Abstract

19 The Nanjing University of Information Science and Technology Earth System Model
20 version 3 (NESM v3) has been developed, aiming to provide a numerical modeling
21 platform for cross-disciplinary earth system studies, project future Earth's climate and
22 environment changes, as well conduct subseasonal-to-seasonal prediction. While the
23 previous model version NESM v1 simulates well the internal modes of climate variability,
24 it has no vegetation dynamics and suffers considerable radiative energy imbalance at the
25 top of the atmosphere and surface, resulting in large biases in the global mean surface air
26 temperature, which limit its utility to simulate past and project future climate changes.
27 The NESM v3 upgraded the atmospheric and land surface model components and
28 improved physical parameterization and conservation of coupling variables. Here we
29 describe the new version's basic features and how the major improvements were made.
30 We demonstrate the v3 model's fidelity and suitability to address the global climate
31 variability and change issues. The 500-year pre-industrial (PI) experiment shows
32 negligible trends in the net heat flux at the top of atmosphere and the Earth surface.
33 Consistently, the simulated global mean surface air temperature, land surface temperature
34 and sea surface temperature (SST) are all in a quasi-equilibrium state. The conservation
35 of global water is demonstrated by the stable evolution of the global mean precipitation,
36 sea surface salinity (SSS) and sea water salinity. The sea ice extents (SIEs), as a major
37 indication of high latitude climate, also maintain a balanced state. The simulated spatial
38 patterns of the energy states, SST, precipitation, SSS fields are realistic, but the model
39 suffers from a cold bias in the North Atlantic, a warm bias in the Southern Ocean and
40 associated deficient Antarctic sea ice area, as well as a delicate sign of the double ITCZ

41 syndrome. The estimate radiative forcing of quadrupling carbon dioxide is about 7.24
42 Wm^{-2} , yielding a climate sensitivity feedback parameter of $-0.98 \text{ Wm}^{-2}\text{K}^{-1}$, and the
43 equilibrium climate sensitivity is 3.69 K. The transient climate response from the $1\% \text{ yr}^{-1}$
44 CO_2 (1pctCO2) increasing experiment is 2.16 K. The model's performance on internal
45 modes and responses to external forcing during the historical period will be documented
46 in an accompanying paper.

47

48 **1. Introduction**

49 Large internal variability of the Earth climate system involves complex feedbacks
50 among the atmosphere, hydrosphere, cryosphere, land surface and biosphere. As an
51 essential tool to reproduce the Earth's paleoclimate evolution, project future climate
52 change, and understand the mechanisms governing climate variability and change, the
53 Climate System Model (CSM) and Earth System Model (ESM) have attracted greatest
54 attention of the scientific community. Starting from 1995, the World Climate Research
55 Programme (WCRP) established and regularly organized Coupled Model
56 Intercomparison Projects (CMIPs) (Meehl et al. 2000). The CMIP has not only stimulated
57 the coupled model development, facilitated model output validation, deepened scientific
58 understanding of the Earth climate change, but also provided scientific guidance for the
59 Intergovernmental Panel on Climate Change (IPCC).

60 The first generation of Nanjing University Information Science and Technology
61 (NUIST) Earth System Model (NESM v1, Cao et al 2015) was established with the
62 atmospheric model ECHAM v5.3, ocean model NEMO v3.4, sea ice model CICE v4.1

63 and coupler version 3 of the Ocean-Atmosphere-Sea-Ice-Soil Model Coupling Toolkit
64 (OASIS3.0-MCT). It was targeted to meet the demand of seamless climate prediction,
65 simulate the past and project future climate change, and study of climate variability of
66 high-impact weather events. The performances of NESM v1 model have been evaluated
67 (Cao et al. 2015) and further developed into a seasonal prediction system (NESM v2) by
68 modification and tuning of convective parameterization and cloud microphysics. The
69 NESM v1 was also used to study the changes in Last Glacial Maximum climate and
70 global monsoon, demonstrating reasonable model response with external forcing (Cao et
71 al. 2016). Numerical experiments with NESM v2 were conducted to confirm the sources
72 of predictability of the Indian summer monsoon rainfall (Li et al. 2016) and the winter
73 extremely cold days in East Asia (Luo and Wang 2018).

74 However, the previous model versions have no vegetation dynamics in the land
75 surface model and cannot be used to study carbon cycle (Cao et al. 2015); and the
76 response of the coupled system to carbon dioxide forcing was over-sensitive. Meanwhile,
77 the poorly resolved vertical layers prevented correct simulation of stratosphere
78 phenomena as well as high-level jet stream. They have large land surface temperature
79 biases and a severe double ITCZ syndrome.

80 Facing the forth coming CMIP6, a more comprehensive and improved Earth System
81 Model is needed to perform CMIP6 experiments and to address forcing-related scientific
82 questions. For this purpose, we have developed a new version of NESM v3. The major
83 changes include an updated land surface model with dynamic vegetation and carbon
84 exchange, improved shortwave and longwave radiation schemes, new schemes for

85 description of aerosols and computation of surface albedo, increased vertical resolution of
86 the atmosphere model and horizontal resolution of the ocean and sea ice models.

87 As a registered model of CMIP6, the NESM v3 model is to be used to perform the
88 DECK simulation, historical experiment, and some endorsed MIPs following the CMIP6
89 experiment design protocol (Eyring et al. 2016). The selected MIPs include: Detection
90 and Attribution Model Intercomparison Project (DAMIP), Scenario Model
91 Intercomparison Project (ScenarioMIP), Decadal Climate Prediction Project (DCPP),
92 Global Monsoons Model Intercomparison Project (GMMIP), Paleoclimate Modelling
93 Intercomparison Project (PMIP), Volcanic Forcings Model Intercomparison Project
94 (VolMIP), and Geoengineering Model Intercomparison Project (GeoMIP).

95 This paper documents the main features of the NESM v3, the major model
96 improvement, and the preliminary evaluation of model's long term integration and
97 climate sensitivity to carbon dioxide forcing. In the new version 3, the energy balance is
98 substantially improved, including the net shortwave radiation and outgoing longwave
99 radiation and their balance. The biases are in a few tenths Wm^{-2} and the trends are
100 negligible. This is demonstrated by the PI experiment with perpetual unchanged forcing,
101 and the climate sensitivity is tested through the abruptly quadrupling CO_2 experiment and
102 1pct CO_2 experiment.

103 The model description is presented in Section 2, which is followed by the coupled
104 model tuning strategy (Section 3). In Section 4 and 5, the model long-term stability and
105 the mean climate states are evaluated. Section 6 examines the model climate sensitivity in

106 perturbing atmospheric carbon dioxide concentration. The last section presents a
107 summary.

108 **2. Model description and validation data**

109 The NESM v3 consists of the ECHAM v6.3 atmospheric model, which directly
110 coupled with JSBACH land surface model, the NEMO v3.4 ocean model, the CICE v4.1
111 sea ice model; and the OASIS3-MCT_3.0 coupler. The model structure is illustrated in
112 Fig.1, and brief description of each component model follows.

