

1 Response to Andy Hogg

2 Many thanks for your comments. We have made the following changes:

3 -The ACC transport section has been modified to address the comments. As discussed in the
4 revised text, approximately two-thirds of the density gradient difference between GC2.1-
5 N512O12 and GC2 is due to denser water to the south of the ACC in GC2.1-N512O12
6 consistent with the polynya formation. The reference to Jones has been removed.

7 -The Southern Ocean SST bias approximately doubles between HadGEM2 and GC2. The
8 causes of the change in the bias will be described in a paper led by Pat Hyder which is in
9 preparation.

10 We totally agree regarding the overturning in density space and we are working on including
11 this diagnostic in our future runs.

12

16 **Abstract**

17 There is mounting evidence that resolving mesoscale eddies and western boundary currents as
18 well as topographically-controlled flows can play an important role in air-sea interaction
19 associated with vertical and lateral transports of heat and salt. Here we describe the
20 development of the Met Office Global Coupled Model version 2 (GC2) with increased
21 resolution relative to the standard model: the ocean resolution is increased from 1/4° to 1/12°
22 (28km to 9km at the Equator), the atmosphere resolution increased from 60km (N216) to
23 25km (N512) and the coupling period reduced from 3-hourly to hourly. The technical
24 developments that were required to build a version of the model at higher resolution are
25 described as well as results from a 20 year simulation. The results demonstrate the key role
26 played by the enhanced resolution of the ocean model: reduced Sea Surface Temperature
27 biases, improved ocean heat transports, deeper and stronger overturning circulation and a
28 stronger Antarctic Circumpolar Current. Our results suggest that the improvements seen here
29 require high resolution in both atmosphere and ocean components as well as high frequency

1 coupling. These results add to the body of evidence suggesting that ocean resolution is an
2 important consideration when developing coupled models for weather and climate
3 applications.

4

5 **1 Introduction**

6 On the scale of the Rossby radius, the ocean is rich with mesoscale eddies (Chelton et al.,
7 2011) and oceanic fronts. There is mounting evidence from satellite observations that
8 mesoscale features in the Sea Surface Temperature (SST) field can drive comparable
9 variations in atmospheric winds and surface fluxes (Chelton and Xie, 2010; Frenger et al.,
10 2015). While at the basin scale, observed correlations between SST and surface winds are
11 negatively correlated, indicating that the atmosphere is driving the ocean, in frontal regions
12 with high mesoscale activity, such as those associated with Western boundary currents, SST
13 and surface winds are positively correlated, implying that the ocean is driving the atmosphere
14 (Bryan et al., 2010). While the primary response to SST takes place in the atmospheric
15 boundary layer (Chelton and Xie, 2010), there is also evidence that divergence of surface
16 winds may give rise to vertical motions which may penetrate high into the troposphere
17 affecting storm tracks and clouds (e.g., Minobe et al., 2008; Sheldon and Czaja, 2014). Of
18 particular note is the intense rain band in the North Atlantic that follows the path of the Gulf
19 Stream/North Atlantic Current.

20 The recent CMIP5 ocean models have a horizontal resolution of between 1° and $1/4^\circ$.
21 However, with a resolution of 28km at the Equator down to 6km in the Canadian archipelago
22 (due to the tripolar grid), even $1/4^\circ$ remains insufficient to resolve mesoscale eddies which
23 have a typical scale of 50km in the deep ocean at mid-latitudes (Hallberg, 2013). Several
24 climate modelling groups have now built global coupled models with an “eddy resolving”
25 component (e.g., McClean et al., 2011; Bryan et al., 2010; Delworth et al., 2012; Small et al.,
26 2014; Griffies et al., 2015). In this paper, we describe results from coupling the $1/12^\circ$ ocean
27 model (ORCA12) produced by the Drakkar group (Marzocchi et al., 2015; Deshayes et al.,
28 2013; Treguier et al., 2012) to a 25 km (N512) resolution version of the Met Office Unified
29 Model (MetUM) atmosphere. This is the first version of the HadGEM3/GC series (Hewitt et
30 al., 2011; Williams et al., 2015) to resolve the Rossby radius in the ocean at mid-latitudes
31 (with a resolution of 9km at the Equator down to 2km in the Canadian archipelago) and the
32 first coupled experiment with the NEMO ORCA12 ocean configuration. The development of

1 a global coupled model with atmosphere and ocean components of this resolution as well as
2 hourly coupling is the current state of the art for global climate modelling.

3 Evidence from forced ocean simulations demonstrates that resolution enables a more realistic
4 representation of both eddy kinetic energy (Hurlburt et al., 2009; Griffies et al., 2015), narrow
5 boundary currents (e.g., Marzocchi et al., 2015) and representation of complex topography, in
6 particular the sills which connect ocean basins (e.g., improved overflows in the VIKING
7 model at $1/20^\circ$ resolution; Behrens, 2013). In this paper we investigate how ocean resolution
8 drives large-scale changes not only in the ocean but also in the climate system. Changes in the
9 ocean circulation could be important both for present and future climate; for example, in an
10 ocean-only model with a simple domain, Zhang and Vallis (2013) have shown that the
11 changes in mean circulation due to eddy-resolving resolution can affect the net ocean heat
12 uptake under global warming scenarios.

13 In this paper, the model is described in section 2. Our results (section 3) describe the relative
14 impact of the three changes to the model; ocean resolution, atmosphere resolution and
15 coupling frequency. Finally in section 4 we summarise and discuss the results.

