Abstract. Ice flow models are now routinely used to forecast the ice-sheets contribution to 21st century sea-level rise. For such short term simulations, the model response is greatly affected by the initial conditions. Data assimilation algorithms have been developed to invert for the friction of the ice on its bedrock using observed surface velocities. A drawback of these methods is that remaining
5 uncertainties, especially in the bedrock elevation, lead to non-physical ice flux divergence anomalies resulting in undesirable transient effects. In this study, we compare two different assimilation algorithms based on adjoints and nudging to constrain both bedrock friction and elevation. Using synthetic twin experiments with realistic observation errors, we show that the two algorithms lead to similar performances in reconstructing both variables and allow the flux divergence anomalies to be
10 significantly reduced.

1 Introduction

Robustly reproducing the responsible mechanisms and forecasting the ice-sheets contribution to 21st century sea-level rise is one of the major challenges in ice-sheet and ice flow modelling as highlighted by community-organized efforts such as SeaRISE (Sea-level Response to Ice Sheet Evolution) (Bindschadler et al., 2013; Nowicki et al., 2013a, b) or ice2sea (e.g., Gillet-Chaulet et al., 2012; Shannon et al., 2013; Edwards et al., 2014).

Such projections on decadal timescales are sensitive to the model initial state which can account for an important source of uncertainty in the model response (Aðalgeirsdóttir et al., 2014). Improving the reliability of the model projections requires the model initial state to be better constrained
20 from observations. The problem is that observations are often uncertain, sparse in time and space and indirect, so that the model state depends on many poorly determined physical parameters and

boundary conditions. Inverse methods, such as the control method (Macayeal, 1993) or the Robin
inverse method (Arthern and Gudmundsson, 2010), are efficient means to constrain such model pa-
rameters and boundary conditions. These methods have been implemented and applied with success
25 in ice flow models of different complexity in order to infer the basal drag, one of the most uncertain
model parameters (e.g., Morlighem et al., 2010; Jay-Allemand et al., 2011; Schäfer et al., 2012;
Gillet-Chaulet et al., 2012).

However, remaining uncertainties lead to non-physical ice flux divergence anomalies (Seroussi
et al., 2011) resulting in undesirable transient effects in the free surface evolution. A solution to dis-
30 sipate these transients is to conduct a surface relaxation step prior to the projections (Gillet-Chaulet
et al., 2012). This allows admissible flux divergence rates to be reached but at the expense of the
accuracy of the modelled surface elevation and surface velocities which can then depart significantly
from observations after the relaxation step.

Among the remaining uncertainties, one of the most important is the uncertainty related to the
35 bedrock elevation. The basal topography is derived from ice thickness measurements, mostly ob-
tained from airborne ice penetrating radars. These measurements can have large uncertainties and
are usually at a lower resolution than required model grids (Durand et al., 2011). Standard bedrock
elevation maps for Antarctica and Greenland are then produced by interpolation or Kriging and re-
port standard errors ranging from few tens of meters to several hundreds of meters depending on
40 the distance to observations and local topographic variability (Fretwell et al., 2013; Bamber et al.,
2013). For comparison the uncertainty on the surface elevation is usually one order of magnitude
lower (Fretwell et al., 2013).

Because of these large uncertainties, several methods have been proposed to consider the bedrock
elevation as an optimisation variable. For example, Morlighem et al. (2011) derive the adjoint of the
45 continuity equation for the ice thickness. The depth-averaged velocities and surface mass balance are
the optimised to minimise the mismatch between modelled and measured ice thicknesses. Surface
velocity measurements are used as initial guess for depth-averaged velocities, and by construction
the flux divergence produced by this approach is in equilibrium with the prescribed surface mass
balance. However, there is no constrain that the optimised velocities are solution of the stress equi-
50 librium equations, so that there is no guarantee that a mechanical flow model can match the optimised
divergence field.

van Pelt et al. (2013) develop an iterative algorithm where the discrepancy between the surface
elevation predicted by the model and the observations is used to correct the bedrock elevation. So,
the method does not rely on the accurate computation of the derivative of a cost function as in
55 a control method and is then more similar to nudging methods that have been widely studied in
the past decades in meteorology (e.g., Hoke and Anthes, 1976) and later in oceanography (Verron,
1992; Blayo et al., 1994). However, the method does not use observed surface velocities to control
the model parameters.

Several methods have been explored to construct model states where both the basal friction and
60 the basal topography are treated as optimisation variables. In a pioneer work Thorsteinsson et al.
(2003) developed a least-squares inversion using analytical solutions for the transmission of small
scale basal perturbations to the ice surface. This method has been extended in a non-linear Bayesian
framework by Raymond and Gudmundsson (2009) and applied to an Antarctic ice stream by Pralong
and Gudmundsson (2011). Bonan et al. (2014) have tested the performances of an ensemble Kalman
65 Filter on twin experiments using a shallow ice flow line model. The adjoint method has been tested
by Goldberg and Heimbach (2013) and Perego et al. (2014) with models of different complexity.
All these methods usually show good performances in reconstructing both basal friction and basal
topography when using observations of both surface elevation and surface velocities, so that mixing
between the two variables does not seem to be too problematic for realistic applications (Gudmunds-
70 son and Raymond, 2008). In addition, Pralong and Gudmundsson (2011) and Perego et al. (2014)
show better performance when the rates of surface elevation change are also constrained from ob-
servations.