113 **2.1 Atmosphere and land surface model**

114 The ECHAM v6.3 and JSBACH model are originally adopted from the Max Planck
115 Institute ECHAM serial model. A brief introduction will be presented here; the detailed
116 documentation can be found in Stevens et al. (2012) and Giorgetta et al. (2013). The
117 ECHAM v6.3 employs the spectral/finite-difference dynamic core for adiabatic process.
118 Calculations of all parameterizations and non-linear terms are transferred to Gaussian
119 grids. A hybrid sigma-pressure coordinate system (Simmons et al. 1999) is used in the
120 vertical discretization. The shortwave and longwave radiation schemes are both from the
121 Rapid Radiation Transfer Model for General Circulation model's (RRTM-G) scheme
122 (Iacono et al. 2008), which takes the two-stream approach. The upward and downward
123 irradiance are calculated over a predetermined number of pseudo wavelengths, or g -
124 points, an approach is usually referred to as the correlated- k method, where k denotes
125 absorption and g indexes the cumulative distribution of absorption within a band
126 (Zdunkowski et al. 1980). The frequency of radiation calculation is two hours. The
127 turbulent transport employs the turbulent kinetic energy scheme (Brinkop and Reockner

128 1995), and the surface fluxes are calculated using the bulk-exchange formula which is
129 based on Monin-Obukhov similarity theory. The model parameterizes shallow, deep and
130 midlevel convection separately. The deep convection is based on mass-flux framework
131 developed by Tiedtke (1989) and further improved by Nordeng (1994). Currently, the
132 shallow, deep and midlevel convection are parameterized by the Tiedtke, Nordeng, and
133 Tiedtke scheme, respectively. The stratiform cloud scheme contains the prognostic
134 equations for the vapor, liquid, and ice phase, respectively, a cloud microphysical scheme,
135 and a diagnostic cloud cover scheme (Sundqvist et al. 1989). The ECHAM v6.3
136 implements the Subgrid Scale Orographic Parameterization scheme (Lott and Miller 1997,
137 Lott 1999) to represent the momentum transport arising from subgrid orograph.

138 The JSBASH land surface model simulates fluxes of energy, momentum, moisture,
139 and tracer gases between the land surface and atmosphere (Raddatz et al. 2007). The
140 JSBACH model contains a 5-layer soil, a dynamic vegetation scheme and a land albedo
141 scheme. The tiled structure of land surface is divided into eight natural Plant Functional
142 Types (PFTs), four anthropogenic PFTs and two types of bare surface (Brovkin et al. 2013).
143 The dynamic vegetation scheme is based on the assumption that the competition between
144 different PFTs is determined by their relative competitiveness expressed in the annual net
145 primary productivity, as well as natural and disturbance-driven mortality. The surface
146 albedo is calculated at each tile of the land surface for near-infrared and visible range of
147 solar radiation.

148 **2.2 Ocean model**

149 The ocean component model of NESM v3 is Ocean PARallelise (OPA), the ocean part
150 of NEMO v3.4 (Nucleus of European Modelling of the Ocean). The primitive equation of
151 ocean model is numerically solved on an orthogonal curvilinear grid. It uses the isotropic
152 Mercator projection south of 20 °N, and a stretched grid north of 20 °N with two poles in
153 Canada and Siberia, which removes the singularity of spherical coordinate in the Arctic
154 ocean and allows the cross polar flow (Madec and Imbard, 1996). The ORCA1
155 configuration of ocean model corresponds to a resolution of 1 degree of longitude and a
156 variable mesh of 1/3 to 1 degree of latitudes from the equator to pole. It has 46 vertical
157 layers which adopts the z-coordinate with partial steps (Adcroft et al., 1997; Bernard et
158 al., 2006). At the ocean surface, the linear free surface method is used (Roullet and
159 Madec, 2000). Advection of tracer uses the total variance dissipations scheme (TVD)
160 (Zalesak, 1979). Horizontal momentum is diffused with a Laplacian operator and 2-D
161 spatially-varying kinematic viscosity coefficient. The vertical mixing of tracer and
162 momentum is parameterized using turbulent kinetic energy scheme. Besides, the lateral
163 diffusion is solved on the neutral direction (Redi, 1982) and includes eddy-induced
164 advective processes (Gent and McWilliams, 1990). The incoming solar radiation is
165 distributed in the surface layers of the ocean using simplified RGB and chlorophyll-
166 dependent attenuation parameters (Lengaigne et al., 2009). The model uses a diffusive
167 bottom boundary layer (Bechmann and Doscher 1997).

168 **2.3 Sea ice model**

169 The sea ice model in the NESM v3 is CICE v4.1, which is originally developed at the
170 Los Almos National Laboratory. The model solves dynamic and thermodynamic
171 equations for five categories of ice thickness. The lower bound for the five thickness

172 categories are 0, 0.6, 1.4, 2.4, and 3.6 m, respectively. The sea ice deformation is
173 computed basing on the Elastic-Viscous-Plastic scheme (Hunke and Dukowicz 2002)
174 with the ice strength determined by using the formulation of Rothrock (1975). The ice
175 thermodynamics are calculated at five ice layers corresponding to each thickness
176 category instead of zero-layer thermodynamic option.

177 **2.4 Coupling method with OASIS3-MCT**

178 The coupling method is the same as the previous version of NESM v1, and the detail
179 information is described in Cao et al (2015). But the coupler has been upgraded from
180 OASIS3-MCT to OASIS3-MCT_3.0 (Valcke and Coquart 2015), which is a fully
181 parallelized tool for coupled model. The coupler is used to synchronize, interpolate and
182 exchange the coupling fields among the atmospheric, oceanic and sea ice component
183 models. To conserve the exchange coupling fields, the second order conservation
184 interpolation is used in remapping the energy, mass, momentum, and tracers, so to avoid
185 energy, momentum loss and spurious climate drift. The component models are coupled
186 daily.

187 **2.5 Configuration**

188 Two subversions are included in the NESM v3, namely the standard-resolution
189 version (sr) and low-resolution (lr) version. In the atmospheric model, the sr and lr
190 versions have a horizontal resolution of T63 and T31, respectively. The T63 corresponds
191 to about 1.9° in meridional and zonal directions. The sr (lr) version has 47 (31) levels in
192 the vertical which extends from the surface up to 0.01 (1.0) hPa. The resolution of land
193 surface model is the same as the atmospheric model. The resolution of ocean model is

194 higher than atmospheric model with the horizontal resolution of $1^\circ \times 1^\circ$ in sr and $2^\circ \times 2^\circ$ in
195 lr version. The resolution in the meridional direction is refined to $1/3^\circ$ and $2/3^\circ$,
196 respectively, over the tropical region. In the vertical direction, the sr (lr) version has 46
197 (31) vertical layers with the first 15 (9) layers at the top 100 meters. In both sr and lr
198 versions, the sea ice model resolution is about $1^\circ \times 1/2^\circ$ in meridional and zonal directions
199 with four sea ice layers and one snow layer on the top of the ice surface.

200 **2.6 Validation data**

201 To validate the model performance, the following observational data are used: (1) the
202 combined precipitation data of Global Precipitation Climatology Project (GPCP) version
203 2.2 and Climate Prediction Center Merged Analysis of Precipitation (CMAP) (Xie and
204 Arkin, 1997; Lee and Wang, 2014); (2) Hadley Centre Global Sea Ice and Sea Surface
205 Temperature (HadISST), (Rayner et al., 2003); (3) the land surface temperature from
206 CRU-TS-v3.22 (Harris et al. 2014); (4) the radiative fluxes from edition 2.8 of the Clouds
207 and the Earth's Radiant Energy System- Energy Balanced and Filled (CERES-EBAF,
208 Loeb et al. 2009); (5) the atmospheric zonal wind, temperature and specific humidity
209 from ERA-interim (Dee et al. 2011); (6) the ocean temperature and salinity from World
210 Ocean Atlas 2009 (WOA09) (Locarnini et al. 2010).

