Abstract. The Stochastic Time-Inverted Lagrangian Transport (STILT) model is comprised of a compiled Fortran executable that carries out advection and dispersion calculations as well as a higher level code layer for simulation control and user interaction, written in the open source data analysis language R. We introduce modifications to the STILT-R codebase with the aim to improve the model's applicability to fine-scale (< 1km) trace gas measurement studies. The changes facilitate placement of spatially distributed receptors and provide high level methods for single and multi-node parallelism. We present a kernel density estimator to calculate influence footprints and demonstrate improvements over prior methods. Vertical dilution in the hyper near-field is calculated using the Lagrangian decorrelation timescale and vertical turbulence to approximate the effective mixing depth. This framework provides a central source repository to reduce code fragmentation between STILT user groups as well as a systematic, well documented workflow for users. We apply the modified STILT-R to light-rail measurements in Salt Lake City, Utah, United States and discuss how results from our analyses can inform future fine-scale measurement approaches and modeling efforts.

1 Introduction

Cities are the source of over 70% of global fossil-fuel carbon dioxide (CO₂) emissions (International Energy Agency, 2008; Hoorweg et al., 2012; Gurney et al., 2015), the largest anthropogenic forcing on climate change (Canadell et al., 2007). As governing bodies examine ways to address climate change, urban areas are appropriately a focus for emissions regulation. Atmospheric measurements (Duren and Miller, 2012; McKain et al., 2012) provide a top-down constraint for estimating urban carbon emissions, especially when combined with bottom-up information from fuel consumption statistics, traffic data, and building characteristics that result in highly resolved emission inventories (Gurney et al., 2009, 2012). However, traditional evaluation strategies for estimating CO₂ emissions that focus on quantifying regional scale (10² to 10³ km) averages at coarse resolutions are unable to resolve urban areas beyond bulk estimates. Implementing and evaluating effective policies for emissions mitigation requires understanding where, when, and how emissions occur at a within-city scale.

Novel measurement strategies are emerging to help resolve fine-scale within-city trace gas concentrations, such as measurements made from trains, buses, and cars (Apte et al., 2017; Bush et al., 2015; Lee et al., 2017) as well as dense networks of inexpensive sensors (Shusterman et al., 2016; Turner et al., 2016). However, traditional atmospheric modeling tools were not designed for densely located and spatially distributed measurements. Simulating atmospheric transport for multiple locations over time often increases the number of simulations by factors of 10^1 to 10^3 , necessitating the use of scalable parallel computing to best utilize available hardware and reduce total simulation time. To make use of recent measurement advances, modeling approaches must structure the model framework in ways that enable simulations to execute in parallel, adapt to finer spatial scales, and facilitate simulating atmospheric mixing ratios for locations distributed across space and time.

The link between measured atmospheric mole fractions and upstream surface fluxes is often established using Lagrangian particle dispersion models (LPDMs), popular tools for simulating atmospheric transport and dispersion in the Planetary Boundary Layer (PBL) (Lin, 2013). The LPDMs simulate transport of an ensemble of theoretical particles (representing air parcels) using a combination of mean winds interpolated from meteorological model fields with stochastic fluctuations representing turbulent motions introduced as a Markov process. This approach offers advantages over Eulerian methods by explicitly simulating transport trajectories and better representing atmospheric mixing, turbulent eddies, and convection (Lin, 2013). Particle motion can be simulated either forward in time from an emissions source or backward in time from a location of interest, referred to as the “receptor”. The forward configuration is often used to simulate pollutant concentrations downstream from an emission source (Stohl et al., 2005) whereas backward simulations determine the source of observed emissions and quantify surface fluxes (McKain et al., 2012, 2015; Stein et al., 2015). As receptors are often greatly outnumbered by sources, significant computational savings are realized by applying LPDMs in the receptor-oriented configuration (Lin, 2013).

The Stochastic Time-Inverted Lagrangian Transport (STILT) model couples Lagrangian particle dispersion with the mean advection scheme from the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Stein et al., 2015). STILT simulations are reversible in time (Lin et al., 2003), enable quantitative evaluation of transport error (Lin and Gerbig, 2005), and are closely coupled with the commonly used Weather Research and Forecasting mesoscale meteorological model (Nehrkorn et al., 2010), on which the High Resolution Rapid Refresh (HRRR) model is based (Sun et al., 2014). STILT is most commonly used to follow the backwards time evolution of a particle ensemble and calculate a receptor’s footprint, a sensitivity matrix defining the upstream area that contributes to tracer mole fractions observed at the receptor. Footprints can be convolved with emissions inventories and an atmospheric background signal to calculate atmospheric mole fractions at the receptor, which is among the most common applications of the STILT model (Gerbig et al., 2003; Lin et al., 2004; Kort et al., 2008; Macatangay et al., 2008; Mallia et al., 2015; Miller et al., 2008).

This paper discusses limitations within the existing STILT codebase and introduces an updated framework intended to improve the model’s applicability to fine-scale spatially distributed measurement approaches. We introduce the hyper near-field (HNF) area, typically covering length scales of 1 - 10 km and time scales of 0.1 - 1 hr, from which surface fluxes are diluted to a fraction of the PBL height and thus more strongly influence the receptor. Parameterizations within the STILT model were originally intended for regional scales and require refinements to improve source-receptor relationships in the HNF. We also describe a footprint calculation scheme using kernel density estimation, rescaling of the effective mixing depth for fluxes

in the HNF, and methods for parallelizing simulations. The value of STILT as a tool for interpreting within-city CO₂ mole fractions is shown using an example of data collected on the roof of a train car on Salt Lake City's light-rail system. We discuss how results from our analyses can inform future measurement approaches and modeling efforts.

