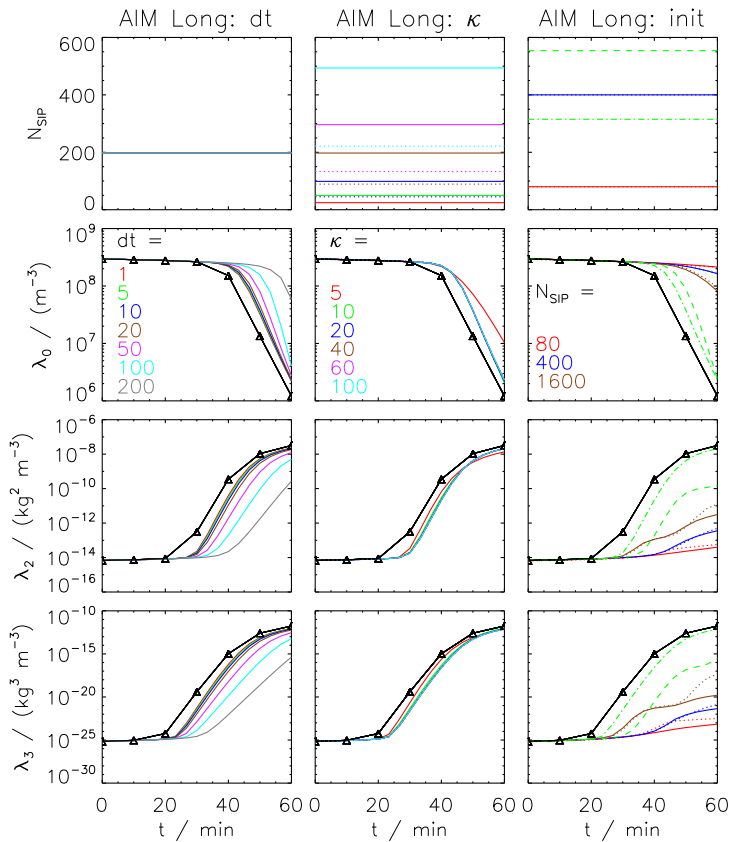

Figure 11. SIP number and moments λ_0 , λ_2 and λ_3 as a function of time obtained by the AIM algorithm for the Long kernel. The black curves show the moments of the reference solution. All other curves depict the AIM results (average over 50 realisations). The left column shows a variation of $\Delta t = 1, 5, 10, 20, 50, 100, 200$ s for $\kappa = 40$. The middle column a variation of $\kappa = 5, 10, 20, 40, 60, 100$ for $\Delta t = 10$ s. Either, the default singleSIP-init (solid) or the singleSIP-init with $r_{critmin} = 5 \mu\text{m}$ (dotted) is used. The right column displays simulations with different initialisation techniques and $\Delta t = 10$ s: the ν_{const} -init (solid) and ν_{draw} -init (dotted) with $N_{SIP} = 1600, 400, 80$ as well as the $\nu_{random,rs}$ -init (dashed) and $\nu_{random,lb}$ -init (dash-dotted) with $(\alpha_{high}, \alpha_{med}, \alpha_{low}) = (10^{-2}, 10^{-3}, 10^{-13})$ and threshold radius $r_{lb} = 16 \mu\text{m}$.

Figure 12. Mass density distributions obtained by the AIM algorithm for the Hall kernel from $t = 0$ to 60 min every 10 min (from black to cyan). The solid curves show the reference solution, the dotted curves the simulation result of the AIM algorithm as an average over 50 realisations. The default settings are: Probabilistic singleSIP-init, $\kappa = 40$, $\nu_{critmin} = 10^{-9} \max(\nu_i)$, $\Delta t = 1$ s (column 1); Δt increased to 20 s (column 2).

657 The ν_{random} -simulations give another example of the importance of the init method. Even though
 658 both techniques, $\nu_{random,rs}$ (dashed line) and $\nu_{random,lb}$ (dash-dotted line), are similar in design
 659 and differ only in the creation of the largest SIPs (see Fig. 1), the outcome of the simulations is quite
 660 different. For the $\nu_{random,lb}$ -init, the solution matches the best AIM solution, whereas for $\nu_{random,rs}$
 661 the moments λ_2 and λ_3 stagnate at too low levels. The latter test pinpoints the main weakness of the
 662 AIM which is also reflected in its name (average impact). The initial weighting factors of those SIPs
 663 (in relation to ν of the remaining SIPs) controls how strong this growth is and how the large droplet
 664 mode emerges.

665 All quantities shown in Fig. 9 and 11 are averages over 50 realisations of the initial SIP ensemble.
 666 All individual realisations yield basically identical simulation results and it would have been
 667 sufficient to carry out and display simulations of a single realisation.