In this paper, we explore two different algorithms to infer both the basal friction and the basal
topography and initialise the model state using simultaneous observations at a given time. The first
75 algorithm is in line with Goldberg and Heimbach (2013) and Perego et al. (2014) since it uses the
adjoint solution of the force balance equation. We use the Shallow Shelf Approximation to facilitate
the derivation of the adjoint. Indeed, in this case the ice thickness appears as a state variable, while
it changes the geometry of the domain for higher order approximations (Perego et al., 2014). In
its simplest formulation, the algorithm minimises the misfit between model and observed surface
80 velocities, but an additional constraint where the flux divergence is close to a given surface mass
balance can be added. The second method is an algorithm combining inversion of basal friction
using the adjoint method and nudging of the bedrock topography. The control from the surface
velocity observations is imposed by the adjoint step while the nudging step allows to decrease the
discrepancy between the flux divergence and the surface mass balance. The main motivation of
85 this second algorithm is its ease of implementation as no inversion of the model with respect to
the ice thickness is required. To our knowledge, this second method has never been explored to
reconstruct the bedrock topography in a systematic manner. Both algorithms are implemented in
the finite element ice-sheet / ice flow model Elmer/Ice (Gagliardini et al., 2013). The methods and
algorithms are described in details in Sec. 2. To test their performances, we design a twin experiment
90 in Sec. 3. The results are discussed in Sec. 4.

2 Methods

2.1 Direct Model

For the force balance, we use the standard vertically integrated Shallow-Shelf Approximation (SSA) equations (MacAyeal, 1989). This approximation neglects the effects of vertical shearing and is, hence, more adapted to model the flow in areas where the friction is low, resulting in an ice motion dominated by sliding. The horizontal velocity field (u, v) is a solution of :

$$\begin{aligned} \frac{\partial}{\partial x} \left(2H\nu \left(2\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) \right) + \frac{\partial}{\partial y} \left(H\nu \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \right) - \beta u &= \rho g H \frac{\partial z_s}{\partial x} \\ \frac{\partial}{\partial x} \left(H\nu \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \right) + \frac{\partial}{\partial y} \left(2H\nu \left(\frac{\partial u}{\partial x} + 2\frac{\partial v}{\partial y} \right) \right) - \beta v &= \rho_i g H \frac{\partial z_s}{\partial y} \end{aligned} \quad (1)$$

where β is the friction coefficient, ν the effective mean viscosity, ρ_i the ice density, g the gravity, and $H = z_s - z_b$ the thickness, with z_s and z_b the top and bottom surface elevations, respectively.

Natural boundaries are the calving fronts where the Neumann condition results from the difference between the ice pressure and the sea water pressure:

$$\begin{aligned} 4H\nu \frac{\partial u}{\partial x} n_x + 2H\nu \frac{\partial v}{\partial y} n_x + H\nu \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial x} \right) n_y &= (\rho_i g H - \rho_w g H_0) n_x \\ 4H\nu \frac{\partial v}{\partial y} n_y + 2H\nu \frac{\partial v}{\partial x} n_y + H\nu \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial x} \right) n_x &= (\rho_i g H - \rho_w g H_0) n_y \end{aligned} \quad (2)$$

where ρ_w is the water density, H_0 the ice thickness below sea level and n_x and n_y the two components of the horizontal unit vector normal to the calving front. Dirichlet boundary conditions are prescribed for other non-natural boundaries. The continuity equation for the ice thickness is given by:

$$\frac{\partial H}{\partial t} + \frac{\partial(uH)}{\partial x} + \frac{\partial(vH)}{\partial y} = a, \quad (3)$$

where a is the surface mass balance and accumulation/ablation at the bedrock interface is neglected.

2.2 Inverse methods

The objective of the methods is to produce a model state from Eq. (1) that best fits the observations of surface velocities and the rates of change of ice thickness. To minimise the discrepancy between the model and the observations, the optimisation parameter space p contains both the basal friction coefficient β and the bedrock elevation z_b .

2.2.1 Cost Functions

The misfit between the model and the corresponding observations is evaluated using cost functions. The first cost function measures the difference between modelled (\mathbf{u}) and observed (\mathbf{u}_{obs}) surface velocities :

$$J_v = \int_{\Gamma} \frac{1}{2} (|\mathbf{u} - \mathbf{u}_{obs}|)^2 d\Gamma, \quad (4)$$

where Γ is the model domain.

The second cost function measures the misfit between modelled and observed thickness rates of change:

$$J_{div} = \int_{\Gamma} \frac{1}{2} \left[\left(\frac{\partial H}{\partial t} \right) - \left(\frac{\partial H}{\partial t} \right)_{obs} \right]^2 d\Gamma. \quad (5)$$

125 The modelled rate of change of ice thickness $\partial H/\partial t$ is evaluated from Eq. (3) as the difference between the flux divergence solution of Eq. (1) and the prescribed surface mass balance. Observed rate of change of ice thickness $(\partial H/\partial t)_{obs}$ can be estimated from surface elevation trends extracted from radar altimetry measurements (Flament and Rémy, 2012).

The objective is then to find the parameter space p that minimises J_v and J_{div} . This can be
 130 achieved in different ways as illustrated in the following sections.

2.2.2 Adjoint method

The two cost functions have an implicit dependence on the parameter space p through the model surface velocities \mathbf{u} which are solution of Eq. (1). The gradient of the cost functions with respect to p can be computed efficiently using the adjoint equations of Eq. (1). The derivation of the continuous
 135 adjoint equations and the gradient of J_v with respect to the friction coefficient β can be found in Macayeal (1993). This can be easily extended for the computation of the gradient with respect to H .

The implementation in Elmer/Ice is carried out in a way that stays as close as possible to the differentiation of the discrete implementation of the direct equations. This method should lead to a better accuracy on the gradient computation than the discretisation of the continuous equations. It
 140 is similar to Martin and Monnier (2013) except that the iterative algorithm used to solve the non-linearity of the direct equations, arising from the explicit dependence of the ice viscosity on the velocity field, is not reversed in our adjoint computation. However as our direct solver is equipped with a Newton linearisation of the ice viscosity it remains self-adjoint (Petra et al., 2012). The other parts of the discrete source codes have been differentiated manually.