2 Modifications to the STILT model

5 2.1 Software enhancements

The R component of the STILT model exists as a group of core functions used to track particle locations, calculate footprints, and apply surface flux grids. User groups have built upon these functions, adding scripts for common modeling workflows and additional functionality. Key components of the higher level functions remain unpublished and undocumented prior to this paper, including a description of methods used to aggregate the particle ensemble to calculate footprints. Here, we adopt a
10 widely-used collaborative software development platform (GitHub) as a common source code repository that meets the needs of STILT users. This repository is built upon existing advection and dispersion calculations but has restructured and modernized the core functions used to interact with the model (Fig. 1).

A single script (*run_stilt.r*) defines model inputs such as receptor locations and meteorological fields, controls and executes the parallelized model, and outputs footprints. Footprints are saved in a netCDF format consistent with conventions for Cli-
15 mate and Forecast metadata (cfconventions.org), the standard for gridded model datasets by the University Corporation for Atmospheric Research (UCAR). This format is compatible with most popular data analysis software platforms and facilitates analysis of model output. The script *run_stilt.r* serves as the primary STILT interface, interacting with R functions which in turn call Fortran subroutines for the bulk of calculations and providing a systematic, well documented workflow for users.

2.2 Model parallelization

20 Executing simulations in parallel is essential to leverage the full capability of computing resources. STILT receptors are defined in a table of space (x, y, z) and time (t) coordinates enabling users to fix a receptor in space and model the time evolution of the influence field, distribute receptors across space and capture a snapshot at a single time, or distribute the receptors across both space and time. Since each STILT simulation is computationally independent, total simulation time can be reduced by distributing batches of simulations between parallel threads (Fig. 2). As the number of parallel threads increases, the size of
25 each simulation batch decreases. Within-node parallelism is achieved through process forking, in which batches of receptors are allocated across multiple parallel threads on a single machine. Multi-node parallelism is accomplished by interfacing with the Simple Linux Utility for Resource Management (SLURM), an open-source tool that provides the framework for interfacing with clusters of computer nodes (Jette and Grondona, 2003). SLURM allocates computational resources with low overhead and can be used to dispatch job arrays of STILT simulations to multiple nodes. SLURM is used to parallelize *between*
30 nodes and process forking by the modified STILT framework is used to parallelize *within* nodes. Process forking can be used independently to execute parallel simulations on a single machine or combined with SLURM to parallelize simulations within

each SLURM node. Provided that memory limits are not exceeded, these methods enable total simulation time to decrease linearly with available CPU cores.

2.3 Hyper Near Field vertical mixing depth

The influence of surface fluxes on air arriving at the receptor depends upon vertical dilution within the atmospheric column.

- 5 The STILT model determines the height of the boundary layer z_{pbl} using a modified Richardson number method (Vogelezang and Holtlag, 1996). In the original STILT model, surface fluxes are instantaneously diluted within an effective mixing depth of $h^* = 0.5 \cdot z_{pbl}$ for which the vertical mixing timescale is comparable to the model timestep for advection (Gerbig et al., 2003). As described in Lin et al. (2003), an atmospheric column of height $h(x, y, t, p)$ is used to relate surface fluxes $F(x, y, t)$ to the mole fraction influence $S(x, y, t, p)$ for each particle p as

$$10 \quad S(x, y, t, p) = \begin{cases} \frac{F(x, y, t) m_{air}}{h(x, y, t, p) \bar{\rho}(x, y, t, p)} & z \leq h \\ 0 & z > h \end{cases} \quad (1)$$

where $\bar{\rho}$ is the average air density below h and m_{air} is the molar mass of dry air. Thus, particles below h perceive surface fluxes diluted within an atmospheric column of depth h . However, the advective timescale is often too short for complete turbulent mixing of HNF fluxes to h before arrival at the receptor. Thus, this method underrepresents the influence of HNF fluxes on the tracer mole fraction arriving at the receptor.

- 15 We apply a method of calculating the effective mixing depth in the HNF based on homogeneous turbulence theory, described by Taylor (1922). Each model time step component k of the HNF mixing depth h' at time t_k will be of the form

$$h'_k(p, t) = z_r + \int_0^{t_k} \sigma_w \sqrt{2T_L \left(t + T_L \left(e^{-\frac{t}{T_L}} - 1 \right) \right)} dt \quad (2)$$

- where z_r is the height above ground of the receptor, σ_w is the standard deviation in vertical velocities encountered by p during the integration timestep, and T_L is the Lagrangian decorrelation timescale. This method grows the dilution depth over time relative to local turbulence. Substitution of $h = \min(h', h^*)$ into Eq. (1) enhances the mole fraction influence of HNF sources on the receptor (Fig. 3). For surface based applications, h' grows to h^* over roughly 10 minutes, affecting a spatial domain of approximately 1 km adjacent to the receptor.

2.4 Kernel density estimation of footprint field

- Prior to methods described in this section, STILT footprints have been calculated by accumulating the influence of particles over an averaging volume. To lessen grid noise from few particles spread throughout the grid, the spatial extent of the particle ensemble was used to dynamically coarsen the size of the averaging volume by a factor of 2 as the particle cloud spreads, first shown in Gerbig et al. (2003). However, at finer resolutions, this method results in excessive smoothing, removing information calculated by the advection and dispersion routines (Fig. 3).