668 Figure 12 shows DSDs of simulations with the Hall kernel. Compared to the Long simulations,
 669 small droplets are much more abundant (see reference solution), as the collection of small droplets
 670 proceeds at a lower rate. This makes the simulation less challenging from a numerical point of view
 671 and AIM DSDs come closer to the reference than in the Long simulations. Consequently, the AIM
 672 moments agree very well with the reference as shown in Fig. 13. For $\Delta t \leq 20$ s and $\kappa \geq 20$, all
 673 solutions are similar to the best AIM solution.

674 3.3 Performance of All-Or-Nothing (AON) Algorithm

675 Fig. 14 shows the AON results for the Golovin kernel. An excellent agreement with the reference
 676 solution is found which proves at least the correct implementation of AON. Switching to a version
 677 without multiple collections (i.e. SIP i collects at most ν_i droplets in every time step) does not affect
 678 the solution as cases with $p_{crit} > 1 \Leftrightarrow \nu_k > \nu_i$ occur rarely. The AON moments closely follow the
 679 reference solution, even when the time step is increased from 1 s to 10 s or fewer SIPs are used when
 680 κ is decreased from 40 to 10 (left column of Fig. 15). Unlike to AIM, AON is successful, even when

Figure 13. SIP number and moments λ_0, λ_2 and λ_3 as a function of time obtained by the AIM algorithm for the Hall kernel. The black curves show the moments of the reference solution. All other curves depict the AIM results (average over 50 realisations). The left column shows a variation of $\Delta t = 1, 5, 10, 20, 50, 100, 200$ s for $\kappa = 40$ and the right column a variation of $\kappa = 5, 10, 20, 40, 60, 100$ for $\Delta t = 10$ s

Figure 14. Mass density distributions obtained by the AON algorithm for the Golovin kernel from $t = 0$ to 60 min every 10 min (from black to cyan). The solid curves show the reference solution, the dotted curves the simulation result of the AON algorithm (ensemble average over 50 realisations). The parameter settings are: probabilistic singleSIP-init, $\kappa = 40$, $\nu_{critmin} = 10^{-9} \max(\nu_i)$, $\Delta t = 1$ s. The columns show various variants of the algorithm: default version, version disregarding multiple collections and version disregarding self-collections (from left to right).

Figure 15. SIP number and moments λ_0 , λ_2 and λ_3 as a function of time obtained by the AON algorithm for the Golovin kernel. The black curves show the moments of the reference solution. All other curves depict the AON results (average over 50 realisations). The default settings are: Probabilistic singleSIP-init, $\kappa = 40$, $\nu_{critmin} = 10^{-9} \max(\nu_i)$ and $\Delta t = 1$ s. Left column: default simulation (red), larger time step ($\Delta t = 20$ s, blue) and fewer SIPs ($\kappa = 10$, brown). Right column: ν_{const} -init (brown), ν_{draw} -init (blue) and singleSIP-init with $r_{critmin} = 1.6 \mu\text{m}$ (red).

Figure 16. Mass density distributions obtained by the AON algorithm for the Long kernel from $t = 0$ to 60 min every 10 min (from black to cyan). The solid curves show the reference solution, the dotted curves the simulation result of the AON algorithm. Columns 1 and 2 show individual realisations (each *-symbol depict a non-zero g -value). Columns 3 and 4 show averages over 50 and 500 realisations. For each bin, the interquartile range is determined and depicted by +-symbols with a dashed bar (only for $t = 60$ min). If there is only one +-symbol, the 25th percentile is too small to be visible. The settings are: Probabilistic singleSIP-init, $\kappa = 40$, $\nu_{critmin} = 10^{-9} \max(\nu_i)$, $\Delta t = 20$ s.

681 the initial SIP ensemble is created with the ν_{const} -init or ν_{draw} -init (right column of Fig. 15). The
 682 moments are averages over 50 realisations. For the ν_{draw} -init method, the deviation in λ_3 towards
 683 the end of the simulated period is due to a single outlier realisation where the initial values of the
 684 moments λ_2 and λ_3 were already much higher than λ_2 and λ_3 of the reference solution. Column 2
 685 of Fig. 1 already illustrated the large uncertainty of the initial values, which becomes increasingly
 686 larger for higher order moments. Hence, this outlier behaviour is associated with a deficiency of the
 687 init technique rather than being an algorithm-intrinsic feature.

688 Nevertheless, the simulations reveal large differences between individual realisations which de-
 689 serves a closer inspection. Fig. 16 displays DSDs of AON for the Long kernel. The two left panels
 690 show DSDs of single realisations. The *-symbol depicts the g -value for each bin. Those symbols
 691 are connected by default. An interruption of the connecting line indicates one or more empty bins
 692 ($g = 0$) where no SIPs exist in this specific radius interval. This occurs frequently and the solutions
 693 are full of spikes and irregularly over- and undershoot the reference solution, particularly in the large
 694 droplet mode. The small droplet mode is underestimated in the first realisation and overestimated in
 695 the second realisation. The advantages of AON become apparent when the DSDs are averaged over
 696 many realisations as shown in columns 3 and 4. Then the DSDs come close to the reference solution
 697 and the interquartile range indicates the broad envelope the individual realisations span around the
 698 reference solution. Whereas the average over 50 realisations still has some fluctuations, the average
 699 over 500 realisations produces a smooth solution. There are two sources that are potentially respon-
 700 sible for the large ensemble spread: the probabilistic SIP initialisation and the probabilistic AON
 701 approach. In a sensitivity test, 50 realisations are computed, all using the same SIP initialisation ob-
 702 tained by a deterministic singleSIPinit. Figure 17 compares those simulations to regular simulations