145 Inverse problems are often ill-posed leading to instabilities. It is then necessary to add regularisation terms to the cost function to avoid over-fitting of data. This can be done in the form of a Tikhonov regularisation. Here we define two different regularisations. The first one measures the norm of the first spatial derivative of p , thus allowing to give preference to smooth solutions:

$$J_{reg} = \frac{1}{2} \int_{\Gamma} \left(\frac{\partial p}{\partial x} \right)^2 + \left(\frac{\partial p}{\partial y} \right)^2 d\Gamma. \quad (6)$$

150 The second forces the optimisation variables to stay close to a certain prior or background information p_b . This background can be based on observations or on empirical knowledge. This second regularisation term is written as

$$J_b = \frac{1}{2} \int_{\Gamma} \frac{1}{\sigma_p^2} (p - p_b)^2 d\Gamma, \quad (7)$$

where σ_p is a spatial parameter allowing to give more or less weight to the prior information p_b .

155 The computation of the gradients of these two functional with respect to p is trivial. How these regularisation terms are weighted with respect to the model-data misfit functionals Eq. (4) and Eq. (5) is described in more details with the description of the algorithms in Sec. 2.3.

Using the gradients, the minimisation of the functionals is achieved using the quasi-Newton routine MIQN3 (Gilbert and Lemaréchal, 1989) implemented in Elmer/Ice. This method uses an ap-
160 proximation of the second derivatives of the cost function and is therefore more efficient than a fixed-step gradient descent.

2.2.3 Nudging

By definition, the steady-state solution of Eq. (3) where a is replaced by the apparent mass balance $a - (\partial H / \partial t)_{obs}$ is the minimum for J_{div} . Running the model forward in time with a constant forc-
165 ing is then a simple way to minimise J_{div} , equivalent to a relaxation step. Here we assume that the surface elevation is known so that computed changes in ice thickness are used to correct the bedrock elevation z_b . During this process, the ice thickness can substantially deviate from observations. Nudging methods, also called Newtonian relaxation, can remedy to this problem by con-
straining the thickness to fit observations through an additional call-back term in Eq. (3), which now
170 writes:

$$\frac{\partial H}{\partial t} + \frac{\partial(uH)}{\partial x} + \frac{\partial(vH)}{\partial y} = a - \left(\frac{\partial H}{\partial t} \right)_{obs} - k(H - H_{obs}), \quad (8)$$

where the coefficient k defines the amplitude of the call-back in each node of the model. These meth-
ods imply a trade-off, adjustable through k , between model physics and observations. The call-back
term can depend on many different criteria such as observation accuracy or distance to observation
175 (Hoke and Anthes, 1976). Here, we take k as a Gaussian function of the distance to the closest ob-
servation so that the call-back is maximum where an observation is available and decreases to zero
far from all observations.

2.3 Algorithms

From the methods presented in the previous section we design two algorithms to infer simultaneously
180 the friction coefficient β and the bedrock elevation z_b . To ensure that the friction coefficient remains
positive during the inversion we use the following change of variable

$$\beta = 10^\alpha \quad (9)$$

2.3.1 Adjoint method with two parameters (ATP)

This algorithm uses the gradients of the cost functions derived using the adjoint method to optimise
185 both α and z_b . For the regularisation, a constraint on the smoothness is imposed for α using Eq. (6)

while a constraint on the background information is imposed for z_b using Eq. (7). The total cost function then writes

$$J_{ATP}(\alpha, z_b) = J_v + \gamma J_{div} + \lambda_\alpha J_{reg_\alpha} + \lambda_{z_b} J_{b_{z_b}} \quad (10)$$

where γ is a constant fixed to give a similar weight to J_v and J_{div} while λ_α and λ_{z_b} are two constants allowing to adjust the weight given to the regularisation terms. Following Fürst et al. (2015), several couples $(\lambda_\alpha, \lambda_{z_b})$ are tested using a L-curve approach, and optimal values are taken from the combinations that avoid two extremes: overfitting of the observations or excessive regularisation.

2.3.2 Adjoint-nudging coupling (ANC)

In this algorithm, the adjoint method is first used to optimise α only by minimising the following total cost function

$$J_{ANC}(\alpha) = J_v + \gamma J_{div} + \lambda_\alpha J_{reg_\alpha}. \quad (11)$$

The bedrock elevation is then updated using the nudging method by solving Eq. (8) for a given time period T . T should be neither too short nor too long to allow to reduce J_{div} without over-fitting observations. The sensitivity of the method to T is discussed in the results section.

These two steps are then repeated iteratively until changes in J_v and J_{div} between two iterations are less than 1%.

3 Manufactured data sets

A twin experiment is design to investigate the ability of the two methods to reproduce simultaneously good estimates of the basal friction coefficient and the bedrock elevation. A flowline geometry is preferred to reduce the computational cost and easily test the method, however all the algorithms can be applied to 2D plane view simulations. A reference experiment for which all the model parameters are prescribed is produced to generate synthetic observations. These observations are then used to test the performances of the two algorithms.

3.1 Reference experiment

A flowline of Jakobshavn Isbrae, Greenland, is used to test the two algorithms with realistic conditions. Jakobshavn Isbrae is one of Greenland's three largest outlet glaciers and has one of the largest drainage basin on the ice sheet's western margin (Bindschadler, 1984). It is also the fastest Greenland glacier with a terminus velocity greater than 13 km a^{-1} (Joughin et al., 2008, 2014). The flowline is 550 km long and runs from the ice divide to the ice front. The surface and bedrock elevations are taken from available digital elevation models (Bamber et al., 2013). The basal friction coefficient field is first adjusted so that the model velocities fit observed velocities (Joughin et al.,

2010). To have realistic thickness rates of change, the free surface is relaxed to steady state. The surface mass balance a in Eq. (3) has been calibrated so that the steady state is close to the initial geometry, and is meant to take into account the flow convergence or divergence along the flowline.