Here we introduce a kernel density estimator to spatially allocate the influence of particles to the footprint grid and show improvements over the prior method at fine spatial resolutions. This method distributes the influence of each particle using a Gaussian weighted spatial kernel centered over the particle's position. The size and intensity of the spatial kernels are defined by the kernel bandwidth, which is determined at each model time step using elapsed time and total dispersion of the stochastic ensemble as proxies for uncertainty in the locations of individual particles. Dispersion of the particle cloud at each time step is represented using a nondimensionalized standard deviation of particle locations σ_d given by

$$\sigma_d = \sqrt{\sigma_x^2 + \sigma_y^2} \quad (3)$$

where σ_x^2 and σ_y^2 are Euclidean variances in horizontal particle positions in degrees. We find σ_d to agree with other dispersion metrics for the particle ensemble, such as the average pairwise distance ($r^2 > 0.99$), with less computational expense. Kernel bandwidths are then given by

$$b = f \frac{0.06\sqrt{t\sigma_d}}{\cos\phi} \quad (4)$$

where t is time elapsed in days, ϕ is latitude used for approximation for meridional grid convergence, and 0.06 is an empirically derived constant. f defaults to 1 and is provided as a user defined smoothing adjustment to enable manual manipulation of kernel sizing.

Next, we test the new footprint calculation methods against a brute force simulation with an atypically large particle ensemble size ($N = 10^5$) aggregated over a homogeneous grid (Fig. 4). This large simulation is computationally expensive but generates an idealized, physically constrained footprint without smoothing algorithms. The simulation receptor was positioned at a Salt Lake City CO₂ measurement site on a summertime afternoon and particles were followed backward in time for 24 hours. We then demonstrate differences between the new kernel density estimator and the old dynamic grid coarsening footprint calculation methods (Fig. 3) for a typical particle ensemble ($N = 200$) and for an extreme case with atypically few particles ($N = 10$). The effects of varying the smoothing parameter ($f = 1, 2$) are also shown.

For the typical case ($N = 200$ and $f = 1$), the kernel method shows improved agreement with the brute force method, preserving a Gaussian plume adjacent to the receptor, a clustered area of high influence, and capturing split flow upstream. When the kernel bandwidths are doubled by increasing the smoothing parameter ($f = 2$), the footprint field becomes over-smoothed and loses similarity with the brute force case. In the extreme case using atypically few particles ($N = 10$), the dynamic grid coarsening method produces a footprint field dominated by noise from individual particles. The kernel density estimator ($f = 1$) improves results but shows fragmentation further from the receptor. In this case, the scarcity of particles can be compensated for by increasing the smoothing parameter ($f = 2$). While tracer mole fraction differences between the two footprint calculation methods vary depending upon the locations of footprint differences relative to sources, tracer mole fraction calculated using the kernel density estimator improves similarity with the idealized brute force case.

3 Evaluation

3.1 Salt Lake City light-rail measurements

We demonstrate these changes to STILT by comparing CO₂ mixing ratios simulated by the STILT model with corresponding measurements on-board an electric Salt Lake City, Utah light-rail commuter train during July 2015. The Salt Lake Valley (SLV) is a 1,300 km² area encompassing Salt Lake City and its surrounding suburbs, bounded by the Wasatch mountain range to the east, the Oquirrh mountain range to the west, the Traverse mountain range to the south, and the Great Salt Lake to the northwest. A light-rail train is equipped to measure high-frequency (1 Hz) CO₂ mole fractions in repeated transects of the SLV using a Los Gatos Research Ultraportable Greenhouse Gas Analyzer. CO₂ and CH₄ mole fractions are corrected for water vapor dilution and spectrum broadening and are calibrated every hour using a compressed whole air tank with known tracer mole fractions traceable to World Meteorological Organization standards. For details related to the measurement platform, refer to Mitchell et al. (in review).

The observations generally show higher CO₂ mole fractions in Salt Lake City's urban center and along the north-south oriented urbanized corridor centered in the SLV (Fig. 7), consistent with urban spatial CO₂ gradients observed in previous studies (Idso et al., 2001; Pataki et al., 2007). The lowest mole fractions were observed in the southwest corner of the SLV at the margin of recent suburban developments. At a finer scale, the high-frequency measurements show mole fraction enhancements near busy roads and intersections. Measured mole fractions are also consistently higher along a 3 km section of the light-rail track running along the center of a busy six-lane road.

3.2 Surface flux inventories

The Hestia bottom up anthropogenic CO₂ emissions inventory characterizes carbon fluxes by estimating emissions at the scale of individual buildings and roadways (Gurney et al., 2012). Hestia is available for a handful of U.S. cities including Indianapolis, Los Angeles, Baltimore/D.C., and Salt Lake City. Details pertaining to the Salt Lake County Hestia product are described by Patarasuk et al. (2016). For this simulation, Hestia anthropogenic CO₂ fluxes are aggregated hourly to a 0.002° grid (Fig. 6).

Anthropogenic CO₂ emissions outside of Salt Lake County are derived from the 1km × 1km ODIAC (Oda and Maksyutov, 2011) emissions inventory. These flux estimates are temporally allocated to hourly time steps using methods described by Nassar et al. (2013).

The biological CO₂ inventory determines land surface types using the 2011 National Land Cover Database (Homer et al., 2007) and 1 m LIDAR derived discrete land cover classifications across the SLV. The link between land cover classification and CO₂ exchange is established using AmeriFlux eddy covariance data that provides a robust estimate of biologic fluxes from different vegetation types (Strong et al., 2011). A lookup table with independent axes for temperature, incoming shortwave radiation, and week of year is used to describe the relationship between land cover classification and biological fluxes (Strong et al., 2011) over a 0.01° grid. For details pertaining to the biological flux inventory, refer to Strong et al. (2011) and Catharine et al. (in preparation).

3.3 STILT configuration

STILT receptors are defined by averaging light-rail measurements hourly over a 0.002° grid (roughly 200 m at $\phi = 41^\circ$ N) to pair analyses with the Hestia inventory that has the finest spatial and temporal resolution of the flux inventories used. This method results in 33,608 unique receptors for the month of July, 2015, necessitating the use of parallel simulations and fine scale footprint calculation included in the modified framework. From each receptor, 24 h backward trajectories of 200 particle ensembles are calculated using meteorological fields from the HRRR model, available at an hourly interval with a 3 km grid resolution.