Figure 17. Moments λ_0 , λ_2 and λ_3 as a function of time obtained by the AON algorithm for the Long kernel. Each realisation was initialised with a different SIP ensemble (probabilistic singleSIP, red) or all realisations started with the same SIP ensemble (deterministic singleSIP, green). In both cases, the curves show an average over 50 realisations with the vertical bars indicating the interquartile range. The crosses show the minimum and maximum values and the circle the median value. The black symbols depict the reference solution. The parameter settings are $\Delta t = 20$ and $\kappa = 40$.

Figure 18. Mass density distributions obtained by the AON algorithm for the Long kernel from $t = 0$ to 60 min every 10 min (from black to cyan). The solid curves show the reference solution, the dotted curves the simulation result of the AON algorithm as an average over 50 realisations. The default settings are: Probabilistic singleSIP-init, $\kappa = 40$, $\nu_{critmin} = 10^{-9} \max(\nu_i)$, $\Delta t = 1$ s (column 1); version disregarding multiple collections at $\Delta t = 10$ s (column 2); ν_{const} -init technique with $N_{SIP} = 160$ (column 3).

703 with differing SIP initialisations. In both cases, we find a substantial ensemble spread. Starting with
 704 identical SIP initialisations the spread is, however, smaller suggesting that both sources contribute
 705 to the ensemble spread.

706 Fig. 18 shows AON results with 50 realisations and probabilistic initialisation which gives a good
 707 trade-off between computational cost and representativeness. Clearly, AON DSDs are less smooth
 708 than those of AIM. Column 1 shows a default simulation with singleSIP init and shows very good
 709 agreement with the reference solution. Disabling multiple collections (column 2), far too few small
 710 droplets become collected and their abundance is substantially overestimated. As a consequence, the
 711 mass transfer from small to large droplets is slowed down and the large droplet mode is underesti-
 712 mated. Using the ν_{const} -init, the large droplet mode is not well matched and results are again useless.
 713 Fig. 19 shows the temporal evolution of moments λ_0 , λ_2 and λ_3 for a large variety of sensitivity tests.
 714 Column 1 shows a variation of Δt for the singleSIP-init. The larger Δt is chosen, the more often
 715 combinations with $p_{crit} > 1$ occur and the more crucial it becomes to consider multiple collections.
 716 Even for the smallest time step considered, the version without multiple collections does not col-
 717 lect enough small droplets and hence overestimates droplet number. With the regular AON version
 718 considering multiple collections, reasonable results are obtained for time steps $\Delta t \leq 20$ s. Column 2
 719 shows a variation of κ for singleSIP-init. Whereas the higher moments perfectly match the reference,
 720 the droplet number shows a non-negligible dependence on κ . For $\kappa < 100$, droplet number decrease
 721 is faster, the finer the resolution is. For $\kappa > 100$, a variation of κ has no effect, hence convergence is
 722 reached. However, those simulations underestimate the droplet number. Best results are obtained for
 723 an intermediate resolution of $\kappa = 40$. Using the MultiSIP-init, the simulations show the same unde-
 724 sired behaviour. Hence, increasing the SIP concentration in the middle part of the initial DSD has no
 725 positive effect despite using around 160% more SIPs. In another experiment, the hybrid singleSIP-