220 The steady state solution is used as the reference of the twin experiment.

The geometry is discretised through a mesh of 500 linear elements, increasingly refined to the front of the glacier. The element size decreases from ~ 2 km in the upper part of the glacier to ~ 400 m down to the front.

225 Results will only be presented on the first 100 km upstream of the glacier front where velocities are above 100 m a^{-1} and where the SSA is more appropriate but the inversion is done all along the flowline up to the ridge.

3.2 Synthetic observations

Synthetic observations are generated by sampling and/or adding noise to the reference simulation. Details for each required field are given below. These synthetic observations and initial fields for the
230 inverse methods are compared to the reference in Fig. 1.

3.2.1 Surface velocities

Surface velocities are assumed to be observed at the same resolution as the reference simulation but with a white Gaussian noise with a mean $\mu = 0$ and a standard deviation $\sigma = 50 \text{ m a}^{-1}$. This corresponds to a root mean squared error of 47.8 m a^{-1} for the entire flowline. The reference and
235 noisy observed surface velocities are shown in Fig. 1c together with their absolute difference.

3.2.2 Surface mass balance and thickness rate of change

The surface mass balance, a , and thickness rate of change, $(\partial H/\partial t)_{obs}$, in Eq. (5) are assumed to be perfectly observed. As the reference simulation corresponds to a steady-state, $(\partial H/\partial t)_{obs} = 0$. However, the methods are also tested in Sec. 4.3 for cases where $(\partial H/\partial t)_{obs} \neq 0$ to show their
240 ability to initialise the model when the flux divergence is not in equilibrium with the surface mass balance.

3.2.3 Surface elevation

The surface elevation is assumed to be perfectly observed.

3.2.4 Bedrock elevation

245 For the bedrock elevation z_b , we simulate observations representing airborne radar measurements crossing the flowline. Bedrock elevations are sampled every 10 km with a Gaussian noise centred on zero and with a standard deviation of $\sigma = 50$ m. This leads to a rms error of 62.4 m on the 55

observation points of the entire flowline. This error is similar to the errors given in practice on recent
bedrock elevation maps (Fretwell et al., 2013; Bamber et al., 2013). For the mesh nodes between the
250 observations, the bedrock is linearly interpolated as shown in Fig. 1a. This is used as the first guess
for the inverse methods and as the background information for the regularisation, Eq. (7).

3.2.5 Model parameters

The ice viscosity is assumed to be perfectly known and corresponds to the viscosity used in the
reference experiment.

255 Assuming that no observation of the friction coefficient is available, an initial solution has to be
postulated. A good first guess for β is provided by using the driving stress to estimate the basal shear
stress :

$$\beta_{ini}(x) = \frac{\rho_i g H(x) \theta(x)}{u(x)} \quad (12)$$

where $H(x)$, $\theta(x)$, and $u(x)$ are respectively the ice thickness, the surface slope and the surface
260 velocity at position x . The reference and initial values are shown in Fig. 1b.

The rms errors on the surface velocities and the rate of change of ice thickness between the initial
state and the synthetic observations are, respectively, 761 m a^{-1} and 357 m a^{-1} , while the relative
mean error on the basal shear stress is 394 %. The performances of the two algorithms in reducing
these initial errors are presented in the following section and will be compared to these initial errors.

265 4 Results

4.1 Adjoint method with two parameters (ATP)

A set of 255 couples $(\lambda_\alpha, \lambda_{z_b})$ is tested to adjust the weighting of the regularisation terms of Eq. (10).
The constants $\lambda_\alpha = 10^{11}$ and $\lambda_{z_b} = 10^7$ show an optimum between data fitting and regularisation.
The constant γ is fixed to 1 since J_v and J_{div} have the same order of magnitude.

270 The optimisation of both α and z_b simultaneously allows to reach a rms misfit of 49.7 m a^{-1} on
velocities, very similar to the observation rms error, showing no overfitting of velocity data. The
rate of change of ice thickness misfit is also largely decreased with a rms value of 19.2 m a^{-1} . The
resulting β and z_b as well as the misfit for the surface velocities are given in Fig. 2. The friction
variability is accurately reproduced with a corresponding relative misfit of only 25 % for the entire
275 flowline with respect to the reference basal shear stress, i.e. more than 10 times less than the misfit
obtained with β_{ini} . We only notice local over-estimations of slipperiness in bedrock pits without
significant impacts on the flow velocities. Indeed, under a defined value of β corresponding to a
nearly perfectly sliding case, an additional reduction in friction has no impact on the flow. The
same reasoning applies to a nearly perfectly sticky case, where an increased friction would not
280 involve more decrease of the velocity. The bedrock elevation z_b is well reconstructed in the first

50 km upstream of the glacier front. The discrepancy with respect to the reference bedrock is larger upstream where the cost function J_v is less sensitive because of lower velocities. This could possibly be improved by using a cost function measuring the logarithm of the misfit as in Morlighem et al. (2010), but with a greater risk of fitting noise since the relative observation error is higher in these
285 regions.

In order to assess the influence of accounting for J_{div} on the method, the optimisation is repeated without the J_{div} term in the total cost function Eq. (10). The couple $(\lambda_\alpha, \lambda_{z_b})$ is kept equal to the previous case since the optimum is hardly affected by the absence of J_{div} in the total cost function. The result is given and compared to the previous one in Fig. 2. The friction coefficient β is again pretty
290 well reconstructed, with a corresponding relative misfit of 31 % on basal shear stress to be compared to the 25 % obtained with the optimisation of the J_{div} term. However, z_b shows non-consistent high frequencies involving a higher discrepancy with respect to the reference bedrock elevation that in the case of optimising J_{div} . Therefore, the optimisation J_{div} has a clear regularisation effect on the parameter z_b , by reducing the non-consistent high frequency oscillations of the solution.