16

17 **2 Model description**

18 The development of the high resolution coupled climate model is based on the Met Office
19 Global Coupled model version 2 (GC2; Williams et al., 2015). GC2 is comprised of the Met
20 Office Unified Model (MetUM; GA6) atmosphere, the JULES land surface model (Best et al.,
21 2011; GL6), the NEMO ocean model (Madec, 2014; GO5; Megann et al., 2014) and the Los
22 Alamos CICE sea-ice model (Hunke et al., 2010; GSI6; Rae et al., 2015). The standard
23 configuration for GC2 has a 60km resolution atmosphere coupled to $1/4^\circ$ (28km at the
24 Equator reducing polewards) ocean (N216-ORCA025) with coupling between the
25 components (as described in Hewitt et al., 2011) every three hours. GA6 has 85 vertical levels
26 while GO5 has 75 vertical levels with 1m resolution in the top 10m of the ocean (Megann et
27 al., 2014). Although vertical resolution is not explored here, we include details of the vertical
28 levels in appendix A.

29 In addition to GC2, this paper describes three modified versions of GC2 with increased
30 atmosphere resolution, increased coupling frequency and increased ocean resolution. The
31 different model experiments are described below and summarised in Table 1.

1 GC2 has been run with a high 25km (N512) atmosphere resolution and the standard
2 (ORCA025) resolution ocean and we will refer to this as GC2-N512. The scientific
3 differences between N216 and N512 are minimal, as described in Walters et al. (in prep), and
4 are principally associated with the time step (modified from 15min to 10min) and the
5 resolution of the external boundary conditions such as the orography.

6 To facilitate direct scientific comparison with the 1/12° ORCA12 (9km at the Equator
7 reducing polewards) configuration of NEMO, which was developed using NEMO v3.5 rather
8 than 3.4 (Marzocchi et al., 2015), a modified configuration of GC2, referred to here for
9 convenience as GC2.1 was developed. The key scientific and technical changes made to
10 GC2.1 are:

- 11 • a reduction in the coupling period from 3-hourly to hourly
- 12 • an upgrade to the non-linear free surface scheme rather than the linear free surface
- 13 • a small reduction in the ocean timestep from 1350s to 1200s (to accommodate hourly
14 coupling)
- 15 • small changes associated with river outflows; outflows prescribed over 15m rather
16 than 10m with an enhanced vertical mixing in the outflow region of $1 \times 10^{-3} \text{m}^2 \text{s}^{-1}$ rather
17 than $2 \times 10^{-3} \text{m}^2 \text{s}^{-1}$
- 18 • an upgrade of the sea ice model from CICE4 to CICE5 (Hunke et al., 2015). This
19 upgrade was for technical reasons and the science of the sea ice configuration remains
20 unchanged.

21 The reduction of the coupling period in GC2.1 did not lead to coupled ocean/sea ice
22 instabilities as described by Hallberg (2014).

23 To assess the impact of ocean resolution, a traceable GC2.1 configuration with ORCA12 was
24 then built (further technical details and model performance issues are discussed in appendix
25 B). We chose to increase the atmosphere resolution to N512 in order to maintain a similar
26 ratio of atmosphere to ocean grids. We will refer to this configuration as GC2.1-N512O12
27 (i.e., increased atmosphere and ocean resolution).

28

29 The differences between ORCA025 and ORCA12 in GC2.1 are:

- 30 • a reduction in the time step from 1200s to 240s
- 31 • a reduction in the isoneutral tracer diffusion from $300 \text{m}^2 \text{s}^{-1}$ to $125 \text{m}^2 \text{s}^{-1}$

- 1 • a reduction in the bilaplacian viscosity from $1.5 \times 10^{11} \text{ m}^2 \text{ s}^{-1}$ to $1.25 \times 10^{10} \text{ m}^2 \text{ s}^{-1}$

2 We note here that the parameter settings in GC2.1-N512O12 have not been tuned for the
3 coupled model; the model was run using the majority of parameter settings from the forced
4 ocean-only ORCA12 runs of Marzocchi et al. (2015). While reducing the isoneutral tracer
5 diffusivity is consistent with the increase in resolution, we note that results may have some
6 sensitivity to its magnitude. Experiments to investigate the impact of this parameter in GC2
7 were not performed but will be pursued in future work with GC3 (the next version of the
8 coupled model).

9 GC2.1-N512O12 was found to be very sensitive to features that had not proved to be a
10 problem in previous ocean-only integrations (e.g., Marzocchi et al., 2015). For example, the
11 model became unstable on the east coast of the UK every 6-12 months of simulation due to
12 extreme values in the velocity field, likely due to the lack of tidal dissipation in the model
13 which is very important in this region. The model was restarted from these failures with a
14 small random perturbation to the atmosphere temperature field in a similar way to treatment
15 of “grid-point instabilities” previously seen in atmosphere models (e.g., Mizielinski et al
16 2014). The underlying problem with this unstable ocean point will be addressed in future
17 developments of the ORCA12 configuration.

18 The GC2 and GC2.1 experiments were run for 20 years with fixed atmospheric radiative
19 forcing representative of the present day (with greenhouse gas and aerosol values for the year
20 2000). All experiments were initialised in the following way:

- 21 • atmosphere: N216 and N512 both from September year 18 of the model state of a
22 previous N512 GA6 (Walters et al., in prep) forced atmosphere integration with
23 forcing representative of the year 2000, so that the land surface properties are at quasi-
24 equilibrium;
- 25 • ocean: temperature and salinity from the EN3 observational dataset (Ingleby and
26 Huddleston, 2007) 2004-8 September average with velocities initialised to zero;
- 27 • sea ice: 20 year September mean from a HadGEM1 (Johns et al., 2006) experiment
28 representative of a period centred on 1978.
- 29 • These latter two are the standard method for initialisation of “present day” coupled
30 simulations at the Met Office.