We compute footprint fields using the legacy dynamic grid coarsening (LEG) algorithm as well as gaussian kernel density estimation with the HNF dilution correction (GWD) and without the HNF dilution correction (GND) to illustrate the differences between methods. Further, these three methodologies are applied for two model domains, resulting in six different permutations of footprint fields for each receptor. A fine-scale 0.002° grid encompasses the SLV and is used to apply SLV anthropogenic emissions. A 0.01° grid covering a larger area of Northern Utah is used to apply biological fluxes and non-SLV anthropogenic emissions. Computation of the 33,608 particle trajectories and a single set of footprints completed in 5.5 hours utilizing 80 parallel threads across 5 nodes, each equipped with 64 GB of memory with two 8-core Intel XEON E5-2670 2.6 GHz processors. 6.7% of simulations failed to complete due to short-term outages in the HRRR data product.

Footprints are convolved with anthropogenic and biological CO_2 fluxes and added to background CO_2 mole fractions that are representative of CO_2 mole fractions that have not been influenced by urban emissions (Mitchell et al., in press). The background mole fractions are taken from a nearby high elevation measurement site at Hidden Peak at the top of the Snowbird ski resort in the Wasatch Mountains (Stephens et al., 2011). We use a similar approach to prior studies (e.g. McKain et al. (2012)) and focus this analyses on the afternoon and early evening hours (12:00-19:00 Local Daylight Time, LDT) to lessen the influence of boundary layer development, nocturnal stratification of the boundary layer, and shallow turbulence on measured mole fractions that would not be represented in the 3 km resolution of the HRRR meteorological fields.

3.4 Results

Observed and simulated mole fractions are averaged by hour of day to generate mean diel cycles, shown in Fig. 5. Observations show elevated mole fractions at night and early morning, decreasing into the afternoon as convective mixing increases (Mitchell et al., in press). All three of the simulated diel cycles derived from the different footprint algorithms systematically underestimate nighttime and early morning mole fractions, consistent with previous studies (Macatangay et al., 2008; McKain et al., 2015; Mallia et al., 2015; Lauvaux et al., 2016). However, during afternoon hours the simulated values track more closely with the observations, with GWD exhibiting closer correspondence than GND and LEG (Fig. 5).

Correlations over space between the time-averaged modeled and measured concentrations are highest for GWD ($r = 0.52$) followed by GND ($r = 0.46$) and lastly LEG ($r = 0.45$). While we have demonstrated GND to compare favorably with idealized footprints calculated with brute force particle simulations, this analysis found modeled concentration differences between

GND and LEG fall within the uncertainties in surface flux inventories. As GWD agrees most closely with observations over time and space, we focus on GWD for the remainder of analyses.

Footprints convolved with surface flux inventories (Fig. 6) show measurements made on the light-rail train to be highly sensitive to fluxes in the HNF domain. Spatially averaged model results capture the mole fraction gradient between the urban center and surrounding suburbs (Fig. 7). The lowest modeled mole fractions occurred in the southwest corner of the SLV, in agreement with measurements. The model also reproduced mole fraction enhancements (ΔCO_2) downwind from major roadways (Fig. 6) as well as the evening rush hour enhancement (Fig. 5). On average, we found the largest contributor to modeled CO_2 mole fractions is the SLV anthropogenic fluxes ($\Delta\text{CO}_2 = 4.18\text{ppm}$), followed by biological fluxes ($\Delta\text{CO}_2 = -0.89\text{ppm}$), and the smallest contribution is from non-SLV anthropogenic fluxes ($\Delta\text{CO}_2 = 0.37\text{ppm}$).

Key differences between modeled and measured mole fractions exist near HNF sources at the sub-grid scale (Fig. 7). While the model does capture localized mole fraction enhancements near busy roads and intersections ('I' in Fig. 7), measured mole fractions are systematically higher than corresponding model estimates in these areas. These results indicate that the light-rail measurement platform is sampling emissions prior to mixing with the surrounding air. This is evident along the section of light-rail track that shares the six-lane road with other vehicles ('R' in Fig. 7) on which large discrepancies between measurements and model estimates are regularly observed. By diluting emissions throughout a larger grid cell, the model predicts elevated mole fractions localized within and downwind from cells containing significant sources but does not fully capture the magnitude of enhancement resulting from the close proximity to the emissions source.

To demonstrate the benefits of the fine-scale approach, we use the above 0.002° grid as well as spatially degraded 0.01° and 0.1° grid resolutions for footprints and fluxes (Fig. 8) to compare against light-rail measurements. Correlations over space between the time-averaged modeled and measured concentrations are highest for the 0.002° grid ($r = 0.52$). We find that degrading the resolution to 0.01° still captures the SLV-scale urban-suburban-rural mole fraction gradient but fails to resolve much of the roadway and intersection scale enhancements, resulting in a modest decrease in agreement with measurements ($r = 0.48$). However, degrading the resolution to 0.1° prevents the model from resolving much of the spatial mole fraction variation ($r = 0.25$). Further, evaluating the spatially-averaged concentration by hour of day shows improved agreement with measurements among the finer grid resolutions (0.002° , 0.01°) over the more coarse 0.1° resolution (Fig. 9). While all three resolutions mimic the temporal pattern in the observed mole fraction enhancements due to the temporal variability assigned to emissions inventories, the finer resolutions better capture the mole fraction enhancements observed by the light-rail train in both time and space.