295 Introduction of a Gaussian noise on $(\partial H/\partial t)_{obs}$ has been experienced in order to assess its effect on the optimisation of J_{div} . Different levels of standard deviation σ have been tested. Experiences show that the optimisation is little affected by this noise even for standard deviations σ going up to the same order of magnitude than the surface accumulation a . Introduction of systematic bias on $(\partial H/\partial t)_{obs}$ in a physically acceptable range, i.e. of the same order of magnitude than surface
300 accumulation a , also have little consequences on the optimisation.

4.2 Adjoint-nudging coupling (ANC)

The steps consisting in the optimisation of α only are conducted with a value $\lambda_\alpha = 5.10^9$ and a value $\gamma = 1$. In order to find the optimal time period for the nudging steps, different T are tested looking at the resulting convergence on J_v and J_{div} after each cycle. The convergence is substantially similar
305 for T from 1 to 4 years. Longer periods mainly involve a worse minimisation of J_v since there is no control on velocities during nudging. Shorter relaxation times do not involve sufficient change of z_b inducing a lower minimisation of J_{div} for a given number of cycles. Therefore, a relaxation time T of 1 year is adopted, which seems sufficient to allow significant changes of z_b without too much adaptation to the previous intermediate value of the friction coefficient. The algorithm is stopped
310 after 10 cycles, corresponding to the stopping criterion of Sec. 2.3.2.

The model is in good agreement with observations with a rms misfit of 46.1 m a^{-1} in the range of observation noise, for velocities and 15.8 m a^{-1} for thickness rates of change. The friction coefficient β is close to the reference one despite exacerbated variations at some locations. The corresponding relative misfit on basal shear stress is 30 % for the entire flowline. The reconstructed bedrock elevation z_b is also close to the reference on almost 100 km upstream of the front of the glacier. This
315 reflects, especially in fast flowing region, a real improvement of the basal knowledge with respect

to the first guess. Moreover, the use of nudging, instead of adjoint method, does not show the same problem of non-sensitivity in region of slower flow velocities, as mentioned in Sec. 4.1. Note however that z_b significantly departs from the reference bedrock elevation in the 80 to 100 km to the front region, strongly linked to the poorer fit of β (see Fig. 3).

As for ATP, introduction of a Gaussian noise in the observed thickness rate of change $(\partial H/\partial t)_{obs}$ has also been tested. Results show no significant impacts on the optimisation. Nevertheless, introduction of systematic bias in $(\partial H/\partial t)_{obs}$ has direct consequences on the nudging steps inducing an offset of z_b of the range of the systematic bias cumulated on the nudging period T . ANC is therefore more sensitive to systematic bias than ATP.

4.3 Further sensitivity experiments

In order to evaluate the efficiency of both algorithms in transient states, we construct new reference cases where $(\partial H/\partial t)_{obs} \neq 0$. This is achieved by multiplying β_{ref} by a factor 2, 3, 4, 5 and 10. Therefore, these increases in the basal friction involve a disequilibrium of the glacier, an ice thickening and a decrease of ice flow velocities.

The time period for the glacier to come back to equilibrium, after this change of friction parameter, depends on the amplitude of the perturbation. Here, the perturbation is only applied during 5 years in order to keep the five cases in disequilibrium. Resulting thickness rates of change $(\partial H/\partial t)_{obs} \neq 0$ are in the same order of magnitude than the tuned surface mass balance a . The five new reference cases are presented in Fig. 4.

The results of the optimisations for the five cases of perturbation are shown in Fig. 5 for ATP and Fig. 6 for ANC. The velocity misfit for ATP increases with the amplitude of perturbation with rms values between 47.8 m a^{-1} and 52.3 m a^{-1} while the rms misfit for thickness rate of change increase from 12.7 m a^{-1} to 21.8 m a^{-1} . ANC reaches rms misfit from 45.9 m a^{-1} to 47.2 m a^{-1} for velocities and 12.5 m a^{-1} to 21.5 m a^{-1} for thickness rate of change. The friction coefficient β is well reconstructed for both methods. The corresponding average relative error (with respect to each reference) on basal shear stress varies from 22 to 30 % for ANC and 20 to 28 % for ATP, still according to the amplitude of the perturbation. Both algorithms also allow to improve the knowledge of the bedrock elevation z_b with regard to the first guess. We notice a tendency to overestimate the amplitude of bumps and pits in some locations which generally corresponds to an under estimation in the amplitude of variations of β . This last behaviour highlights the limits of the algorithms and the difficulty of distinguishing the effects of two basal parameters as closely linked as the friction and the bedrock topography. This behaviour had been already highlighted in Goldberg and Heimbach (2013) and Gudmundsson and Raymond (2008) where a higher ice thickness with respect to the reference is compensated by a higher basal friction and conversely.

4.4 Flow divergence in transient model

In this section, we assess the impact of our initialisation algorithms on the prognostic response of the model forward in time assuming the same constant forcing used to build the reference state. By doing so, if the initialisation was perfect, one would expect no change of the geometry and ice flow during this prognostic simulation. The experiment is performed from ATP and ANC initial states. A third initialisation state is constructed for which only the friction coefficient has been optimised, keeping z_b equals to the *a priori* z_{b_0} . This third initialisation, called " β only" involves a rms misfit on velocities of 43.3 m a^{-1} and a relative mean error of 36 % on basal shear stress, similar to the ATP and ANC initial states. However, the rms misfit on the thickness rate of change is significantly higher, 147.8 m a^{-1} .

The prognostic simulations are conducted on a 10 years period in order to see how the initial thickness rate evolves during this time and how it impacts the final ice thickness and ice surface. The thickness rate of change after 1 and 10 years of simulation are shown in Fig. 7a and b respectively, while the mismatch on the surface elevation after 10 years is shown in Fig 7c.