1 The choice of the most appropriate ratio between ocean and atmosphere resolution remains an
2 open research question worthy of further study. Short (two year) integrations using both
3 higher and lower atmosphere resolutions coupled to ORCA12 were completed, although due
4 to the short length of the integrations, they are not analysed here. In particular, a configuration
5 using an N768 (17km) atmosphere led to a marked increase in the frequency of the type of
6 model instabilities described earlier (from 1-2 per year to 5-6 per year).

7

8 **3 Impact of model resolution on surface properties, heat transport and ocean** 9 **circulation**

10 The results shown in this section derive from 20 year simulations of the four experiments
11 described in table 1, initialised and forced in an identical way.

12

13 *a. Surface Properties*

14 The pattern of large-scale biases in SST fields in Hadley Centre coupled climate models have
15 remained largely unchanged since the models first ran without flux correction (e.g., Gordon et
16 al., 2000); the large-scale biases exhibit warming in the Southern Ocean, cooling in the North
17 Pacific and North Atlantic and warming in upwelling/stratocumulus regions off the western
18 coasts of South America and Africa. Many of these biases are also very common in other
19 models (e.g. Small et al., 2014). In contrast to the pattern, the magnitude of the SST biases
20 has changed between model versions; in particular, comparing GC2 and HadGEM2-AO
21 (Figure 1 of Williams et al., 2015), shows that the magnitude of the Northern hemisphere
22 cooling was reduced in GC2 while the magnitude of the Southern Ocean warming was
23 approximately doubled. ~~increased~~ Reducing SST biases in the Southern Ocean is the topic of
24 ongoing work.

25 The time-series of the global mean Top of Atmosphere (TOA) radiation imbalance in the four
26 models (Figure 1a) shows that the experiments with high (N512) atmosphere resolution have
27 TOAs that are generally higher at the start of the experiments. However after 20 years all the
28 experiments are starting to converge to a similar net TOA, as the shortwave and long-wave
29 components adjust. Although the TOA-SST relationship is poorly defined (since the TOA
30 imbalance is related to the rate of change of net ocean heat content; Palmer and McNeill,
31 2014), the integrated effect of the higher net TOA in the N512 experiments can be seen in the

1 timeseries of the global mean SST (Figure 1b) with GC2-N512 and GC2.1-N512O12 having
2 higher global mean SSTs.

3 In spite of the differences in global mean SST, major changes to the pattern and magnitude of
4 SST biases are only seen with both high atmosphere and ocean resolution (Figure 2). In
5 GC2.1-N512O12, the large-scale underlying SST biases are reduced relative to GC2 and
6 GC2.1 (Figure 3): the warm bias in the Southern Ocean; cold bias in North Atlantic and North
7 Pacific and warm biases in stratocumulus regions. Similar reductions in SST biases with high
8 atmosphere and ocean resolution were also seen in Small et al. (2015). The increase in ocean
9 resolution is key to this improvement: when only atmosphere resolution is increased (compare
10 Figures 2a and b), there is only a small reduction in the warm bias associated with
11 stratocumulus regions (west of South America and Africa), while increased coupling
12 frequency (compare Figures 2a and c) shows only minor changes in SST biases.

13 In GC2 there is a cold bias in the North Atlantic subpolar gyre (SPG), Greenland-Iceland-
14 Norwegian (GIN) Seas and the Arctic. GC2.1-N512O12 shows a warming of several degrees
15 in the SPG and GIN seas relative to GC2 (see reduced cold bias in Figure 2d) and a very large
16 warming in the Central Arctic. The warming in the Central Arctic is associated with a
17 warming in the subpolar gyre, enhanced northward heat transport into the Arctic and melting
18 back of the sea ice edge in the Arctic (see below).

19 Resolution appears to have less of an impact on Sea Surface Salinity (SSS; Figure 4).
20 Nevertheless, there are reductions in high salinity biases in the Indian Ocean and the Pacific
21 (in particular, in the salinity maximum in the subtropical gyre of the South Pacific) as well as
22 reductions in the Arctic biases (although these are very sensitive to the distribution of sea ice).

23

24 *b. Sea ice*

25 The changes to the SST also affect sea ice distribution in both hemispheres. The seasonal
26 cycle of ice extent in the Arctic (Figure 5a) shows that the warm SSTs in GC2.1-N512O12 at
27 high Northern latitudes reduce the ice extent throughout the year. The March ice
28 concentrations in the Arctic (Figure 6) clearly demonstrate that the impact on the sea ice is
29 concentrated in the GIN seas with the sea ice edge in GC2.1-N512O12 much further north
30 than seen in GC2 with the edge being north of Spitzbergen and into the Barents Sea.

1 In comparison, the reduction in the warm bias in the Southern hemisphere leads to only
2 modest increases in the total sea ice extent (Figure 5b); the overall warming bias associated
3 with the lack of super-cooled liquid clouds (Bodas-Salcedo et al., 2014; Bodas-Salcedo et al.,
4 in press) still dominates the melting of sea ice. The small increase in sea ice extent is very
5 inhomogeneous; indeed, some regions in the Southern Ocean such as the Weddell Sea
6 actually show reductions in sea ice extent in GC2.1-N512O12 (Figure 6). The reduction in the
7 Weddell Sea is associated with the formation of polynyas in that region (see below).