211 **3. Model improvement and tuning**

212 Model sub-grid processes are represented by physical parameterizations.
213 Improvement of physical parametrizations and calibration the parameters within the
214 parametrization schemes using constraints obtained from observation, physical
215 understanding or empirical estimation is an integral part of the model development cycle.

216 Our strategy to improve model performance and tuning parameters includes three
217 elements. First, our principle is that the final tuning of all parameters must be conducted
218 using the fully coupled climate model. Second, to efficiently identify the model's
219 weakness and the effects of the tuning, we designed a standard metrics for evaluation of
220 the model's climatology and major modes of variability, which include total of 160 fields
221 covering the climatology of the atmosphere, ocean, land and sea ice, and internal and
222 coupled modes of variability such as Madden-Julian oscillation (MJO), Arctic oscillation
223 (AO), Antarctic Oscillation (AAO), North Atlantic Oscillation (NAO), global monsoon,
224 El Nino-Southern Oscillation (ENSO), Atlantic Meridional Overturning Circulation
225 (AMOC), Atlantic multidecadal Oscillation (AMO), Pacific Decadal Oscillation (PDO),
226 and major teleconnection patterns etc. Result from each tuning experiment is compared
227 with the corresponding observations when they are available or CMIP5 multi-model
228 ensemble means when observations are not available. This assessment process helps to
229 identify the models' major problems and the consequences of the tuning, and to
230 understand how the tuning works. Third, a low-resolution version model, the NESM v3lr,
231 is developed, which allows integration about four times faster than the standard
232 resolution version so that the tuning experiments can get results quickly. Once the tuning
233 is successful in the low-resolution model, similar tuning is applied to the standard
234 resolution version with necessary resolution-dependent adjustment.

235 The early developmental version of the v3 model has considerable trends in the
236 surface air temperature and SST, which is associated with the reduced net solar radiation
237 and outgoing longwave radiation (OLR), as well as a large energy imbalance at the top of
238 the atmosphere (TOA). The global mean surface air temperature (TAS) and SST was

239 about 1 K lower than the observed and suffered a continuing drift. Meanwhile, the sea ice
240 extent and sea ice thickness in both Hemispheres kept increasing in the long-term
241 integration. Our first task was aimed at obtaining a nearly balanced global mean energy at
242 the TOA and surface, as well as a reasonable global mean surface temperature with
243 perpetual pre-industry forcing. This is critical for achieving a stable long-term integration
244 in pre-industry simulation which acts as the benchmark experiment for entry card for
245 CMIP6 (DECK) and historical run as well as some other MIPs. Another tuning
246 consideration is the long-term climatology and internal modes of the Earth System in the
247 current climate condition. Efforts are made to minimize the biases in the simulated SST,
248 sea level pressure (SLP), precipitation, zonal mean temperature and wind, ocean mean
249 state (sea surface salinity, mix layer depth etc.) as well as ENSO, global monsoon, and
250 MJO. In addition, the historical evolution of surface temperature is an important
251 measurement of the model's fidelity. This is along with the abrupt quadrupling and
252 gradually increased $1\% \text{ yr}^{-1}$ CO_2 experiments in estimating the model climate sensitivity.

253 The key tuning parameters in the v3 versions are related to the stratiform cloud,
254 cumulus convection, ocean mixing process, and sea ice albedos. Iterative tunings were
255 conducted in the standalone component models with observed/reanalysis forcing and in
256 the coupled model during the PI control run. To achieve a better global mean radiative
257 energy level and a near zero (within a few tenth W m^{-2}) net global mean heat flux budget,
258 the parameter calibrations are conducted on the relative humidity threshold that is related
259 to cloud forming process and the estimated cloud cover (Mauritsen et al. 2012). The
260 parameters involved in the cloud microphysics are also tuned, including the accretion of
261 cloud water (ice) to rain (snow), auto-conversion rate of cloud water to rain, and ice

262 crystal and rain drop fall speeds, which are recognized as effective parameters in
263 affecting both short and longwave radiation (Mauritsen et al. 2012, Hourdin et al. 2017).

264 Even with reasonable global mean SST, the model simulated excessive sea ice extent
265 over the Arctic, especially over the Davis Strait, Fram Strait and North Atlantic during
266 winter (figure not shown). The export of sea ice from Davis Strait significantly increases
267 the SST and salinity biases. To mitigate the North Hemisphere sea ice extent bias, the sea
268 ice albedo and ice transport-related parameters were adjusted. Sea ice albedo is one of the
269 most effective tunable parameter to adjust sea ice extent and thickness (Hunck 2010). The
270 default sea ice albedo parameterization takes into account the radiative spectral band, ice
271 thickness and others. The visible and near-infrared albedos are set to 0.73, 0.31 for ice
272 greater than 0.3 m, and the corresponding cold snow albedos are 0.93 and 0.65,
273 respectively. Those values are slightly smaller than the corresponding default
274 configurations, which are 0.73, 0.31, 0.93, and 0.65 respectively. On the other hand, the
275 sea ice motion is largely driven by the ocean currents, sea surface height gradients and
276 wind stress. The efficiencies of air-ice and ocean-ice drag are important for sea ice
277 transport, as well as sea ice extent during winter and spring (Urrego-Blanco et al. 2016).
278 In this model, the ice surface roughness was decreased and the ocean-ice drag coefficient
279 was increased to decrease the sea ice export over Davis and Fram Strait. This is based on
280 the understanding that the air-ice and ocean-ice drag parametrizations have large
281 uncertainty in the current CICE model.

282 Concerning the internal modes, ENSO and Intraseasonal oscillation (ISO) are
283 recognized as the dominate modes on the interannual and intraseasonal time scale,
284 respectively. They significantly influence the tropical and global climate through

285 atmospheric teleconnections. Much attention was paid to improve the simulation of
286 ENSO and ISO in v3.

287 The ENSO-related SST variability, ENSO phase locking to annual cycle, and the
288 equatorial Pacific cold SST bias are closely related (Ham and Kug 2014). CMIP5 models'
289 results suggested that the models having less cold tongue SST bias reproduce more
290 realistic ENSO phase locking owing to models' simulation of more realistic coupled
291 feedbacks. The change of cloud parametrization has an effect on the mitigation of the
292 cold tongue SST bias, which can lead to an improved ENSO phase locking (Wengel. et al.
293 2018). In the NESM v3 model, the parameter of deep convective entrainment and
294 convective mass flux above the buoyance layer have been increased which resulted in a
295 reduced cold tongue bias and zonal wind stress over the equatorial Eastern Pacific,
296 removal of the excessive SST variance over the central Pacific, and improved ENSO
297 phase locking.

298 The entrainments in deep and shallow convections are associated with the moisture
299 supply in the free atmosphere. Strong convection plumes can increase the water supply
300 for the formation of stratiform clouds, leading to an increase of stratiform precipitation.
301 The interaction between wave dynamics and precipitation heating is essential for the
302 development and propagation of intraseasonal oscillation (Fu and Wang 2009). The
303 entrainment rates associated with convections are adjusted which allow more stratiform
304 precipitation formed in the coupled model. It strengthens the ISO signal and also
305 significantly enhances the MJO eastward propagation.