4 Summary and Conclusions

In this paper, we have introduced modifications to the STILT-R code that have improved the spatial averaging of the footprints and the model speed. These changes improve the functionality of the STILT model for applications investigating fine-scale patterns in urban emissions. Given the importance of footprints in the STILT workflow, a kernel density estimator was applied and shown to improve agreement with an idealized brute force method over prior methods. High level methods for single and

multi-node parallelism were introduced in this distribution, significantly reducing total simulation time. We then applied STILT to simulate CO₂ mole fractions observed along a light-rail train in Salt Lake City, at high resolution and show that the model and observations track one another in terms of average spatial and temporal patterns during the afternoon period. However, key differences remain between modeled and measured mole fractions at night and in the proximity of HNF sources.

- 5 Results indicate that fine-scale inverse analyses will be sensitive to the proximity of observations to upwind sources. Modeling difficulties arise when emissions within the HNF are distributed throughout a larger grid cell that no longer reflects the close proximity of fluxes to the receptor. Fine-scale measurements and modeling approaches are useful for applications such as quantifying pollution exposure in different neighborhoods or locating large point source emitters. However, fluxes originating within the HNF domain can often dominate the modeled signal and error. Observation techniques that are strongly influenced
- 10 by HNF fluxes such as trains and cars can have limited usefulness in larger scale applications for which LPDMs have previously been used, such as bulk flux estimates from urban areas. Measurements striving to quantify emissions or assess the validity of emissions inventories should seek to reduce the influence of HNF sources. Prioritizing measurement placement at the top of tall buildings or towers or at least 0.5 km from large sources such as busy roadways enables natural dilution of emitted species, reduces direct sampling of emissions, and improves model agreement with observations.
- 15 *Code availability.* The source code and documentation can be obtained through <https://uataq.github.io/stilt/>. Development of the model is ongoing and updates will continue to become available through this repository. Contributions are welcome and should be submitted via pull request. Issues should be reported to the integrated issue tracking system. Questions should be directed to the author.

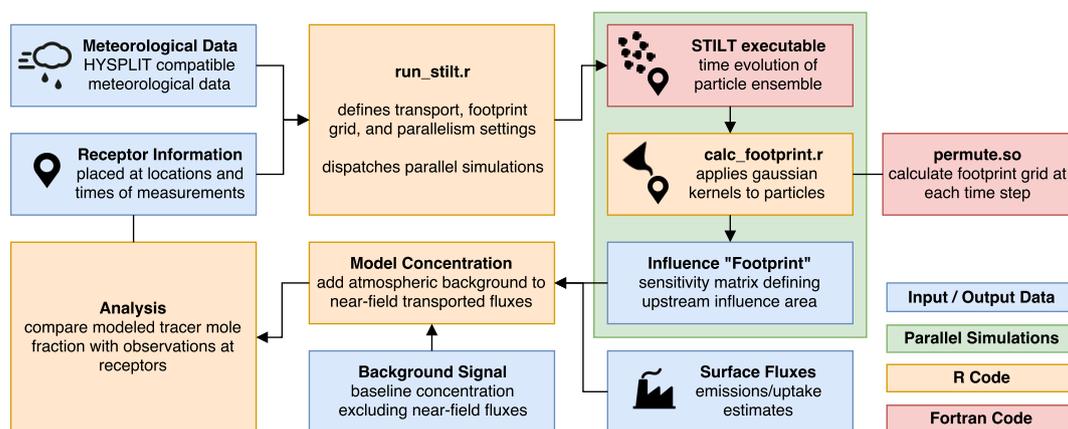

Figure 1. STILT workflow to model tracer mole fraction at a receptor. STILT advects particles and calculates the influence footprint for each receptor. Footprints are convolved with surface fluxes and an atmospheric background signal to model the tracer mole fraction.

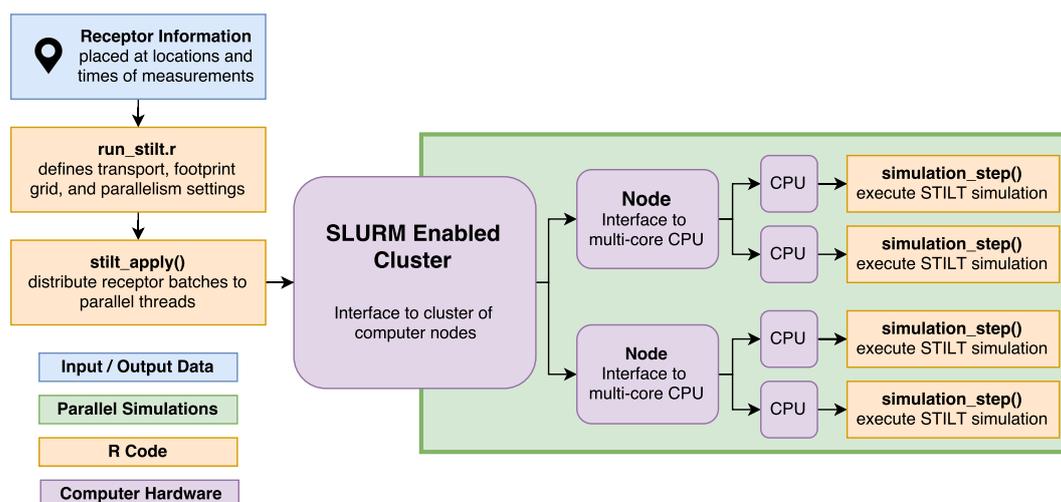

Figure 2. Receptor batches are distributed across parallel threads to enable multiple concurrent simulations. Provided memory limits are not exceeded, the total simulation time decreases linearly with the number of CPU cores available.