8

9 *c. Sub-surface ocean drifts*

10 Conservation of heat within the climate system implies that the net heat uptake by the ocean
11 should nearly balance the net radiative imbalance at the TOA. GC2.1-N512O12 has the
12 highest TOA imbalance of the four models (Table 2) and therefore will have the greatest net
13 heat uptake. Both models with increased atmosphere resolution (GC2-N512 and GC2.1-
14 N512O12) have a higher TOA imbalance than the models with lower atmosphere resolution
15 (GC2 and GC2.1).

16 The global temperature profiles (Figure 7a) show that GC2-N512 and GC2.1-N512O12 do
17 indeed have greater increases in temperature as a function of depth than either of the low
18 resolution models (GC2 and GC2.1), which is consistent with the higher TOA imbalance. The
19 main difference between GC2-N512 and GC2.1-N512O12 is that the increase in heat uptake
20 extends deeper in GC2.1-N512O12. This difference is also apparent in the global mean SST
21 anomaly (Table 2); the SST anomaly for years 11-20 in GC2.1-N512O12 is 0.44 K compared
22 with 0.60 K in GC2-N512, while the TOA imbalance is 2.02 W/m² and 1.79 W/m²
23 respectively. This shows that the ORCA12 version of the model is able to transport heat to
24 depth more effectively.

25 An increase in heat uptake in GC2.1-N512O12 relative to GC2-N512 is unexpected when
26 considering the results of Griffies et al. (2015). Griffies et al. (2015) show that an increase in
27 eddy activity produces upward eddy transport with a net effect of reduced heat uptake. Our
28 results do not show a similar result suggesting that either the mean circulation is more
29 effectively transporting heat downwards (which is consistent with an increased overturning
30 circulation) or perhaps that there is an increase in spurious diapycnal mixing. Producing a
31 budget analysis in the future would help to address this issue.

1 The distribution of the subsurface temperature changes varies depending on the latitudinal
2 range. South of 30°S (Figure 7b), near surface warming is reduced in GC2.1-N512O12
3 relative to the other models. In the Tropics (30°S-30°N; Figure 7c), GC2.1-N512O12 shows
4 increased warming shallower than 500m relative to the low resolution models but reduced
5 relative to GC2-N512. The Tropics also show increased warming at depth in GC2.1-
6 N512O12. The largest increase in near surface temperatures in GC2.1-N512O12 relative to
7 the other models occurs north of 30°N (Figure 7d) with the surface warming displacing a cold
8 bias to deeper in the water column. The warming is particularly concentrated north of 65°N
9 (Figure 7e) where it has previously been shown that Arctic sea ice melts back.

10 Drifts in sub-surface salinity show that GC2.1-N512O12 generally has larger salinity drifts
11 between 500 and 1000m (Figure 8a) which is largely associated with the region south of 30°S
12 (Figure 8b). In the northern hemisphere, drifts in salinity between 1000 and 2000m are also
13 more pronounced in GC2.1-N512O12 than the other models (Figure 8d). In contrast, large
14 fresh biases north of 65°N in most of the models is much reduced in GC2.1-N512O12 (Figure
15 8e). Understanding salinity drifts and their relationship to freshwater forcing is complex (eg,
16 Pardaens et al. 2003) and this aspect of the model performance will require further
17 investigation.

18

19 *d. Mixed layer depths*

20 In general over the open oceans, the mixed layer depths¹ (Figure 6) are very similar across the
21 different models and it is in the deep water formation regions where we see inter-hemispheric
22 changes. Winter mixed layers in the Northern hemispheres in GC2.1-N512O12 show a
23 reduction in the North Atlantic subpolar gyre. Most notably, in GC2.1-N512O12 deep mixed
24 layers are less extensive south of Greenland than in GC2 and are confined to the centre of the
25 Labrador Sea. Similar changes in Labrador Sea deep convection have been seen in sensitivity
26 experiments when overflow properties are improved (Graham et al., in prep.). The deeper
27 mixed layers in the Arctic in GC2.1-N512O12 are consistent with warmer SSTs and reduced
28 sea ice extent in that region exposing open water.

¹ Mixed layer depth is calculated as the depth at which density changes by 0.01 kg m⁻³ relative to the density at 10m

1 The similarity of the mixed layer depths across the Southern Ocean demonstrate that it is not
2 changes to the mixed layer depths that lead to a reduction in the Southern Ocean warm bias.
3 As mentioned in the previous section, in the Weddell Sea, GC2.1-N512O12 has very deep
4 mixed layers (maximum of 800m in the decadal mean) linked to the formation of polynyas.
5 Polynya formation varies both spatially and on an interannual basis over the last 9 years of the
6 simulation (Figure 9); the polynya first appears in year 12 and persists for 5 years before
7 disappearing, starting to re-emerge in year 18 and reaching a depth of 2070m in year 20. The
8 appearance of the polynya in this decade explains the lack of increase of sea ice extent in that
9 region (as seen in Figure 6). Deeper winter mixed layers in GC2.1-N512O12 are also evident
10 through the mid-latitudes in the formation zones for Sub-Antarctic Mode Waters and
11 Antarctic Intermediate Waters. These could be due to the reduced warm bias (cooler SSTs) in
12 these regions (Figure 2).