306 **4. Model stability under fixed external forcing**

307 The standalone spin-up of ocean and land states is an efficient method to accelerate
308 the spin up process in the coupled model, especially in the PI control simulation. The
309 ocean component model is spun up with 2000s' atmospheric and sea ice climatological
310 forcings, such as radiation, winds, precipitation, sea ice concentration and so on. The
311 offline integration length is 2000 (4000) model years for ocean component of NESM v3sr
312 (v3lr) model. The land surface initial condition is adopted from MPI-ESM-LR model
313 which has active dynamic vegetation and carbon cycle. The initial conditions of the
314 atmospheric and sea ice model in the coupled system used the modern observations. The
315 pre-industry control simulation is performed following the CMIP6 protocol with forcings
316 fixed at the year 1850 or decadal mean of 1850s based on the characteristic of forcing
317 agents. The choice of forcing in 1850 or of decadal mean in 1850s is to peruse a near
318 equilibrium state of the earth system, as well as minimize the initial shock of the ensuing
319 historical simulation. The earth orbital parameters, greenhouse gases, ozone
320 concentration, land surface conditions are fixed at their 1850 values. The solar constant
321 used is the 11 years mean from 1850-1860. The natural tropospheric aerosol and 1850s
322 mean stratospheric aerosol forcing were employed in the coupled system. During the
323 whole PI simulation, there was no land use/land cover change. The coupled model was
324 spun up for 400 years so that the model reached an equilibrium state. After that, a 500
325 years PI simulation is conducted and evaluated in this study.

326 One of major purposes of the PI control experiment is to verify the model's stability in
327 the perpetual, unchanged forcing conditions. In this section, emphasis will put on
328 evaluation of the equilibrium state of the top-of-atmosphere (TOA), atmosphere-ocean-
329 sea ice interface to reveal the energy, water, and mass conservation of the whole system.

330 The energy input at the TOA is the major energy source for the Earth System. It is vital to
331 minimize the net energy imbalance at the TOA and surface, which can mitigate
332 temperature drift in the system. At the air-sea interface, the major indicators are the land
333 surface temperature and ocean surface temperature; they also work as the direct monitor
334 of system energy conservation. The precipitation is the most important part of global
335 hydrological cycle, which involves the energy exchange, as well as mass exchange
336 among each climate system components. The ocean salinity is sensitive to the state of
337 surface hydrological cycle, land runoff and sea ice melting/formation process. Sea ice
338 extent is a good indicator of sea ice amount in both Arctic and Antarctic regions, and it is
339 sensitive to ocean heat content drift and high latitude energy transfer. To better quantify
340 the climate drifts, linear trends were calculated for all evaluation variables.

341 The time evolution of global mean energy budget at the TOA, Earth surface and ocean
342 surface are shown in Fig. 2. The global mean net shortwave radiation at the TOA
343 averaged over the 500-year integration is 238.55 W m^{-2} and the corresponding outgoing
344 longwave radiation (OLR) is -238.39 W m^{-2} , resulting in a net atmospheric energy gain of
345 0.17 W m^{-2} . The net heat budget at the TOA shows a negligible decreasing trend of -
346 $0.0041 \text{ W m}^{-2}(100\text{yr})^{-1}$. At the Earth surface, the net energy imbalance is 0.31 W m^{-2} in
347 the whole integration period with an insignificant decreasing trend of $-0.00576 \text{ W m}^{-2}$
348 $(100\text{yr})^{-1}$. The negative trends are shown at both the TOA and surface, indicating the
349 coupled system could lead to a more stable state when the integration extends. Note that
350 there is a difference of 0.14 W m^{-2} between surface and TOA net energy budget, which
351 means the model atmosphere produces artificial energy. This problem is found also in the

352 AMIP experiment and it probably due to the energy non-conservation in the model
353 dynamical core.

354 The trends in the surface temperature indices, namely global mean surface air
355 temperature, land surface temperature and SST, reveal the energy conservation and
356 stability as well as the stability of sea-sea ice-air interaction in the coupled system (Fig.
357 3). The mean value of the near surface air temperature (TAS) is 14.9 °C in the entire
358 period, and the linear trend of TAS is 0.00214 °C (100yr)⁻¹. This trend is mainly
359 attributed to the land surface temperature rather than SST. The linear trend of land
360 surface temperature is -0.00984 °C (100yr)⁻¹. The slow balance of terrestrial (land)
361 vegetation may be one of the reasons. The global time-mean SST is 17.7 °C, which is
362 consistent with the observation measured during the decade of 1870-1880. The negligible
363 SST trend (0.00731°C (100yr)⁻¹) indicates the global mean SST reached a quasi-
364 equilibrium state. As the most important component of global hydrological cycle, the
365 global mean precipitation has nearly no trend (Fig. 3). It is of interest that the global
366 mean SST exhibits a long-term variability with a period of 50-100 years in this
367 simulation. Possible mechanism and processes causing this variability will be discussed
368 in a follow-up study.

369 To further verify the stability of ocean component model, more variables are
370 represented in Fig. 4. At the beginning of the PI experiment (coupled model spin up), the
371 sea surface salinity (SSS) has a quick adjustment process. The global mean SSS is
372 decreased from 34.6 psu to 34.2 psu in 30 years. After the spin up, the mean value of SSS
373 is 34.2 psu, which is 0.5 psu fresher than the observed value. The long-term trend of SSS
374 is -0.0077 psu (100yr)⁻¹, which indicates the ocean water flux is maintained at a relatively

375 stable state. Meanwhile, the global mean sea water salinity (SWS) is 34.7 psu with a
376 linear trend of $-0.0038 \text{ psu (100yr)}^{-1}$. The total sea water temperature has an increase
377 trend of $0.032 \text{ }^\circ\text{C (100yr)}^{-1}$, this is consistent with the surface energy budget which shows
378 a 0.43 W m^{-2} heating at the ocean surface. Furthermore, the linear trend at the last 100
379 year is smaller than the first 100 year. The decrease of linear trend implies the model
380 becomes more and more stable during the integration.

381 Atlantic Meridional Overturning Circulation (AMOC) is a major source of
382 decadal/multidecadal variability of the Earth system and influences the Arctic sea ice
383 extent variability over Atlantic sector (Mahajan et al. 2011). The time series of the
384 maximum strength of the Atlantic Meridional Overturning Circulation (AMOC) at
385 $26.5 \text{ }^\circ\text{N}$ is evaluated. The mean strength of AMOC is 14.8 sv, which is underestimated
386 comparing to the modern observational value of 18.5 sv (Cunningham et al. 2007). The
387 AMOC strength has a small linear trend and significant multidecadal variability.