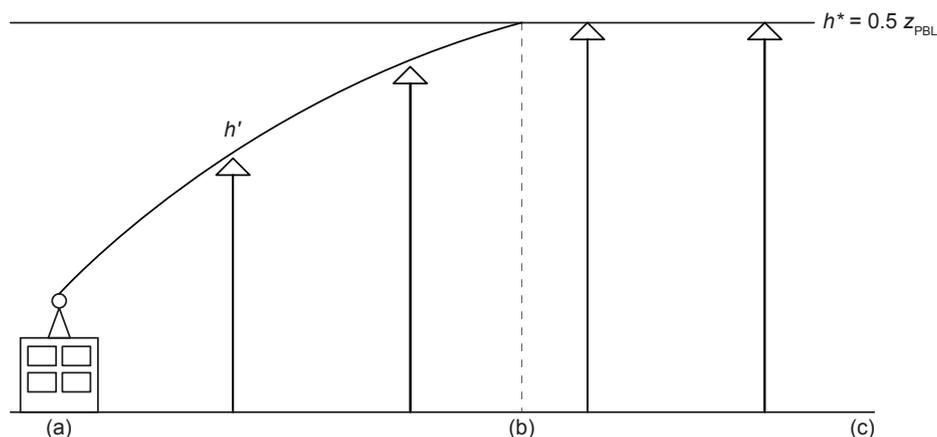

Figure 3. Growth of the effective mixing depth. From the receptor (a), surface fluxes are diluted within an atmospheric column depth of h' in the HNF until $h' = h^*$ (b), amplifying the contribution of Hyper Near Field (HNF) sources and sinks on the receptor. Once h' has reached h^* , surface fluxes are diluted to depth h^* until the end of the simulation (c).

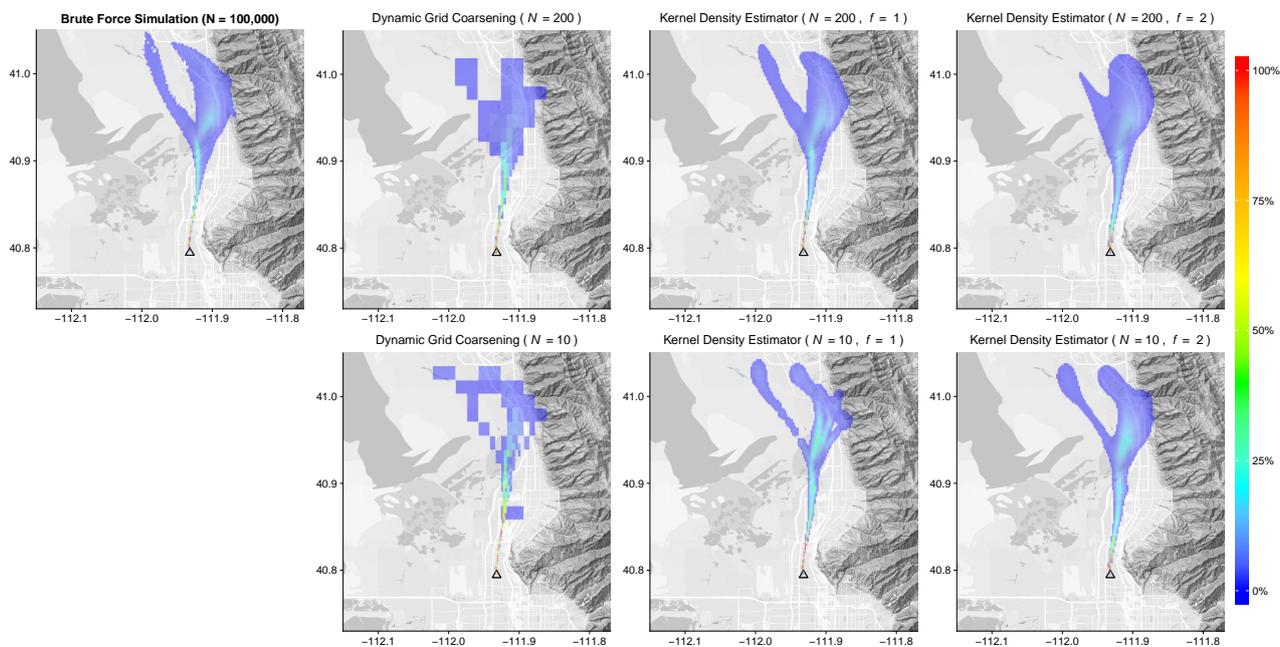

Figure 4. Comparison of footprint calculation methods. Simulating a large number of particles ($N = 10^5$) and gridding by location (top left) gives a physically constrained expectation for the footprint. Using subsets of 200 particles (top) and 10 particles (bottom), the kernel density estimator demonstrates considerable improvements over the traditional dynamic grid coarsening. Modifying the kernel bandwidths ($f = 2$) can improve results in uncommon cases, such as the 10 particle ensemble.