13

14 *e. Ocean Circulation*

15 The improvements seen in the large-scale SST biases with high atmosphere and ocean
16 resolution (Figure 3) represent an overall improvement in the model simulation with warming
17 in the Northern hemisphere and cooling in the Southern hemisphere. This pattern is
18 reminiscent of inter-hemispheric modes that occur as a result of changes in the large-scale
19 thermohaline circulation (Vellinga and Wu, 2004). The meridional overturning at 24°N in our
20 simulations increases by O(1.5 Sv) in GC2.1 and in GC2.1-N512O12 by a further O(1.5 Sv)
21 (Table 2). At 30°S, a change of O(3 Sv) is only seen in GC2.1-N512O12. The enhanced
22 meridional overturning is therefore attributed to the increased ocean resolution in combination
23 with the increased coupling frequency. The changes in the meridional overturning circulation
24 (Figure 10) are dominated by changes in the cell associated with North Atlantic Deep Water
25 (NADW) with changes extending into the Southern hemisphere. Examination of the
26 overturning in density space would further support this analysis but this was not possible with
27 the diagnostics available from this simulation and will be addressed in future simulations.

28 At the northern end of the NADW cell, we see increases in the volume flux of dense
29 overflows between the GIN Seas and the Atlantic (Table 2) that are consistent with the
30 NADW cell being strengthened both by the GIN sea sources and better representation of sills.
31 The volume flux of overflow waters across Denmark Straits generally reduces fairly rapidly
32 in ORCA025 runs (Figure 11a) but in GC2.1-N512O12 the overflow remains closer to the

1 observed value of 2.9 - 3.7 Sv (Dickson and Brown, 1994; Macrander et al., 2005; Jochumsen
2 et al., 2012). This appears to also contribute to a deeper (as well as stronger) NADW outflow
3 in GC2-N512O12 (Figure 10) and we suggest that this is likely to be associated with the
4 increased resolution of the topography in the region of the overflows.

5 The Antarctic Circumpolar Current (ACC) usually drifts in the ORCA025 GC models from
6 an initial value of approximately 150 Sv to below 100 Sv (Figure 11b). Increased ocean
7 resolution counteracts that, with the ACC stabilising close to 130 Sv in GC2.1-N512O12.
8 This value is close to the observations which suggest an ACC transport of 137 ± 8 Sv
9 (Cunningham et al., 2003; Meredith et al., 2011). The ~~reduced drift~~increase in the ACC
10 transport ~~in the ACC~~ can be explained by changes in the density field; the meridional density
11 gradients across the ACC ~~(not shown)~~ are strongerincreased in GC2.1-N512O12 (with steeper
12 isopycnals) than in GC2. ~~The change in density gradient can be driven by. This result is~~
13 ~~consistent with increased southward flow, and stronger upwelling, of NADW to the north of~~
14 ~~the ACC (Allison et al., 2011) and increased convection in a polynya to the south of the~~
15 ~~ACC in the Weddell Sea (Hirabara et al., 2012) giving denser water south of the ACC and/or~~
16 ~~by changes in winds and upwelling of NADW (Allison et al., 2011) giving lighter water north~~
17 ~~of the ACC. The Southern Ocean winds (not shown) respond differently across the four~~
18 ~~simulations (including a small increase in GC2.1 N512O12 and a decrease in GC2.1).~~
19 Approximately two-thirds of the difference in density gradient between GC2.1-N512O12 and
20 GC2 is due to the presence of denser water to the south of the ACC in GC2.1-N512O12. This
21 is consistent with the polynya formation discussed in the previous section. Future work will
22 look at the robustness of the ACC changes in longer simulations of high resolution models.
23 ~~Jones et al. (2011) have shown that the transient response of the ACC to changes in winds can~~
24 ~~be seen within 10 years, suggesting that it is not surprising that we are able to detect changes~~
25 ~~in the ACC in this set of experiments.~~

26

27 *f. Heat transport*

28 As described in Gordon et al. (2000), drifts in volume averaged ocean temperature can be
29 related to discrepancies between the actual heat transports by the ocean and the heat transport
30 implied by the surface fluxes, i.e.

$$31 \quad \frac{\partial \rho c_p \langle \theta \rangle}{\partial t} + \oint \rho c_p (\bar{v}\bar{\theta} + \overline{v'\theta'}) dS + \oint \rho c_p A_{iso} \nabla_{\rho} \theta dS = \int F dA, \quad (1)$$

1 where $\langle \theta \rangle$ is the volume integrated temperature, $\bar{v}\bar{\theta}$ and $\overline{v'\theta'}$ are the time mean and time
2 varying components of the ocean meridional heat transports, ρc_p is density multiplied by
3 specific heat capacity, A_{iso} is the isoneutral diffusivity, $\nabla_\rho \theta$ is the isoneutral gradients of
4 temperature, F is the surface heat flux, dS ($=dx*dz$) is the cross sectional area (x and z denote
5 the zonal and vertical directions) and dA is the surface area of the region. For our purposes
6 here, we make the assumption that the isoneutral fluxes are generally smaller than the other
7 terms (isoneutral diffusive fluxes are very small when integrated over full depth).