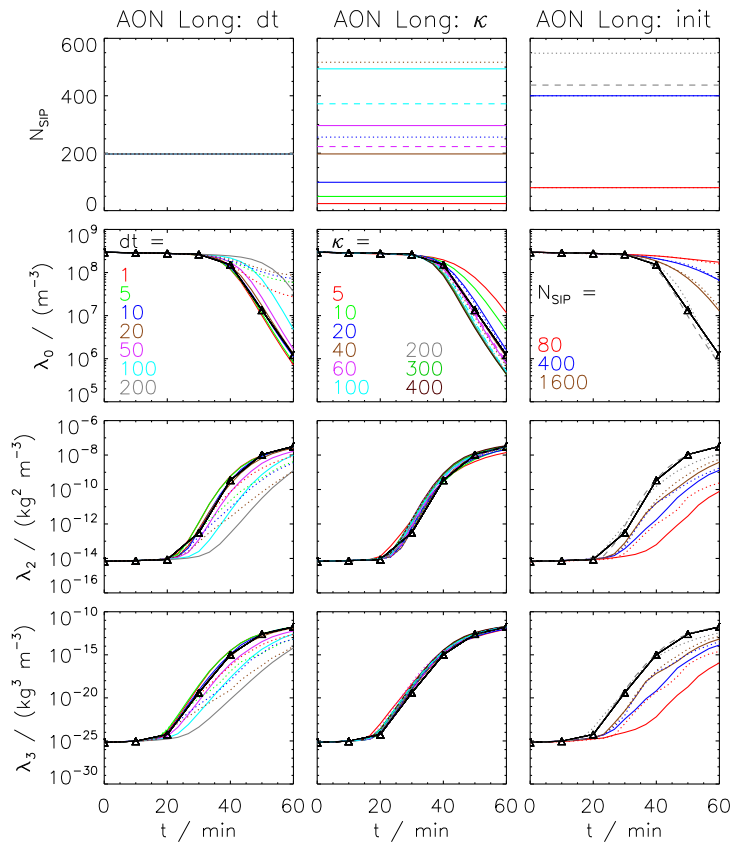

Figure 19. SIP number and moments λ_0, λ_2 and λ_3 as a function of time obtained by the AON algorithm for the Long kernel. The black symbols depict the moments of the reference solution. All coloured curves show the AON results (average over 50 realisations). The left column shows a variation of $\Delta t = 1, 5, 10, 20, 50, 100, 200$ s for $\kappa = 40$ for the regular AON version (solid) and for a version disregarding multiple collections (dotted, only cases with $\Delta t \leq 20$ s are displayed). The middle column shows a variation of $\kappa = 5, 10, 20, 40, 60, 100, 200, 300, 400$ for singleSIP-init (solid), singleSIP-init with $r_{critmin} = 1.6 \mu\text{m}$ (dashed, only for $\kappa = 60$ and 100) and MultiSIP-init (dotted, only for $20 \leq \kappa \leq 100$). The right column shows simulations with the ν_{const} -init (solid) and ν_{draw} -init (dotted) with $N_{SIP} = 1600, 400, 80$. The gray dashed and dotted line show simulations with $\nu_{random,lb}$ -init and $\nu_{random,rs}$ -init, respectively. All simulations shown in the middle and right panel use $\Delta t = 10$ s.

Figure 20. Droplet number as a function of time obtained by the AON algorithm for the Long kernel. The black symbols show the moments of the reference solution. The solid/dotted curves show simulations with hybrid/regular singleSIP-init for various κ -values (5 to 60, see legend). The hybrid version uses $\kappa = 100$ for radii above $15 \mu\text{m}$ and κ as labeled for radii below $15 \mu\text{m}$. The hybrid version uses more SIPs than the regular version (see N_{SIP} -values listed in the plot). The dotted lines are identical to solid lines in col 2 of 19

726 init was used. Below $r = 16 \mu\text{m}$ SIPs are initialised as usually. Above this radius, a high resolution
 727 with $\kappa = 100$ is always used irrespective of the chosen κ . Clearly, more SIPs are initialised with this
 728 hybrid version relative to the original version (see N_{SIP} -values listed in the figure legend). Figure 20
 729 shows the droplet number evolution for the original singleSIP-init and the new hybrid version. The
 730 sensitivity to κ is basically suppressed when the hybrid version is used. This implies that the AON
 731 algorithm is more or less insensitive to the resolution in radius range $r < 16 \mu\text{m}$, however, it is sensi-
 732 tive to the SIP resolution in the right tail. For example, the $\kappa = 5$ -simulation with the hybrid version
 733 and 87 SIPs performs better than the $\kappa = 20$ -simulation with the regular init and 98 SIPs.

734 In the conventional version, SIPs are initialised down to a radius of $0.6 \mu\text{m}$ (as can be seen in
 735 the top left panel of Fig. 1). Another variation of the singleSIP-init is shown in column 2 of Fig. 19
 736 (dashed curves) where this lower cut-off radius is raised to $1.6 \mu\text{m}$ and around 25% fewer SIPs
 737 are used to describe the DSD. The simulation results are basically identical to the conventional init
 738 version and suggest that those initially small- r_i , small- ν_i SIPs are not relevant for the performance
 739 of AON.

740 Further tests with the singleSIP-init include a variation of the threshold parameter η and a switch
 741 from weak thresholds to strict thresholds. Moreover, we investigated the implications of update-on-
 742 the-fly of the SIP properties. The singleSIP-init produces an initially radius-sorted SIP ensemble and
 743 looping over the i - j combinations in the algorithm starts with combinations of the smallest droplets,
 744 which may introduce a bias. We reversed the order (i.e. started with largest droplet combinations) or
 745 randomly rearranged the order of the SIP combinations. None of those variations had a significant
 746 effect on the results (not shown).