ANC and ATP initial states involve thickness rates of change much closer to zero than the optimisation of " β only". This also leads to a lower mismatch ε_s on the surface elevation with respect to the reference after 10 years of simulation. Indeed, this mismatch is well below 20 m for both ANC and ATP, except on a few kilometres in the upstream region, whereas the optimisation of β only gives rise to a mismatch globally above 20 m with some regions exceeding 50 m.

In that way, the two algorithms implemented in this study show substantial improvements compared to the optimisation of " β only". We especially notice a better reproduction of low scale variations of the surface elevation due to the transfer of similar variations from the bedrock elevation z_b (Fig. 8). These variations tend to disappear with the optimisation of the friction only, giving rise to a lower resolution of the surface. However, we should point out that this direct transfer of bedrock variations to the surface is a consequence of the SSA ice-flow model used and that a full-Stokes model would produce a more diffusive transfer response .

5 Conclusions

The presented algorithms allow the reconstruction of two poorly known parameters: the bedrock topography z_b and friction coefficient β at the same time.

The optimisation of these two parameters mainly relies on the knowledge of some other data easier to measure: ice surface velocities and thickness rates of change. Some local measurements of bedrock elevation and associated errors are necessary in order to define a background z_b . The two algorithms aim to infer the set of parameters which minimises the misfit between the model and the corresponding observations of ice surface velocities and thickness rates of change. If the optimisation of ice surface velocities is usually sufficient to infer β , the inference of a second parameter requires

more information to distinguish the effects of each parameters on the flow. Observations of rates of change of ice thickness are necessary to allow optimising z_b as well.

The two algorithms are based on the optimisation of the friction coefficient β with the adjoint method. The bedrock geometry z_b is reconstructed in two different ways, again with adjoint method
390 for the first algorithm (ATP) and with a nudging method based on mass conservation equation for the second one (ANC).

We have shown that ATP algorithm reproduces β well and the corresponding basal shear stresses while z_b is particularly well reproduced in high velocities regions but does not depart from the background when the velocities become lower. The iterative algorithm coupling adjoint method and
395 nudging (ANC) gives as good results. Moreover, ANC allows a better reconstruction of the bedrock geometry z_b in most regions. This is a very good sign for an adaptation of the method to non depth-integrated flow models such as full-Stokes model. Indeed, there is no need to inverse a shape variable like bedrock topography which is a usual obstacle to adjoint-based methods.

Furthermore, the transient simulations over 10 years from initial states reconstructed with the two
400 algorithms developed give very encouraging results. The model divergence is clearly decreased with respect to usual inversion methods of the friction coefficient only. The integration of observations like thickness rates variation through an optimisation of the divergence during inversion or nudging steps, allows to regularise the solution in a physical way and also clearly improves the results.

Finally, the sensitivity experiments shows that the different algorithms can take into account the
405 disequilibrium of mass balance, which is particularly interesting considering that a large amount of outlet glaciers in both Greenland and Antarctica present this feature.

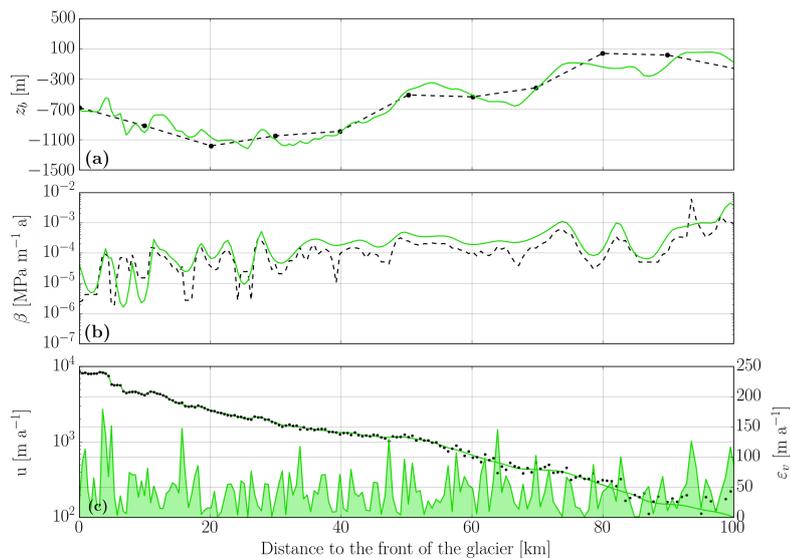

Figure 1. Reference (solid lines) and initial (dashed lines) state for **(a)** the bedrock elevations z_b , **(b)** the friction coefficient β and **(c)** the surface velocities. In **(a)** Synthetic observations every 10 km are the plain black circles. In **(c)** the "observed" velocities are depicted by the circles and the shaded green curve is the absolute difference between observed and reference surface velocities (right axis).