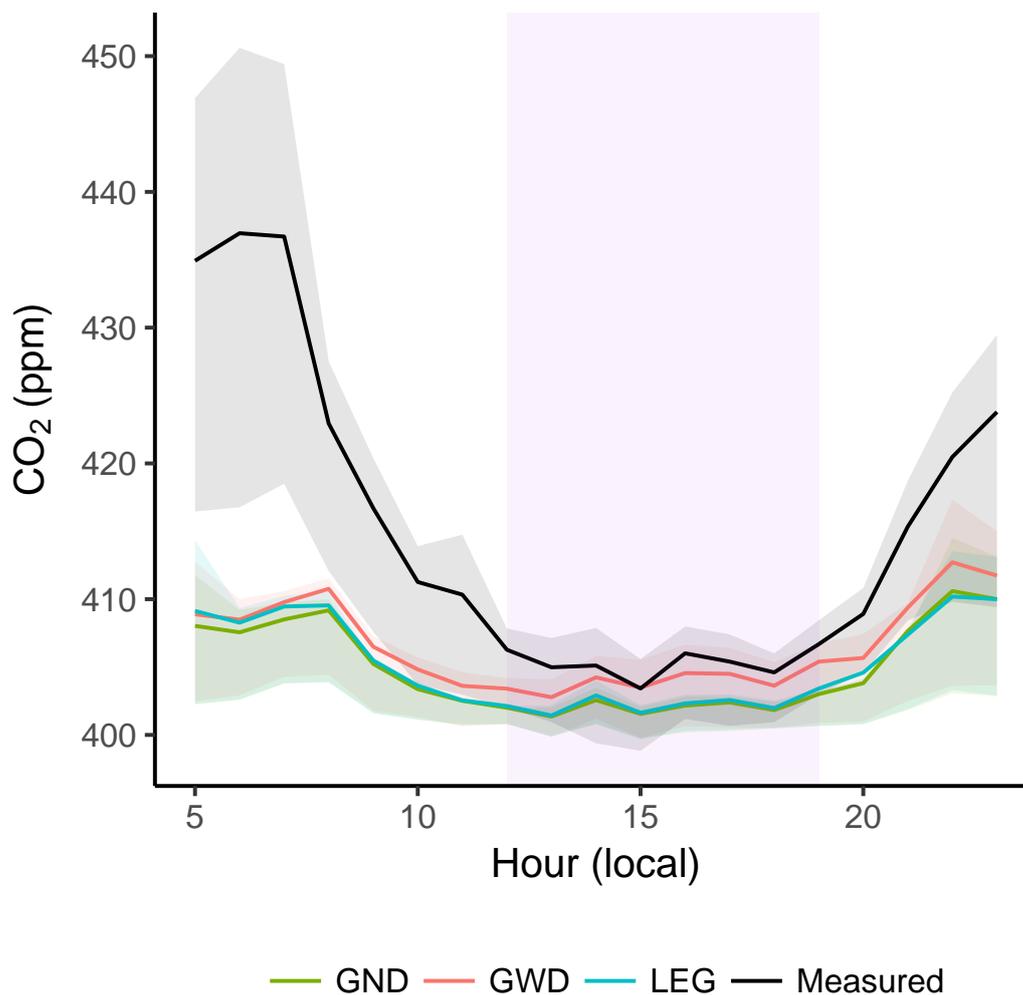

Figure 5. Mole fractions of various footprint calculation methods by hour of day during light-rail operating hours from early morning to late evening. Purple shading indicates afternoon hours used for analyses. Solid lines represent the mean and shading represents the interquartile range. Mole fractions modeled using Gaussian kernel calculated footprints with correction for HNF dilution depth (GWD) modeled mole fractions agree most closely with measurements, with underestimation attributed to sub-grid scale sampling of emissions sources.

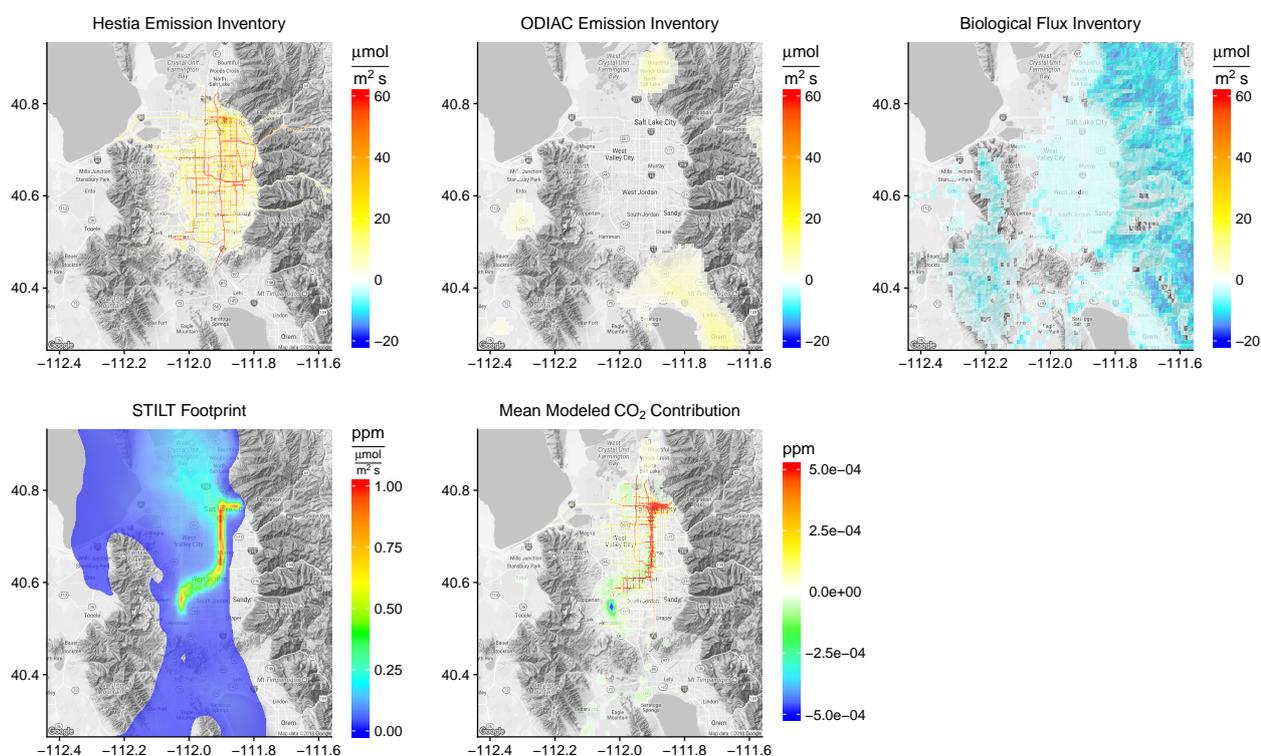

Figure 6. July 2015 afternoon Salt Lake Valley (SLV) Hestia-derived and non-SLV ODIAC-derived anthropogenic CO₂ emissions, biological fluxes, and average STILT footprint. The anthropogenic and biological flux inventories convolved with the footprints give the contribution of near-field fluxes to measured mole fractions in ppm. The light-rail train is highly sensitive to HNF emissions sources and is strongly influenced by large roadways and agriculture adjacent to the line.