747 Finally, the AON performance for other SIP initialisations is discussed (right column of Fig. 19).
 748 As already demonstrated in Fig. 18, AON is not able to produce a realistic large droplet mode, if
 749 a moderate number of SIPs is initialised with the ν_{const} -technique. Hence, the higher moments are

750 underestimated and droplet number is overestimated. Increasing the number of SIPs up to 1600,
751 the solutions get closer to the reference, yet the agreement is still not satisfactory. The performance
752 for the ν_{draw} -init is similar. Keeping in mind the previous sensitivity studies (hybrid singleSIP-init,
753 MultiSIP-init), it is apparent that the ν_{const} -init and ν_{draw} -init suffer from an undersampling of
754 the initially largest droplets. Due to its simplicity, using constant weights for initialisation has been
755 a common approach in previous 3D-LCM cloud simulations (Shima et al., 2009; Hoffmann et al.,
756 2015). Hence, we tested AON extensions aiming at a better performance for equal weights ini-
757 tialisations. Let us consider the possible weighting factors the SIPs can attain in the course of a
758 simulation. In the beginning, all SIPs have $\nu = \nu_{init}$. After a collection event, for both involved SIPs
759 $\nu = \nu_{init}/2$. If such a $\nu = \nu_{init}/2$ -SIP collects a $\nu = \nu_{init}$ -SIP, both SIPs carry $\nu_{init}/2$ droplets.
760 Subsequent collections can generate SIPs with weighting factors $\nu_{init}/4$, $3\nu_{init}/4$ and so on. It may
761 be advantageous, if AON generates a broader spectrum of possible ν -values and produces SIPs with
762 smaller weights more efficiently. So far, the equal splitting approach with $\xi = 0.5$ in a collection
763 event of two equal- ν SIPs has been used. In sensitivity tests, a random number for ξ is drawn in
764 each collection event, either from a uniform distribution $\xi \in [0, 1]$ or from a log-uniform distribution
765 $\xi \in [10^{-10}, 10^0]$. Enhancing the spread of ν -values, more collection events occur in the algorithm,
766 as p_{crit} is smaller when small- ν SIPs are involved. Once most SIPs were part of a collection event,
767 the first option with $\xi \in [0, 1]$ produces a distribution of ν -values that is similar to the initial ν -
768 distribution of the ν_{draw} -init technique. Hence, the new version does not improve the simulation
769 results, as the outcome for the ν_{draw} -init and the standard ν_{const} -init are similar (not shown). Other
770 variations produce smaller weights with $\xi = 10^{-10} \text{ rand}()$ or $\xi = 10^{-10} \text{ rand}()^2$, yet without any no-
771 ticeable improvement in the simulation results (not shown).

772 To complete the analysis for the Long kernel, the right column of Fig. 19 shows simulation results
773 for $\nu_{random,lb}$ and $\nu_{random,rs}$. In short, AON can cope with those initialisations and produces useful
774 results.

775 As already noted in the AIM section, Hall simulations are not as challenging as Long simulations
776 from a numerical point of view. As the collection of small droplets proceeds at a lower rate for the
777 Hall kernel, disabling multiple collections in the AON simulations does not deteriorate the results
778 as much as in the Long simulations (not shown). Besides this, simulations with the Hall kernel lead
779 to similar conclusions as for the Long simulations and are therefore not discussed in more detail.

780 4 Discussion

781 The presented box model simulations can be regarded as a first evaluation step of collection/aggregation
782 algorithms in LCMs. The final goal is the evaluation in (multi-dimensional) applications of LCMs
783 with full microphysics. In order to isolate the effect of collection, other microphysical processes like
784 droplet formation and diffusional droplet growth have been switched off and all box model simula-

785 tions started with a prescribed SIP ensemble following a specific exponential distribution. The eval-
786 uation of different initialisation methods showed that the performance of the collection/aggregation
787 approaches depends essentially on the way the SIPs are initialised, a problem which is inherently
788 absent in spectral-bin models. Their initialisation resembles the singleSIP technique used here, i.e.
789 the number concentration (the weighting factor) within a bin (for a certain mass range represented
790 by one SIP) is directly prescribed. However, LCMs exhibit a larger variety of how an initial droplet
791 spectrum can be translated into the SIP space. The study showed that the singleSIP is advantageous
792 for the correct representation of the collisional growth, since they initialise large SIPs with small
793 weighting factors, which are responsible for the strongest radius growth. On the other hand, the
794 ν_{const} initialisation technique, in which all SIPs have the same weighting factor initially as it is
795 done in many current (multi-dimensional) applications of LCMs, impedes significantly the correct
796 representation of collisional growth.

797 In this idealised study, we were able to control (to a certain extent) the representation of droplet
798 spectra by various initialisation methods. In more-dimensional simulations with full microphysics,
799 however, this is not straightforward nor has it been intended. So far, convergence tests in "real-
800 world" LCM applications simply included variations of the SIP number and have not focused on
801 more detailed characteristics of the SIP ensemble (i.e. the properties that have been discussed in
802 Fig. 1). Droplet formation and diffusional droplet growth, which usually create the spectrum from
803 which collisions are triggered, should be implemented such that "good" SIP ensembles are gener-
804 ated or evolve before collection becomes important. Here, good refers to a SIP ensemble for which
805 the collection/aggregation algorithm performs well. For instance, the basic idea of the initialisation
806 technique ν_{random} , the initialisation of weighting factors uniformly distributed in $\log(\nu)$, might also
807 improve multi-dimensional simulations.