8 Figure 12a shows the global northward heat transport in all four simulations. There are some
9 changes in the northern hemisphere in the GC2.1 simulation with the change to hourly
10 coupling, while changes in the southern hemisphere are only seen in GC2.1-N512O12
11 suggesting that these changes are driven by the increase in ocean resolution. The reduction in
12 southward heat transport in GC2.1-N512O12 centred at 45°S is highly unusual; although the
13 change does not lie outside interannual variability, a change of this magnitude in the multi-
14 year mean heat transport has not been seen in any other development runs of the GC series.
15 The modelled changes in the heat transports suggest that ocean processes are important in this
16 region, which is particularly relevant given the uncertainty in surface heat fluxes in the
17 Southern Ocean (Cerovecki et al., 2011). The increase in total heat transport comes primarily
18 from the time mean heat transport (not shown). This suggests that increased resolution has
19 either changed the mean circulation or the temperature profile. In contrast, if the increased
20 heat transport was due to the time varying heat transport, this would imply a direct role for
21 mesoscale eddies. As seen in previous sections, GC2.1-N512O12 shows changes in both the
22 circulation and the temperature profiles. The decreased southward heat transport in the
23 Southern Ocean of GC2.1-N512O12 could – at least partly - explain the reduced warm bias.

24 By comparing actual ocean heat transports with those implied by surface fluxes (i.e., the
25 second term of the left-hand side of Eqn. 1 with the right-hand side of Eqn. 1), this gives an
26 indication of the volume averaged drift in temperature (first term on the left-hand side of Eqn.
27 1). To remove the effect of the net radiative imbalance, the implied ocean heat transport is
28 calculated by subtracting the globally averaged imbalance from the surface fluxes before
29 integrating zonally and meridionally. This is equivalent to removing a globally integrated
30 temperature drift from the left-hand side of Eqn. 1. This can be described as:

$$1 \quad \frac{\partial \rho c_p \langle \theta \rangle - \bar{\theta}}{\partial t} + \oint \rho c_p (\bar{v}\bar{\theta} + \overline{v'\theta'}) dS = \int (F - \bar{F}) dA, \quad (2)$$

2 where $\bar{\theta}$ and \bar{F} are the global mean temperature and surface flux respectively. Eqn. 2 shows
 3 that a residual imbalance between the implied and actual ocean heat transports is indicative of
 4 local temperature drifts. Both globally and in the Atlantic basin (Figure 12a,b) GC2.1-
 5 N512O12 can be seen to be as close to local balance as any of the other models, suggesting
 6 that the net drifts will be of a similar magnitude (in agreement with Figure 5).

7 Ocean resolution is the driving factor in a 0.2PW increase in the northward heat transport in
 8 the Atlantic; the modelled heat transports in GC2.1-N512O12 are generally within the error
 9 bars of the observations (Ganachaud and Wunsch, 2003; Figure 12b) in contrast to the other
 10 models with the lower resolution ocean component. The change in heat transport is linked to
 11 an increase in the overturning circulation (previous section), which is unsurprising given the
 12 dominant role of the meridional overturning circulation in the Atlantic heat transport (Hall
 13 and Bryden, 1982).

14

15 **4 Summary and Discussion**

16 In this paper we have shown results from a coupled climate model with an eddy resolving
 17 ($1/12^\circ$) ocean component coupled to a high resolution (25 km) atmosphere component. When
 18 the SST bias from this climate simulation is compared to that from the Met Office standard
 19 resolution climate model, with eddy permitting ($1/4^\circ$) ocean component and 60km atmosphere
 20 component, it is apparent that major SST biases in the Southern Ocean and North Atlantic and
 21 North Pacific have been reduced. Comparable experiments increasing only the atmosphere
 22 resolution or the coupling frequency, demonstrate that increased ocean resolution is the key
 23 driver for this change.

24 At the enhanced ocean resolution, the ocean circulation leads to increased poleward ocean
 25 heat transport in the Northern hemisphere and reduced poleward ocean heat transport in the
 26 Southern hemisphere. The change in the northward heat transport is driven at least in part by
 27 an enhanced NADW cell. The stronger ACC at high resolution may be associated with a
 28 number of factors: enhanced windstresses, increased deep water formation in the Weddell Sea
 29 due to the presence of a polynya, enhanced southward transport of NADW and eddy fluxes.
 30 Changes in the global heat transports produce a shift in the large-scale biases, cooling the
 31 Southern Ocean and warming the North Atlantic and North Pacific. We have shown that heat

1 penetrates deeper in our $1/12^\circ$ model; Griffies et al. (2015) have demonstrated that mesoscale
2 eddies transport heat upwards so it is likely that the increased transport of heat to depth is
3 achieved by the time-mean as seen in transient experiments such as Banks and Gregory
4 (2006). Future work will be focused on understanding the relative roles of resolving overflow
5 topography (Behrens, 2013), eddy processes within the ocean including compensation and
6 saturation (e.g., Munday et al., 2013) and air-sea interaction on the eddy scale (Roberts et al.,
7 in prep.) in driving the large-scale changes.

8 Relative to the recent high resolution results of Small et al. (2014) and Griffies et al. (2015),
9 our results emphasise the importance of increasing both ocean resolution and coupling
10 frequency. Griffies et al. (2015) show smaller reductions in SST biases than seen here when
11 moving from $1/4^\circ$ to $1/10^\circ$ resolution presumably related to keeping the atmosphere resolution
12 unchanged. Enhanced coupling frequency along with enhanced vertical resolution near the
13 air-sea interface both in the ocean (Megann et al., 2014) and atmosphere (Walters et al., in
14 prep) is one feature of our model setup that is missing in Small et al. (2014). These aspects of
15 the model setup may be especially important in regions of strong air-sea interaction including
16 the stratocumulus regions where we see large improvements in the GC2.1-N512O12
17 simulation. Further work is required to quantify whether high resolution in the atmosphere
18 component is necessary in combination with the high resolution ocean components and high
19 frequency coupling to produce the results described in this paper.