388 The middle and high latitude climate, as well as AMOC, is largely affected by sea ice
389 state and its variability. Following the IPCC report, the February, September and annual
390 mean of Northern and Southern Hemisphere sea ice extents (SIEs) are diagnosed for the
391 entire PI experiment period. The time evolutions of SIEs are plotted in Fig. 5. In the
392 Northern Hemisphere (NH), the annual mean, February and September mean SIE are 11
393 $\times 10^6 \text{ km}^2$, $12.7 \times 10^6 \text{ km}^2$, and $7.58 \times 10^6 \text{ km}^2$, respectively. The trends of SIE over the
394 NH in the annual mean, February and September mean SIE are $0.039 \times 10^6 \text{ km}^2(100\text{yr})^{-1}$,
395 $0.06 \times 10^6 \text{ km}^2(100\text{yr})^{-1}$, and $0.02 \times 10^6 \text{ km}^2(100\text{yr})^{-1}$, respectively. These trends are small,
396 suggesting that the Arctic SIE maintains a steady state. Over the SH, on the other hand,
397 the trends in the annual mean, February and September mean SIE are $-0.07 \times 10^6 \text{ km}^2$

398 $(100\text{yr})^{-1}$, $-0.002 \times 10^6 \text{ km}^2 (100\text{yr})^{-1}$, and $-0.1 \times 10^6 \text{ km}^2(100\text{yr})^{-1}$, respectively. This
399 indicates that a significant trend exists in the SH September only. The annual mean,
400 February and September mean SIEs are $7.27 \times 10^6 \text{ km}^2$, $1.73 \times 10^6 \text{ km}^2$, and 11.7×10^6
401 km^2 , respectively. The bias of the SH sea ice extent is related to the extensive solar
402 radiation over the Southern Ocean although the model overestimated cloud cover over
403 there (figure not shown). This is in part due to the thinner cloud optical depth in the
404 simulated low-level cloud and shallow mixed layer depth over the Southern Ocean (Sterl
405 et al. 2012).

406 **5. Simulated climatology**

407 The climatological mean states of some key fields for energy and water balance
408 obtained from the average results for the last 100-year of the PI control run are compared
409 with observations, including TOA energy fluxes, SST, land surface temperature,
410 precipitation, atmospheric zonal mean zonal wind, temperature and specific humidity,
411 and sea surface salinity. The observed energy fluxes data covers the period of 2001-2014
412 and the observed SST is averaged over the period of 1870-1880. The observational
413 estimate of the land surface temperature is based on 1901-1910 mean of CRU-TS-v3.22.
414 The rest of mean states are derived for the period of 1979-2008.

415 The observed annual mean net shortwave (SW) radiation and OLR at the TOA and the
416 model bias are shown in Fig. 6. The simulated global mean net solar radiation is 238.65
417 W m^{-2} which is smaller than the observation from CERES-EBAF data (Table 1). The
418 model bias indicates the excessive SW absorption over the ITCZ region and the Southern
419 Ocean, and less SW reflection over the middle latitude oceans that implies the planetary

420 albedo is too high (Fig. 6b) . Figure 6c shows the outgoing longwave radiation (OLR)
421 which is balanced by the TOA net downward solar radiation and represents the
422 atmospheric and cloud top temperature distribution. The global mean OLR is -238.45 W
423 m^{-2} in the model that is close to the counterpart from the CERES data and the differences
424 are within the range of uncertainty among different observations (Loeb et al. 2009). The
425 model simulates well the vigorous deep convection-related low OLR over the Indo-
426 Pacific warm pool as well as the high OLR in the desert and subtropical regions.
427 However, the model overestimates the OLR over the majority of ITCZ, Indo-Pacific
428 warm pool regions, and the off-South American coast region in the South Pacific. The
429 model also underestimates the OLR in the North Atlantic storm track and western part of
430 the Pacific subtropical high regions. These biases arise primarily from the errors in
431 simulated cloud fields.

432 The cloud radiative effect is defined as the difference between the clear-sky and full-
433 sky radiation. It indicates how cloud affects the radiation budget at the TOA. The
434 simulated SW and longwave (LW) cloud radiative effects (CRE) are compared with the
435 CERES-EBAF ed2.8 in Fig. 7. The NESM v3 model simulates a global averaged annual
436 mean SW CRE of -48.4 W m^{-2} compare to the observed value of -47.2 W m^{-2} . The
437 simulated LW CRE is 25.98 W m^{-2} which is close to the observed value of 25.75 W m^{-2} .
438 The total cloud radiative effect in the NESM v3 is -22.5 W m^{-2} , this is comparable with
439 the CERES-EBAF observation (-21.45 W m^{-2}). The bias pattern of SW CRE is similar to
440 that of the net SW radiation at TOA. The model produces positive SW CRE over the
441 tropics although the simulated cloud cover bias is small (figure not shown). This suggests
442 the importance of cloud vertical distribution and cloud properties in determining the CRE.

443 In addition, the LW CRE bias is smaller than the SW CRE indicating the model has
444 better representation of high cloud.

445 The climatological mean SST and land surface temperature (LST) are compared with
446 the observational data in Fig. 8. SST is one of the most important variables in the coupled
447 system which reflects the quality of the model's simulation of atmosphere-ocean
448 interaction processes. The model well captures global distribution of SST with a warm
449 pool in the Indo-Pacific region and the cold tongue over the eastern Pacific. There are
450 warmer biases in the Southern Ocean and off the western coasts of America and Africa
451 (Fig.8 b), which is linked to the excessive downward shortwave radiation induced by the
452 negative bias in simulated stratiform clouds. Significant cold SST biases are found in the
453 high-latitude North Atlantic around 50 °N with a maximum negative bias of -4 K. Cold
454 biases are also seen in the subtropical North Pacific and North Atlantic.

455 The land surface temperature is shown in comparison with CRU-TS-v3.22 (1901-
456 1910). The model well reproduces the basic patterns of the LST, including warm
457 continents in equatorial regions and cold continents close to Polar Regions. The
458 simulated global averaged (70 °S-90 °N) LST is 12.72 °C, which is slightly warmer than
459 the observed value of 12.58 °C (Table 1). The warm temperature bias is mainly found
460 over Central Asian, Canadian and Australian Continent (Fig.8d).

461 Figure 9 compares the spatial pattern of observed and simulated precipitation. The
462 simulated precipitation pattern and intensity resemble the observations (pattern
463 correlation coefficient, PCC=0.86), which capture the observed rain bands over ITCZ,
464 South Pacific Convergence Zone (SPCZ), tropical Indian Ocean and the midlatitude

465 storm track regions. However, the so-called double-ITCZ precipitation bias exists in the
466 Pacific Ocean and Atlantic Ocean, which is partially linked to simulated TOA shortwave
467 radiation bias (Xiang et al. 2017) and the insufficient stratocumulus clouds over eastern
468 Pacific (Bacmeister et al. 2006, Song and Zhang 2009). The precipitation bias shows a
469 dipole pattern over the tropical Indian Ocean. From an atmospheric point of view, such a
470 model deficiency is mainly attributed to the SST bias over the tropics, but it is essentially
471 a coupled model bias.

472 The zonal mean climatological temperature, zonal wind, and specific humidity along
473 with their biases with respect to ERA-interim, are presented in Fig.10. Overall, the model
474 captures the temperature, zonal wind and specific humidity distribution reasonably well.
475 The temperature and zonal wind biases are small over majority of the region. However,
476 there exist 6 K cold biases at 200 hPa over high latitudes in both hemispheres (Fig. 10b).
477 The biases increase the tropics-to-pole temperature gradient in the upper troposphere,
478 which produced an enhanced subtropical jet. The westerly wind bias is about 6 m s^{-1} in
479 the subtropical jet of both hemispheres and over the equator in the upper-troposphere (Fig.
480 10d). The model simulated less water vapor within the boundary layer while
481 overestimated the specific humidity above the boundary layer (Fig. 10f).