808 Generally, the performance of the algorithms is better when the SIP ensemble features a broad
809 range of weighting factors. One viable option to achieve this is the introduction of a SIP splitting
810 technique (Unterstrasser and Sölch, 2014). Why this may improve the performance of the collec-
811 tion/aggregation algorithms is outlined next. Mass fractions represented by individual SIPs, $\tilde{\chi}_i$, are
812 analysed. $\tilde{\chi}_i$ is defined as χ_i/\mathcal{M} , i.e. the total droplet mass in a SIP χ_i is normalised by the total
813 mass within the grid box \mathcal{M} . Figure 21 shows the initial $\tilde{\chi}_i$ -values for the singleSIP-init method
814 and two resolutions $\kappa = 20$ and 100 as a function of their initial radius r_i . The two rows show the
815 same data, using a logarithmic (top row) or linear y -scale (bottom). The log scale version highlights
816 that $\tilde{\chi}_i$ -values spread over many orders of magnitudes. Mainly, the parameter $\nu_{critmin}$ controls the
817 minimum value of χ_i . The heaviest SIPs carry initially up to 6.5% ($\kappa = 20$) or 1.2% ($\kappa = 100$) of
818 the total mass \mathcal{M} (see bottom row). Clearly, the values of the $\kappa = 20$ -simulation are larger, as the
819 total mass is distributed over fewer SIPs. For each SIP, $\tilde{\chi}_i$ is tracked over time and the maximum
820 value, $\tilde{\chi}_{i,max(t)}$, is recorded (red and brown curves in the graphs). Characteristically of AIM, only
821 the largest SIPs grow substantially and collect mass from other SIPs. Hence, only χ_i of those SIPs

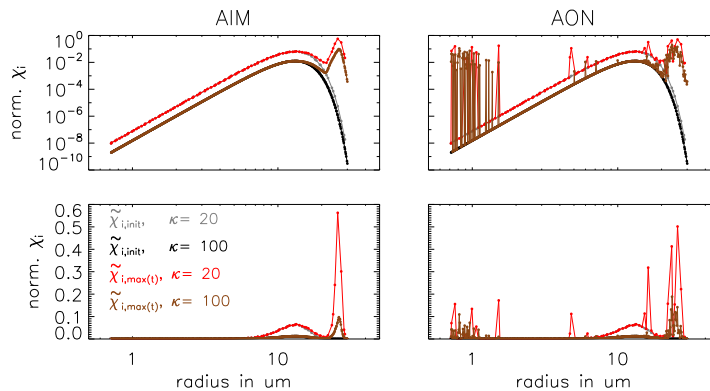

Figure 21. Normalised SIP mass $\tilde{\chi}_i$ as a function of the initial SIP radius r_i . $\tilde{\chi}_i$ is defined as $\tilde{\chi}_i = \chi_i / \mathcal{M} = (\nu_i \mu_i) / \mathcal{M}$, i.e. the total droplet mass in a SIP is normalised by the total mass within the grid box. $\chi_{i,init}$ denotes $\tilde{\chi}_i$ of the initial SIP ensemble. $\chi_{i,max}$ denotes the maximum $\tilde{\chi}_i$ -value each SIP attains over the course of a simulation. The left/right panel shows AIM/AON simulations with $\kappa = 20$ or 100 (see legend), singleSIP-init, $\Delta t = 10$ s.

822 increases. By the way, this also illustrates that the χ_i -values of the smallest SIPs are so small that
 823 all those SIPs can be merged into a single SIP without changing the AIM outcome (see $r_{critmin}$ -
 824 variation before). Using the fine resolution ($\kappa = 100$), heavy SIPs carry up to 10% of the total grid
 825 box mass at some point in time. In the $\kappa = 20$ -simulation, this ratio can be higher than 50%, meaning
 826 that one specific SIP accumulated more than 50% of the total grid box mass at some time. Hence, the
 827 grid box mass is distributed fairly unevenly over the SIP ensemble. Astonishingly, this has no effect
 828 on the performance of AIM as the predicted $\lambda_{k,SIP}$ -values for both AIM simulations are basically
 829 identical (see middle column of Fig. 11). In the AON simulations, we similarly find that the grid
 830 box mass is unevenly distributed over the SIP ensemble. Different to AIM, also many initially small
 831 SIPs and a few initially medium-sized SIPs carry a relevant portion of the grid box mass at some
 832 time. The algorithms may converge better if those heavy SIPs are split into several SIPs during the
 833 simulation.