20 As described in section 2, one of the changes to the ocean model at higher resolution was a
21 reduction in the isoneutral diffusivity. Pradal and Gnanadesikan (2014) show that a reduction
22 in the isoneutral diffusivity from $800 \text{ m}^2\text{s}^{-1}$ to $400 \text{ m}^2\text{s}^{-1}$ in a coarse resolution climate model
23 is associated with cooling of order 1°C at high latitudes after 500 years. Given that the results
24 here exhibit some consistency with those of Pradal and Gnanadesikan (2014) in the Southern
25 Ocean, further work is required to quantify the role of isoneutral diffusivity in producing
26 changes in SST on decadal timescales.

27 One caveat of these results is that the parallel simulations lasted only 20 years. However, the
28 broad similarity of the results presented here compared with those of Small et al. (2014) from
29 over 100 years of simulation suggest that the results are reasonably robust. In terms of model
30 drift, climate models typically have a fast adjustment within the first five years (Sanchez-
31 Gomez et al., 2016). Large adjustments over the first 20 years are generally followed by a
32 multi-centennial drift towards equilibrium between ocean properties and the net TOA flux

1 (Banks et al., 2007). Longer simulations and further analyses will enable the robustness of the
2 results presented here (including wind-SST feedbacks) to be more fully understood.

3 In the results presented here, the $1/12^\circ$ ocean model, which has a resolution of approximately
4 7 km at mid-latitudes, is coupled to an N512 atmosphere model, which has a resolution of 25
5 km. The relative importance of the atmosphere and ocean resolution remains a question which
6 will continue to be addressed in the community. We suggest that an atmosphere:ocean ratio of
7 4:1 may be too high for the atmosphere to fully respond to the details of the ocean mesoscale.
8 Future work will investigate the impact of coupling to even higher resolution atmosphere
9 models to investigate the role of the atmosphere:ocean ratio.

10 As we move towards using coupled models for prediction on timescales from days to
11 centuries, the results presented here are highly relevant to prediction up to decadal timescales
12 where data assimilation is employed. A coupled model that more faithfully produces the
13 current state of the ocean will rely less on data assimilation for correcting large-scale biases
14 and better represent spatial anomalies that control the large-scale variability. While there are
15 many regions where subsurface drifts are improved at ORCA12 resolution, reducing the drifts
16 seen in mid-depth salinity will be important.

17 The ocean data assimilation scheme used in Met Office systems is called NEMOVAR,
18 employed in a 3DVar first-guess-at-appropriate-time (FGAT) mode (Waters et al., 2015). A
19 new version of NEMOVAR has recently been developed (Weaver et al. 2016) which uses a
20 2D implicit diffusion operator to model the horizontal background error covariances, one of
21 the most computationally expensive aspects of the scheme. This new version has been
22 developed in such a way that the number of costly global communications are minimised and
23 is therefore expected to scale well with resolution. Preliminary implementations of this
24 scheme in the ORCA12 configuration indicate that it will be feasible to implement it for
25 operational ocean forecasting applications.

26 A key question for these timescales is whether employing enhanced resolution will address
27 the known problem of low signal-to-noise ratios (Eade et al., 2014) that has led to the need for
28 large ensembles for seasonal to decadal forecasting in lower resolution systems. Future work
29 to understand the drivers of large-scale bias reduction will support targeted experiments to
30 address the relative roles of resolution and ensemble size at these timescales. That said, ocean
31 resolution is clearly not going to solve all the issues in climate models; atmosphere errors

1 often dominate surface biases and, even at high resolution, ocean models need improved
2 representation of sub-gridscale processes.

3
4

5 **Code availability**

6 The MetUM is available for use under licence. A number of research organizations and
7 national meteorological services use the MetUM in collaboration with the Met Office to
8 undertake basic atmospheric process research, produce forecasts, develop the MetUM code
9 and build and evaluate Earth system models. For further information on how to apply for a
10 licence see <http://www.metoffice.gov.uk/research/collaboration/um-collaboration>. JULES is
11 available under licence free of charge. For further information on how to gain permission to
12 use JULES for research purposes see <https://jules.jchmr.org/software-and-documentation>. The
13 model code for NEMO v3.4 and v3.5 is available from the NEMO website ([www.nemo-](http://www.nemo-ocean.eu)
14 [ocean.eu](http://www.nemo-ocean.eu)). On registering, individuals can access the code using the open source subversion
15 software (<http://subversion.apache.org/>). The model code for CICE is freely available
16 (<http://oceans11.lanl.gov/trac/CICE/wiki/SourceCode>) from the United States Los Alamos
17 National Laboratory. In order to implement the scientific configuration of GC2/GC2.1 and to
18 allow the components to work together, a number of branches (code changes) are applied to
19 the above codes. Please contact the authors for more information on these branches and how
20 to obtain them.

1 **Appendix A: Model vertical levels**

2 The sensitivity to vertical resolution is not explored in this paper. However, a reduced
3 description of the vertical levels in GA6 (Table A1) and GO5 (Table A2) are included to
4 allow comparison with other models. For the full vertical levels, see Walters et al. (in prep.)
5 and Megann et al. (2014), respectively.