482 The sea surface salinity (SSS) is an integrated indicator for the hydrological
483 interaction among ocean, atmosphere, land runoff and sea ice, as well as ocean
484 circulation. Accurate simulation of ocean circulation in climate models is essential for
485 correct estimation of the transient ocean heat uptake and climate response, sea level rise,
486 and coupled modes of climate variability. Figure 11 shows the observed climatological
487 SSS and the model bias. In general, the model simulates realistically the high SSS over

488 the subtropics, where precipitation is low and evaporation is high, and the relatively low
489 SSS over the ITCZ region where precipitation is heavy. The global mean SSS has a
490 negative bias of 0.5 psu, which is mainly due to the fresh bias over the North Atlantic and
491 the western equatorial Pacific. Over the western equatorial Pacific, extensive
492 precipitation is the major cause. Over the North Atlantic, the excessive net input of fresh
493 water is a primary cause, which is augmented by weak evaporation at high latitudes. The
494 fresh water bias in the North Atlantic can also be attributed to the bias in simulated North
495 Atlantic Currents and excessive sea ice melt over the Labrador Sea. Previous studies
496 pointed out that the fresh water bias over high latitudes of North Atlantic can weaken
497 ocean convection, so that weaken the AMOC (Rahmstorf 1995).

498 The simulated February and September sea ice concentration in both hemispheres are
499 compared with observation in the period of 1870-1880 (Fig. 12, 13). In the NH, the
500 spatial distribution of summer and winter sea ice concentration is well captured by the
501 NESM v3. Over the Southern Hemisphere, the model significantly underestimates sea
502 ice concentration, especially during austral summer. As discussed in the previous section,
503 there is an extensive solar radiation bias over the Southern Ocean which leads to the
504 warm SST bias, especially during local summer when solar radiation is high.

505 **6. Climate sensitivity to CO₂ forcing**

506 Quantification of climate response to different forcing and estimation of the associated
507 radiative forcing can be benefited from sensitive experiments with a single perturbation
508 forcing, such as an abruptly quadrupling CO₂ (abrupt-4xCO₂) simulation and a 1% yr⁻¹
509 CO₂ increase (1pctCO₂) experiments. Following the CMIP6 protocols, the two CO₂

510 experiments are designed to document basic aspects of the NESM v3 model response to
511 greenhouse gas forcing. They are both branched from the PI simulation and the only
512 difference are the imposed CO₂ concentrations. In the abrupt-4xCO₂ experiment, the
513 atmospheric CO₂ concentration is abruptly quadrupled (1139 ppm) with respect to the PI
514 condition (274.75 ppm) in the very beginning of the experiment. The 1pctCO₂ is
515 designed as gradually increasing the CO₂ concentration at the rate of 1% per year. Both
516 experiments were initiated at the end of year 100 of the PI experiments, and each of them
517 was integrated for 150 yrs.

518 Figure 14 shows the global annual mean surface air temperature (TAS) changes with
519 respect to its mean value in the PI experiment. Once the atmospheric CO₂ instantaneous
520 quadrupling, the radiative forcing defined by the net downward heat flux induced by the
521 changing atmospheric carbon dioxide concentration forces the stratospheric and
522 tropospheric circulations to adjust, thereby changing the surface temperature. The TAS
523 rapidly increases by approximately 4.5 K in the first 20 years in response to the imposed
524 radiative forcing. After the rapid initial increase, the TAS gradually increases, mitigating
525 the energy imbalance at the TOA.

526 The abrupt 4 x CO₂ experiment is used not only to diagnose the fast response of the
527 Earth system, but also to quantify the radiative forcing, as well as to estimate the
528 Equilibrium Climate Sensitivity (ECS). The ECS is regarded as the global equilibrium
529 TAS change in response to the doubling atmospheric carbon dioxide concentration. It is
530 also indicated by the ratio of the radiative forcing to the climate feedback parameter. The
531 regression of TOA energy imbalance and global mean TAS change is an effective
532 method to obtain those estimations (Gregory et al. 2004), since it doesn't require the

533 equilibrium state of GCM. The intersection of regression line and the y-axis is recognized
534 as the adjusted radiative forcing, and the intersection on the x-axis is an indication of the
535 equilibrium temperature. The slope of the regression line is the climate feedback
536 parameter.

537 The relationship between the change in the net TOA energy imbalance and global
538 mean TAS change is plotted in Fig. 15. It shows that the TOA radiative imbalance is
539 around 7.24 W m^{-2} when the assumed global TAS is unchanged, although the radiative
540 forcing is affected by the rapid adjustments of stratosphere in the first year and therefore
541 reduced the effective radiative forcing (Gregory and Webb 2008). To balance the net
542 TOA energy, the regression predicted an equilibrium temperature change of 7.38 K in
543 this model, yields a climate feedback parameter of $-0.98 \text{ Wm}^{-2}\text{K}^{-1}$. Since the radiative
544 forcing is logarithmically related to the carbon dioxide concentration if we approximate
545 the climate feedback parameter as a constant (Hansen et al. 2005), this gives the ECS of
546 3.69 K. Andrews et al. (2012) found that the CMIP5 ensemble mean of regressed $4 \times \text{CO}_2$
547 adjusted forcing is $6.89 \pm 1.12 \text{ W m}^{-2}$, and the climate feedback parameter is -1.08 ± 0.29
548 $\text{Wm}^{-2}\text{K}^{-1}$, with the ECS of $3.37 \pm 0.29 \text{ K}$. The carbon dioxide-induced radiative forcing
549 and climate feedback parameter estimated by the NESM v3 model are comparable with
550 CMIP5 model ensemble, albeit the estimated ECS is about 10% higher.

551 The climate sensitivity parameter consists of the longwave clear sky, shortwave clear
552 sky, longwave cloud forcing and shortwave cloud forcing terms. They are defined by the
553 heat flux differences between the abrupt- $4 \times \text{CO}_2$ experiment and PI experiment. The sum
554 of the longwave cloud forcing and shortwave cloud forcing is the total CRE. Here the
555 downward fluxes are defined as positive. Figure 16 shows the relationships between the

556 changes in the global mean heat fluxes and the change in the surface air temperature. The
557 longwave clear sky feedback strength is $-1.63 \text{ Wm}^{-2}\text{K}^{-1}$, which is partially offset by the
558 shortwave clear sky feedback ($0.68 \text{ Wm}^{-2}\text{K}^{-1}$), resulting in a residual feedback strength of
559 $-0.95 \text{ Wm}^{-2}\text{K}^{-1}$, which is close to the climate sensitivity parameter estimated in this model
560 ($-0.98 \text{ Wm}^{-2}\text{K}^{-1}$). The slopes of the shortwave and longwave cloud forcing have nearly
561 the same magnitude but with opposite signs, yielding a small positive cloud radiative
562 effect ($0.02 \text{ Wm}^{-2}\text{K}^{-1}$) in this model. It could be the reason of slightly high ECS of NESM
563 v3 since the CMIP5 model results suggested that the GCM with higher sensitivity is
564 associated with a positive CRE feedback (Andrews et al. 2012). And the CRE is a major
565 contributor to the uncertainty in climate sensitivity parameter in CMIP3 and CMIP5
566 models, although its magnitude is small compared to other flux terms (Webb et al. 2006,
567 Andrews et al. 2012).