834 In all simulations so far, the mean radius of the initial DSD was $9.3 \mu\text{m}$ where the abundance of
 835 droplets larger than $10 \mu\text{m}$ drops strongly, which poses a challenge to the representation in SIP space.
 836 In a sensitivity test, we start with "more mature" DSDs. The simulations are initialised with Wang's
 837 reference solution after $t_{init} = 10, 20$ or 30 minutes (cf. red, green and blue solid curves in previous
 838 plots of mass density distributions) using the singleSIP-init. Fig. 22 shows the SIP number and
 839 various moments of the DSD for AIM and AON. The initial DSD is broader for a later initialisation
 840 time and hence more SIPs are initialised for a given κ . This implies in particular that the spectrum
 841 above $10 - 20 \mu\text{m}$ is sampled with more SIPs. For both algorithms, the simulation results are close to
 842 the reference solution. Compared to the default $t_{init} = 0$ -case, a much weaker κ -dependence of the

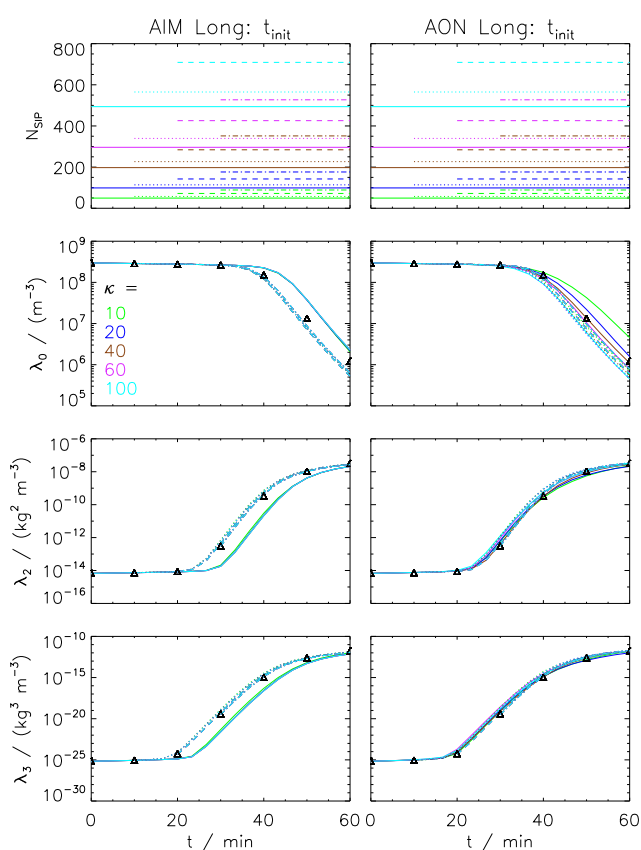

Figure 22. SIP number and moments λ_0 , λ_2 and λ_3 as a function of time obtained for the Long kernel by AIM (left) and AON (right). The black symbols depict the moments of the reference solution. The simulations are initialised with Wang solution after 10 (dotted), 20 (dashed) or 30 (dash-dotted) minutes using the singleSIP-init with various κ -values (see legend). The default AON and AIM simulations initialised at $t = 0$, which have been shown before in Figs. 11 and 19, are depicted by solid lines.

843 AON predicted droplet number is apparent and the AIM results do not lag behind. Even though this
844 sensitivity test cannot be repeated for other init methods (as they require an analytical description of
845 the initial DSD), the singleSIP simulations already indicate that the SIP initialisation is not as crucial
846 when a later initialisation time is chosen and that our default setup with a narrow DSD may overrate
847 the importance of the SIP initialisation. What are the implications of this for simulations with full
848 microphysics? Clearly, the $t_{init} = 20$ min and 30 min-case oversimplify the problem, as such DSDs
849 cannot be produced by diffusional growth only. The $t_{init} = 10$ min-DSD, on the other hand, is still
850 close to the $t_{init} = 0$ min-DSD and may be produced by diffusional growth.

851 In multi-dimensional models, collection/aggregation might be further influenced by the movement
852 of SIPs due to sedimentation or flow dynamics. For instance, sedimentation removes the largest SIPs
853 with the smallest weighting factors, while turbulent mixing is able to add SIPs with their initial
854 weighting factor into matured grid boxes, where collection has already decreased the weighting
855 factors of the older SIPs. Indeed, the additional variability in more-dimensional simulations might
856 compensate for the missing variability in the weighting factors usually present in simulations using
857 the ν_{const} initialisation technique.

858 It is not clear which findings of our evaluation efforts are the most relevant aspects that control the
859 performance of collection/aggregation algorithms in more complex LCM simulations. Nevertheless,
860 the idealised box simulations are an essential prerequisite towards more comprehensive evaluations
861 as they disclosed the potential importance of the SIP initialisation (an aspect that is inherently absent
862 in spectral bin models). All in all, we can state that the behaviour of Lagrangian collection algorithms
863 in more complex simulations demands further investigation. Nevertheless, we have already learned
864 a lot from the box model simulations. A summary will be given in the concluding section.