Level	Rho_height (m)
1	10.00
10	730.00
20	2796.67
30	6196.67
40	10930.12
50	17012.40
60	24710.70
70	35927.89
80	58978.35
85	82050.01

6 Table A1: Reduced list of level in GA6 which has 85 vertical levels

1

Level	Depth (m)	Thickness (m)
1	0.51	1.02
10	13.99	2.37
20	61.11	7.58
30	180.55	18.27
40	508.64	53.76
50	1387.38	125.29
60	2955.57	181.33
65	3897.98	194.29
70	4888.07	200.97
75	5902.06	204.23

2 Table A2: Reduced list of levels and layer thicknesses in GO5 which has 75 vertical levels

3

1 **Appendix B: Model performance and technical aspects**

2 The GC2.1 configuration was the first in which several further technical components of the
3 coupled system were considered essential to make the simulation manageable. The coupler
4 was upgraded from OASIS3 to OASIS3-MCT (Valcke et al, 2015) in order to improve
5 parallelisation of the coupling, particularly given the increased coupling frequency.

6 ORCA025 files are typically written as one file per processor by standard GC2 configurations
7 and combined into a single file prior to analysis as a post processing step. However, as HPC
8 parallel file systems are generally tuned for high bandwidth on large files and as GC2.1-
9 N512O12 configurations allocate 50 of the 80 nodes used by the full coupled system to the
10 ocean, this led to performance and functional issues when running on 1600 or more cores.
11 The NEMO XIOS diagnostic server (Madec, 2014) provides an asynchronous IO server
12 capability that allows the diagnostic files to be output as fewer larger files (although the
13 restart files are still written as one file per processor). Its introduction in the model allowed us
14 to overcome the limitations of the file system.

15 Land suppression was used for the NEMO and CICE models, so that processors are only
16 assigned to regions with active ocean points. This leads to a significant gain in core count,
17 although it meant that the automated large-scale diagnostics usually produced by NEMO
18 (zonal mean heat transports, meridional overturning) could not be generated.

19 Data volumes from this experiment were particularly large due to the output of additional
20 hourly and 3-hourly fluxes in order to examine the coupling processes in more detail. Each
21 month of model output comprised: ocean monthly mean files (netCDF) of 87GB together
22 with 6GB of daily files, sea-ice output (netCDF) of 57GB per month (with an additional
23 48GB of hourly output), and atmosphere output (PP format) of 100 GB per month. In total,
24 the 20 years of simulation produced 85 TB of data.

25 Little optimisation of the model was attempted since GC2.1 is not intended to be supported in
26 the long-term. Its successor, GC3, will be used for CMIP6. The GC2.1-N512O12 model used
27 80 full nodes (each of 32 cores) of an IBM Power 7 HPC, of which 55 were allocated to the
28 ocean/sea ice component (including 5 for the IO servers) and 25 for the atmosphere/land
29 component. The model throughput was 4 months per wall-clock day.

30 For previous model resolutions, the SCRIP utility (Jones, 1998) was used to generate the
31 conservative remapping files used to regrid coupling data between the ocean and atmosphere

1 grids (for temperature and fluxes), with bilinear interpolation used for the winds and surface
2 currents. However, due to the size of the high resolution grids used here, and the serial nature
3 of SCRIP, a different method was required. ESMF (ESMF, 2014; a package of parallelised
4 tools that use the same input grid descriptions as SCRIP, but can be run in parallel) was
5 therefore used to generate the remapping weights.

6

7

8 **Acknowledgements**

9 We thank the Editor and the two reviewers (Stephen Griffies and Andy Hogg) for their
10 constructive comments. Matt Martin provided useful input on data assimilation for ORCA12.
11 This work was primarily supported by the Joint DECC/Defra Met Office Hadley Centre
12 Climate Programme (GA01101). Part of the work was undertaken with National Capability
13 funding from NERC for ocean modelling. We acknowledge use of the MONSooN system, a
14 collaborative facility supplied under the Met Office-NERC Joint Weather and Climate
15 Research Programme (JWCRP). Met Office authors were supported by the joint UK
16 DECC/DEFRA Met Office Hadley Centre Climate Programme (GA01101). MR
17 acknowledges support from the EU FP7 IS-ENES2 project for work on ESMF and regriding
18 tools. We acknowledge the considerable effort on development and evaluation of ORCA12 by
19 the DRAKKAR community. HH thanks IH.

1 Table 1. Coupled models used in this paper

Model	Horizontal Resolution	Coupling frequency
GC2 (Williams et al., 2015)	N216-ORCA025	3-hourly
GC2-N512	N512-ORCA025	3-hourly
GC2.1 (this paper)	N216-ORCA025	1-hourly
GC2.1-N512O12	N512-ORCA12	1-hourly

2
3

4 Table 2. Key metrics from years 11-20 of the experiments and observations. TOA
5 observations from CERES/EBAF for years 2000-2010. Global mean SST error (compared to
6 Reynolds OI). Overflows are calculated as southward flow across the Greenland-Iceland-
7 Scotland ridge below density of 27.8 kg m^{-3} and have standard deviation shown in brackets.

Model	Net TOA (W/m^2)	Global mean SST error (K)	Maximum overturning \pm 30°S (Sv)	Maximum overturning \pm 24°N (Sv)	Net transport from overflows (Sv)
Observations	0.85				
GC2	1.61	0.25	13.7	14.6	4.0 (0.24)
GC2-N512	1.79	0.60	14.3	14.9	3.9 (0.28)
GC2.1	1.64	0.29	14.3	16.4	4.7 (0.26)
GC2.1- N512O12	2.02	0.44	17.5	17.7	5.9 (0.42)