568 Figure 17 displays the global distributions of temperature and precipitation in response
569 to the quadrupling CO_2 forcing, which are defined by the departure of the last 30-year
570 climatology from the corresponding climatology in the PI experiment. The most
571 pronounced warming is seen over the Arctic region where sea ice albedo feedback
572 dominates (Screen and Simmonds 2010). The relative small temperature change is over
573 the Southern Ocean and North Atlantic. The warming is more significant over land than
574 ocean, especially in the Northern Hemisphere. The mean surface temperature over land
575 and ocean are 8.0 K and 5.2 K, respectively. The equatorial Pacific shows an El Nino-like
576 warming. The zonal mean surface temperature change shows an obvious polar
577 amplification, especially over the Arctic Ocean; and stronger warming over the NH high
578 latitudes and weak warming in the SH middle latitudes. The Large NH temperature

579 increase is attributed to the strong warming over the Arctic Ocean and the large land area
580 in the NH.

581 A direct consequence of global warming is the rising atmospheric specific humidity
582 and precipitation. The global mean precipitation is increased from 2.87 mm day⁻¹ to 3.12
583 mm day⁻¹, resulting in a precipitation increase of 1.4% per Kelvin global warming.
584 Significant precipitation increases are seen in the equatorial Pacific and Northern Indian
585 Ocean as well as along the Pacific storm track (Fig. 17). Decreased precipitation is
586 evident in the sub-tropical descent zones. Note that precipitation is decreased over the
587 Amazon region, where the model has a dry bias in climatology. The global distribution of
588 precipitation change appears to be dominated by the wet-get-wetter pattern (Held and
589 Soden, 2006).

590 In reality, the CO₂ increase is gradually rather than abrupt. The 1pctCO₂ experiment is
591 designed to examine the transient climate response (TCR), which is calculated by using
592 the global mean TAS change between the averaged 20-year period centered at the timing
593 of CO₂ doubling (year 60-80 in 1pctCO₂ experiment) and the PI experiment. The time
594 evolution of the global mean TAS anomalies with respect to the PI experiment is shown
595 in Fig. 18. A linear increase of temperature anomalies is presented in the gradually CO₂
596 increasing experiment. The temperature anomalies averaged between year 60 and 80 are
597 2.16 K. This value of TCR is significantly small than the ECS, demonstrating that the
598 ocean heat uptake delays surface warming. The estimation from CMIP5 models shows
599 that the mean TCR is 1.8±0.6 K (Flato et al. 2013), implying that the NESM v3 is
600 comparable to other CGCMs.

601 **6. Conclusion**

602 The development of version 3 of the Nanjing University of Information Science and
603 Technology (NUIST) Earth System Model (NESM v3) aims at building up a
604 comprehensive numerical modeling laboratory for multi-disciplinary studies of the
605 Climate System and Earth System. As a subsequent version of NESM v1, it has upgraded
606 the atmospheric and land surface models, increased the ocean model resolution, improved
607 coupling conservation and modified model physics.

608 The NESM v3 couples the ECHAM v6.3 atmospheric model, JSBACH land surface
609 model, NEMO v3.4 ocean model, and CICE v4.1 sea ice model by using OASIS3-
610 MCT_3.0 coupler. The improvement of model physics mainly focuses on convective
611 parameterizations, cloud macrophysics and microphysics, and ocean-sea ice coupling.
612 The model physics modifications and parameters adjustments are targeted at (1)
613 obtaining stable long-term integrations and reasonable global mean states under the
614 preindustrial (PI) forcing, (2) mitigating the biases in the mean climatology and internal
615 modes of climate variability with respect to the modern observations in the present-day
616 forcing condition, and (3) simulating reasonable climate responses to transient and abrupt
617 CO₂ forcing.

618 A 500-yr PI experiment is conducted and analyzed to test the model's computational
619 stability. As shown in Sec. 4, the long-term climate drifts in NESM v3 are generally
620 negligibly small, especially in the global radiative energy and temperature. The simulated
621 net downward energy flux at the TOA and surface are 0.17 Wm⁻² and 0.35 Wm⁻²,
622 respectively. The near-equilibrium model long-term temperature evolution is benefited

623 from the near-zero energy imbalance and negligibly small trends in the energy balance.
624 The global mean near surface air temperature is 14.9°C with a trend of 0.00214 °C
625 (100yr)⁻¹. The linear trends of the land surface and sea surface temperature are -0.00984°C
626 (100yr)⁻¹ and 0.00731°C (100yr)⁻¹, respectively. However, the total sea water temperature
627 has a warming trend of 0.03°C (100yr)⁻¹, which can be explained by the small but
628 persistent positive downward energy flux into the ocean. The stable long-term evolutions
629 of precipitation, sea surface salinity (SSS) and sea water salinity (SWS) demonstrate the
630 conservation of global water. At the beginning of PI experiments spin up, there was a
631 freshening trend in SSS, which is associated with the ocean adjustment. The fresher SSS
632 has no significant influence on SWS. After the spin up, the global mean SSS and SWS
633 have no appreciable trends although the SSS is fresher than the observed counterpart. The
634 Northern Hemispheric annual mean, February, and September mean SIEs maintain a
635 steady value at 11.4 x 10⁶ km², 13.4x 10⁶ km², and 7.78x 10⁶ km², respectively. However,
636 the simulated Southern Hemisphere SIEs are less than present-day observation. The
637 conservation properties of NESM v3 are encouraging, fulfilling a highly desirable
638 constraint for climate models aiming for multidecadal, centennial and longer simulations.

639 The last 100-year results are compared with the available observations as presented in
640 Table 1. The TOA energy budget and cloud radiative effect are attracted more attention
641 since its importance in understanding the climate change. The model results show a
642 realistic global climate, although the bias of energy state still exists, especially over Indo-
643 Pacific region, which may be related to the treatment of cloud and convection
644 parameterization. The annual mean SST/LST is well produced in the model, but large
645 cold biases exist in the North Atlantic and significant warm biases in the Southern Ocean,

646 and warm temperature bias over the central Asian. The simulated mean precipitation is
647 reasonably realistic, but suffers the double ITCZ syndrome. The fresh bias in SSS in the
648 tropical western North Pacific can be attributed to the extensive precipitation and the
649 fresh bias over the mid-latitude North Atlantic is related to underestimated evaporation.
650 The sea ice coverage is well reproduced by the model over the Arctic in February and
651 September; however, it is underestimated over the Antarctic where SST has a warm bias.

652 The model produces a radiative forcing, under the abrupt quadrupling carbon dioxide,
653 of 7.24 W m^{-2} with a climate feedback parameter of $-0.98 \text{ W m}^{-2}\text{K}^{-1}$, yielding a warming
654 of 7.38 K at the estimated equilibrium state. The transient climate sensitivity is 2.16 K
655 which is estimated from the $1\% \text{ yr}^{-1} \text{ CO}_2$ gradually increasing experiment. The NESM v3
656 model is amongst the more sensitive side of the CMIP5 class of global climate models.

657 At last, this paper isn't aimed at providing a comprehensive evaluation of all model
658 aspect. Its response to given SST forcing in AMIP and the historical forcing in the
659 coupled model, the corresponding modern climatology, internal and coupled modes of
660 climate variability, as well as regional climate variability will be discussed in detail in an
661 accompanying paper later.