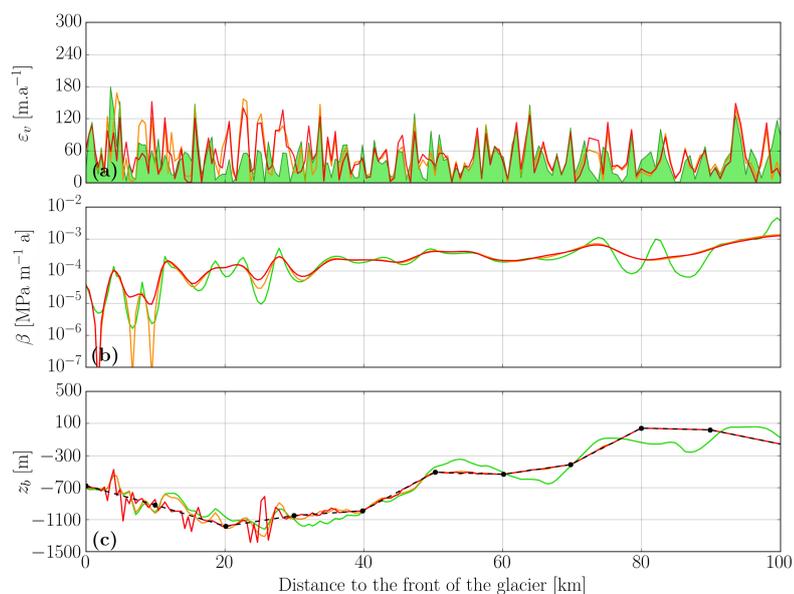

Figure 2. Results of the ATP algorithm with (orange) and without (red) optimisation of J_{div} , i.e. $\gamma = 1$ or $\gamma = 0$, respectively, in Eq. (10): **(a)** absolute difference between observed and model velocities, **(b)** estimated friction parameter and **(c)** estimated bedrock elevation. The green shaded area is the difference between the noisy reference velocities and the true velocities. The green solid lines are the reference values and the black dashed line is the initial guess for the bedrock elevation.

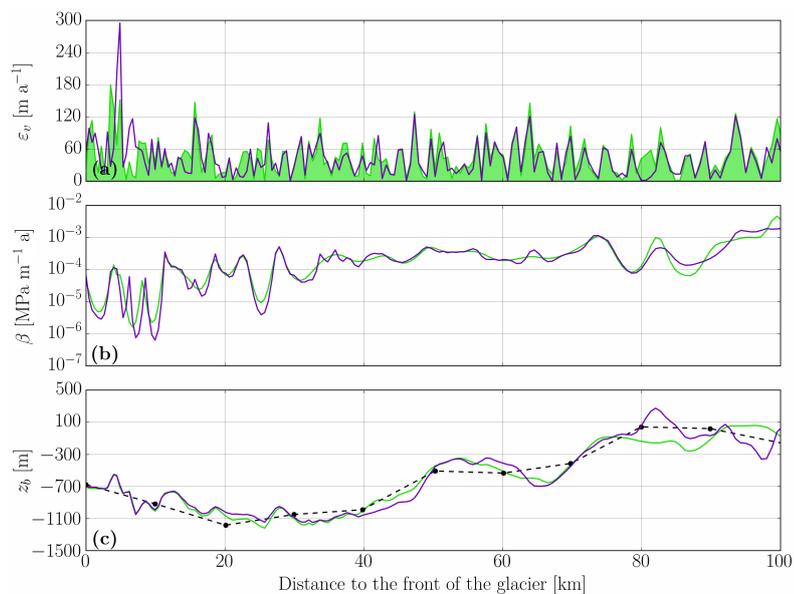

Figure 3. Results of the ANC algorithm (purple): (a) absolute difference between observed and model velocities, (b) estimated friction parameter and (c) estimated bedrock elevation. The green shaded area is the difference between the noisy reference velocities and the true velocities. The green solid lines are the reference values and the black dashed line is the initial guess for the bedrock elevation.

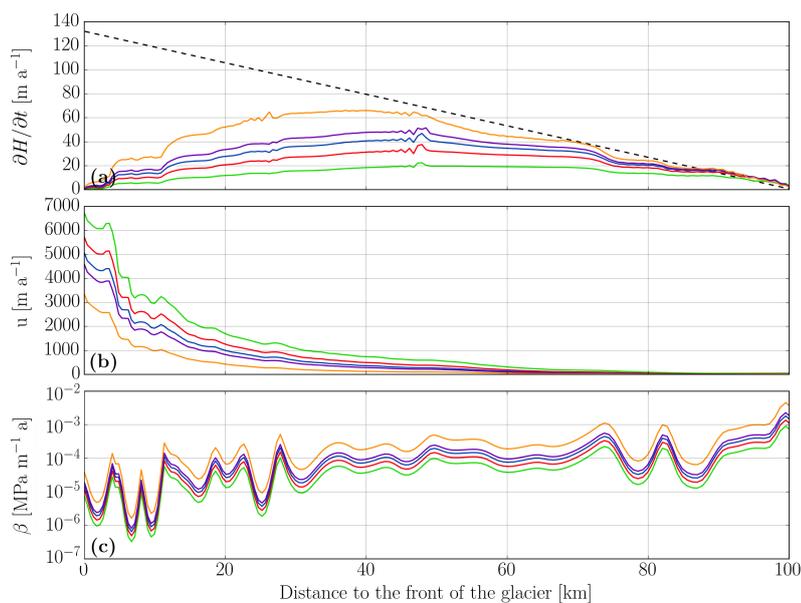

Figure 4. The five new references build from a 5-years perturbation of the initial reference by an increase of the friction parameter: $\beta = 2\beta_{ref}$ (green), $\beta = 3\beta_{ref}$ (red), $\beta = 4\beta_{ref}$ (blue lines), $\beta = 5\beta_{ref}$ (purple) and $\beta = 10\beta_{ref}$ (orange). New references for (a) the thickness rate of change for the different perturbations, (b) velocities (without observation noise), (c) friction coefficients β .