865 Besides the academic Golovin kernel, our simulations used the hydrodynamic kernel with collec-
866 tion efficiencies that are usually employed for liquid clouds (Long and Hall). We found that Hall sim-
867 ulations are not as challenging as Long simulations from a numerical point of view. For ice clouds,
868 usually a constant aggregation efficiency E_a (the analogon to collection efficiency) is chosen, partly
869 due to the lack of better estimates (Connolly et al., 2012). AON simulations with $E_a = 0.2$ indicated
870 that using a constant efficiency makes the computational problem less challenging, e.g. we find a
871 smaller sensitivity to κ compared to the Long simulations shown in Fig. 19 (not shown). Hence, the
872 presented algorithms can be equally employed for aggregation. Certainly, the assumption of spheri-
873 cal particles used here is overly simplistic for ice cloud, in particular, if aggregates form. However,
874 including mass-area relationships (e.g. Mitchell, 1996; Schmitt and Heymsfield, 2010) in the ker-
875 nel expression and using parameterisations of ice crystal fall speed (e.g. Heymsfield and Westbrook,
876 2010) should not change the nature of the problem.

877 5 Conclusions

878 In the recent past, Lagrangian cloud models (LCMs), which use a large number of simulation par-
879 ticles (SIPs) to represent a cloud, have been developed and become more and more popular. Each
880 SIP represents a certain number of real droplets, which is termed the weighting factor of a SIP. In
881 particular, the collision process leading to coalescence of cloud droplets or aggregation of ice crys-
882 tals is implemented differently in the various models described in the literature. The present study
883 evaluates the performance of three different collection algorithms in a box model framework. All mi-
884 crophysical processes except collection/aggregation are neglected and an exponential droplet mass
885 distribution is used for initialisation. The box model simulation results are compared to analytical
886 solutions (in the case of the Golovin kernel) and to a reference solution obtained from a spectral bin
887 model approach by Wang et al. (2007) (in the case of the Long or Hall kernel).

888 LCMs exhibit a large variety of how an initial droplet spectrum can be translated into the SIP space
889 and various initialisation methods are thoroughly explained. The performance of the algorithms de-
890 pends crucially on details of the SIP initialisation and various characteristics of the initialised SIP
891 ensemble (an issue that is inherently absent in spectral bin models and has not been paid much
892 attention in previous LCM studies).

893 The Remapping Algorithm (based on ideas of Andrejczuk et al., 2010) showed a poor perfor-
894 mance, either no realistic rain mode developed or the solutions became unstable. The evaluation
895 exercises presented in Andrejczuk et al. (2010) were not suited to reveal the obvious shortcomings
896 or downplayed its severity. Based on our extensive tests, the algorithm cannot be recommended for
897 further LCM applications, unless the stability issue is solved.

898 The Average Impact (AIM) algorithm (based on ideas of Riechelmann et al., 2012) can produce
899 very good results, however, appears to be inflexible inasmuch as only the initially largest SIPs are
900 allowed to grow in radius space. The performance depends on details of the SIP initialisation much
901 more than, e.g. on the time step or the SIP number.

902 The probabilistic All-or-Nothing (AON) algorithm (based on ideas of Shima et al., 2009; Sölch and Kärcher,
903 2010) yields the best results and is the only algorithm that can cope with all tested kernels. Unlike
904 to AIM, in AON it is not pre-determined which SIPs will eventually contribute to the large droplet
905 mode. By design, any SIP can become significant at some point and the algorithm can cope with SIP
906 initialisations that guarantee a broad spectrum of weighting factors. If an equal weights initialisation
907 is used tremendously many SIPs are necessary for AON convergence as reported by (Shima et al.,
908 2009). Many current (multi-dimensional) applications of LCMs use such SIP ensembles with a nar-
909 row spectrum of weighting factors causing a poor performance of the collection/aggregation algo-
910 rithms. This should be clearly avoided in order to have collection/aggregation algorithms to work
911 properly and/or efficiently. The time step and the bin resolution κ (used in the singleSIP-init) have
912 values similar to those used in traditional spectral-bin models and hence the computational efforts of
913 both approaches for the collection/aggregation treatment are in the same range. The presented box

914 model simulations are a first step towards a rigorous evaluation of collection/aggregation algorithms
915 in more complex LCM applications (multidimensional domain, full microphysics).

916 **6 Code availability**

917 The programming language IDL was used to perform the simulations and produce the plots. The
918 source code can be obtained from the first author. Pseudo-code of the algorithms is given in the text.

919 **7 Competing interests**

920 The authors declare that they have no conflict of interest.

921 *Acknowledgements.* The DFG (German Science Foundation) partly funded the first author (contract number
922 UN286/1-2) and the second author (RA617/27-1). We thank A. Bott for providing us with his fortran code,
923 L.-P. Wang for simulation data, M. Andrejczuk, S. Shima and P. L'Ecuyer for discussions.