891

892 Table and Figure

893 Table 1. Summary of the global averaged annual mean values for radiation, temperature and
894 precipitation compare to observations. The observed energy estimations are from CERES ed2.8
895 on the period of 2001-2014. The observed SST/LST data is derived from Hadley SST/CUR on
896 the period of 1870-1880/1901-1910. The combined CMAP and GPCP precipitation.

897 Figure 1. Coupled structure of NESM v3 model.

898 Figure 2. Radiative energy balances in NESM v3. Time series of the net radiative energy fluxes
899 at TOA (downward, $W m^{-2}$ upper) and the net heat flux at the Earth surface ($W m^{-2}$, bottom) from
900 year 0 to year 500 in the Preindustrial control experiment. The long-term mean value and trend
901 are indicated in the left upper corner. The black lines indicate annual mean values and the red
902 lines indicate their 9-yr running mean values.

903 Figure 3. Results from the Preindustrial control experiment. Annual mean time series of the
904 surface temperature and precipitation from year 0 to year 500 in the Preindustrial control
905 experiment, from top, near surface air temperature ($^{\circ}C$), land surface temperature ($^{\circ}C$), sea surface
906 temperature ($^{\circ}C$), and precipitation ($mm d^{-1}$). The long-term mean value and trend are indicated in
907 the left upper corners. The black lines are annual mean values and the red lines are their 9-yr
908 running mean values.

909 Figure 4. Results from the Preindustrial control experiment. Annual mean time series of the ocean
910 variables from year 0 to year 500 from top, sea surface salinity (psu); sea water salinity (psu); sea
911 water temperature ($^{\circ}C$), AMOC strength at $26.5^{\circ}N$ (sv). The sea water salinity and sea water
912 temperature are the volume-mean values for the full-depth global ocean. The long-term mean
913 value and trend are indicated in the left upper corner. The black lines are annual mean values and
914 the red lines are their 9-yr running mean values.

915 Figure 5. Results from the Preindustrial control experiment. The Northern Hemisphere (NH) and
916 Southern Hemisphere (SH) sea ice extents (SIEs, unit: $10^6 km^2$) time series year 0 to year 500 in

917 the Preindustrial control experiment. The black, blue and green lines represent the annual mean,
918 February and September SIEs, and the red lines are the corresponding 9-yr running mean. The
919 long-term trends of annual mean SIEs are indicated in the left upper corner of each panel.

920 Figure 6. Annual mean TOA net shortwave radiation (left) and OLR (right, units: W m^{-2}) derived
921 from observation (top), and the model bias (bottom). The observed radiation field were derived
922 from the Clouds and the Earth's Radiant Energy System (CERES) dataset (Loeb et al. 2009).

923 Figure 7. Annual mean TOA shortwave (left) and longwave (right) cloud radiative effect (right,
924 units: W m^{-2}) derived from observation (top), and the model bias (bottom). The observed
925 radiation field were derived from the Clouds and the Earth's Radiant Energy System (CERES)
926 dataset (Loeb et al. 2009).

927 Figure 8. The annual mean SST (left) and land surface temperature (right, $^{\circ}\text{C}$) derived from
928 observation (top), and the model bias (bottom). The observed SST climatology was derived from
929 the Hadley Center sea-Ice and Sea Surface Temperature (HadISST, Rayner et al., 2003) for the
930 period of 1870-1880. The observed land surface climatology was derived from the CRU-TS-
931 v3.22 (Harris et al. 2014) for the period of 1901-1910.

932 Figure 9. The climatological mean precipitation (mm day^{-1}) in observation, NESM v3 and model
933 bias. The observed precipitation was derived from a Merged precipitation dataset (Lee and Wang
934 2014), which is the arithmetic mean of the monthly data from the Global Precipitation
935 Climatology Project (GPCP) version 2.2 (Adler et al., 2003) and Climate Prediction Center
936 Merged Analysis of Precipitation (CMAP, Xie and Arkin, 1997).

937 Figure 10. The zonal and climatological mean of temperature (left, K), zonal wind (middle, m s^{-1})
938 and specific humidity (right, g kg^{-1}) in observation (top) and model bias (bottom). The
939 observational data were derived from ERA interim (1979-2008).

940 Figure 11. Same as in Fig. 9 except for the annual mean sea surface salinity (psu). The observed
941 SSS data is from the World Ocean Atlas 2009 (WOA09) (Locarnini et al. 2010).

942 Figure 12. Climatological Arctic sea ice concentration in HadISST (upper), NESM v3 (middle),
943 and model bias (bottom) for February (a,c,e) and September(b,d,f). The observed sea ice
944 concentration is averaged over the period of 1870-1880.

945 Figure 13. As in Fig. 12 except for Antarctic.

946 Figure 14. Results from the abrupt quadrupling CO₂ experiment. Global-mean surface air
947 temperature change relative to the counterpart in the PI experiment.

948 Figure 15. Results from the abrupt quadrupling CO₂ experiment. The relationships between the
949 change in the net TOA radiative flux and the global-mean surface air temperature in NESM v3
950 model. The solid line represents linear least squares regression fit to the 150 years of model
951 output data. The interception at $\delta T = 0$ indicates the adjusted radiative forcing ($F=7.24\text{Wm}^{-2}$). The
952 slope of the regression line measures the strength of the feedbacks in the climate system, the
953 climate feedback parameter ($-0.981\text{Wm}^{-2}\text{K}^{-1}$). The interception at x-axis gives the equilibrium δT
954 (7.38 K).

955 Figure 16. Results from the abrupt quadrupling CO₂ experiment. The relationship between the
956 change in the global mean radiative fluxes and global mean surface air temperature change. The
957 climate feedback parameters ($\text{Wm}^{-2}\text{K}^{-1}$) for the TOA longwave clear sky (red), shortwave clear
958 sky(green), longwave cloud forcing (blue), shortwave cloud forcing (light blue) and net cloud
959 radiative effect (black) are -1.63, 0.675, 0.31, -0.30, 0.02 $\text{Wm}^{-2}\text{K}^{-1}$, respectively.

960 Figure 17. Changes in the surface temperature (top) and precipitation (bottom) derived from the
961 last 30-year climatology in the 150-year abrupt 4 x CO₂ experiments. The changes are with
962 reference to the corresponding climatological mean fields from the PI experiment. The right
963 panels show the corresponding zonal mean changes.

964 Figure 18. Results from the 1%per year CO₂ increases experiment. Global mean annual surface
965 air temperature change relative to counterpart in the PI experiment. The average temperature
966 anomalies between year 60-80 is defined as transit climate sensitivity, which is 2.16 K in the
967 NESM v3 model.

	TOA net	TOA SW	OLR	SW CRE	LW CRE	SST	LST	PR
Obs	0.83	240.51	-239.68	-47.16	25.98	17.2	12.58	2.68
NESM v3	0.2	238.65	-238.45	-48.44	25.75	17.7	12.72	2.86

968 Table 1. Summary of the global averaged annual mean values for radiation (Unit: W m⁻²),
969 temperature (Unit: °C) and precipitation (mm day⁻¹) from last 100-year PI simulation and
970 observations. The observed energy estimations are from CERES ed2.8 on the period of 2001-
971 2014. The observed SST/LST data is derived from Hadley SST/CRU on the period of 1870-
972 1880/1901-1910. The combined CMAP and GPCP precipitation.