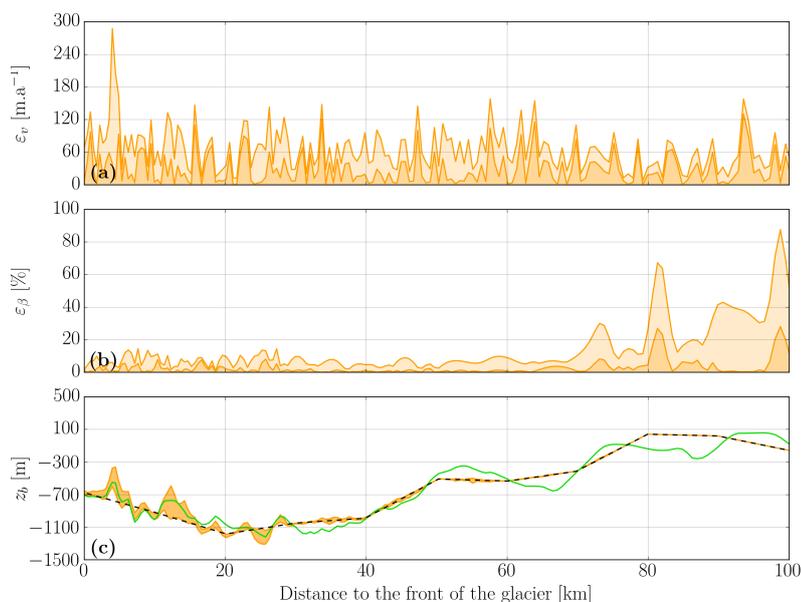

Figure 5. Range of values for ATP algorithm for the 5 perturbations of the friction coefficient β . (a) and (b) minimum (dark orange shade) and maximum (light orange shade) of absolute difference between observed and model velocities and relative error for β respectively. (c) range of values for bedrock elevation z_b (orange shade). The green solid line is the reference value and the black dashed line is the initial guess for the bedrock elevation.

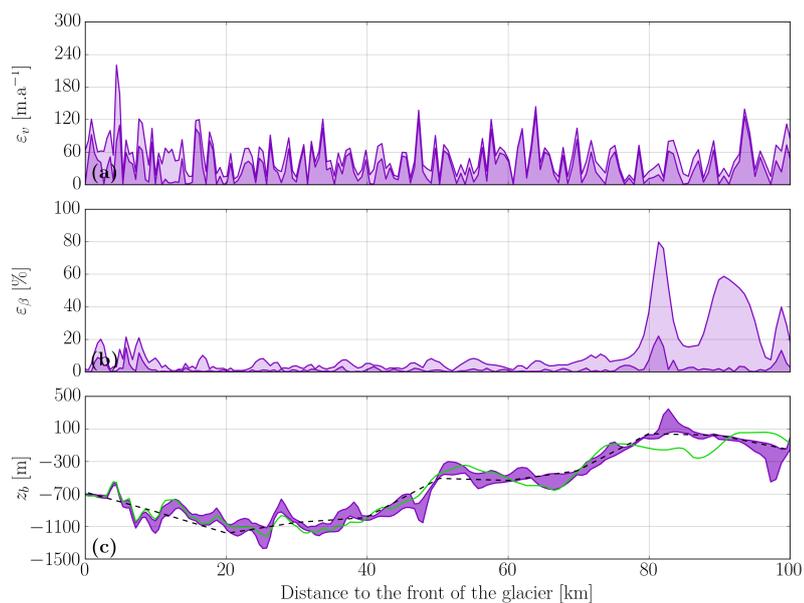

Figure 6. Same as Fig. 5 but for the ANC algorithm.

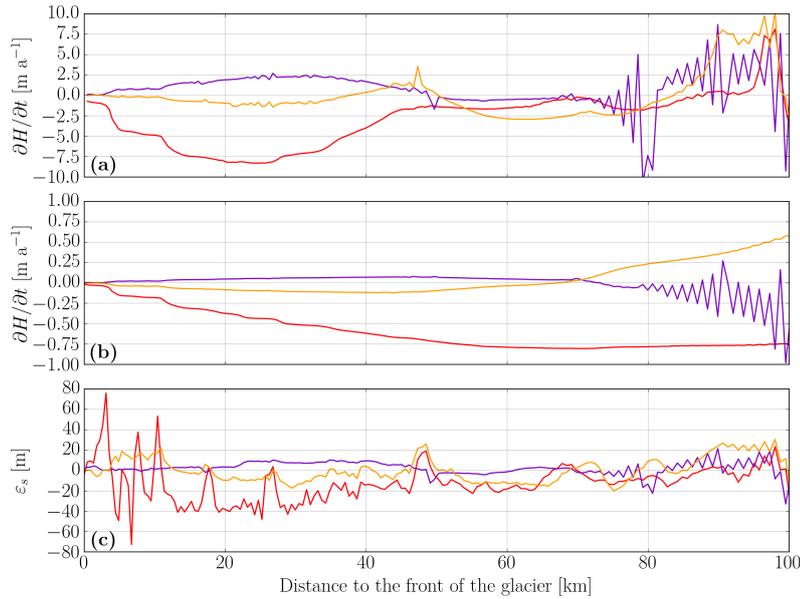

Figure 7. Evolution of $\partial H/\partial t$ after 1 year (a) and 10 years (b) of prognostic simulation and the resulting mismatch after 10 years between surfaces obtained with three different initial states and reference surface (c). The orange and purple lines give the results for ATP and ANC. The red line gives the result for inversion of β only.

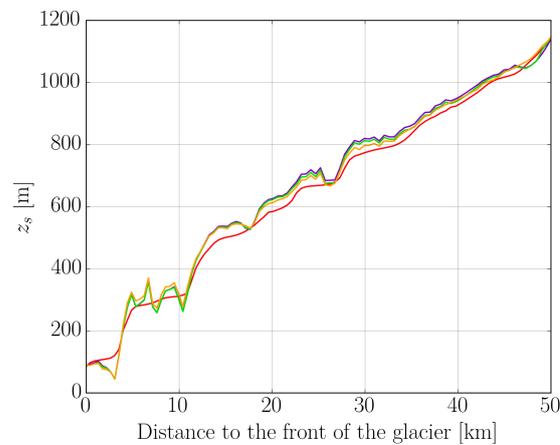

Figure 8. Ice surface elevation z_s after 10 years of prognostic simulation for 3 different initial states : initialisation with ATP algorithm (orange line), with ANC algorithm (purple line) and with the inversion of β only (red line). The green line is the reference surface elevation. The figure focuses on the first 50 km next to the front of the glacier.