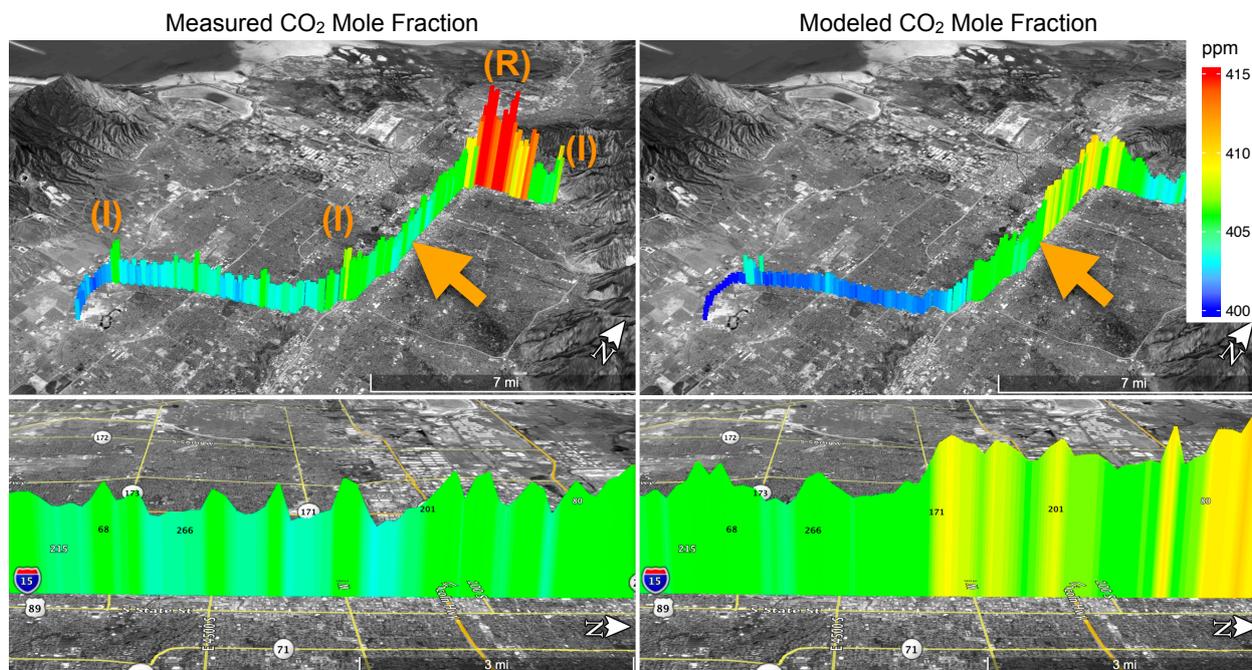

Figure 7. Key differences between measured and modeled tracer mole fraction occur near HNF sources, including passing large roadways and intersections (I) and where the light-rail track is shared by other vehicles on the roadway (R). Orange arrow indicates viewpoint of bottom panels. The model captures the overall urban-suburban-rural CO₂ mole fraction gradient (top) as well as localized enhancements near many busy roads (bottom).

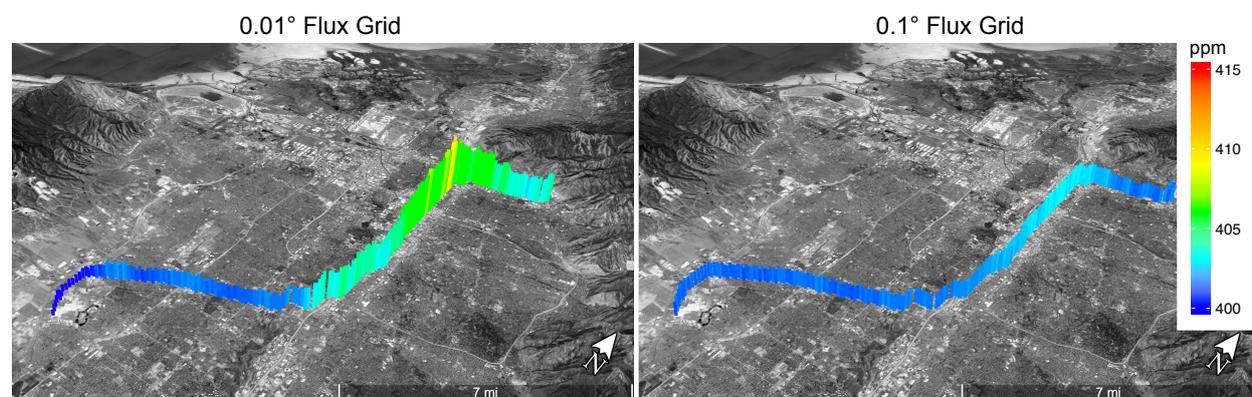

Figure 8. Spatially degraded flux and footprint grids to 0.01° and 0.1° resolutions demonstrates the advantages of the fine-scale, 0.002° grid (Fig. 7). While the 0.01° resolution (left) retains the CO₂ mole fraction enhancements for the SLV-scale urban-suburban-rural gradient, the 0.1° resolution (right) fails to resolve the locations and magnitudes of observed CO₂ variations.

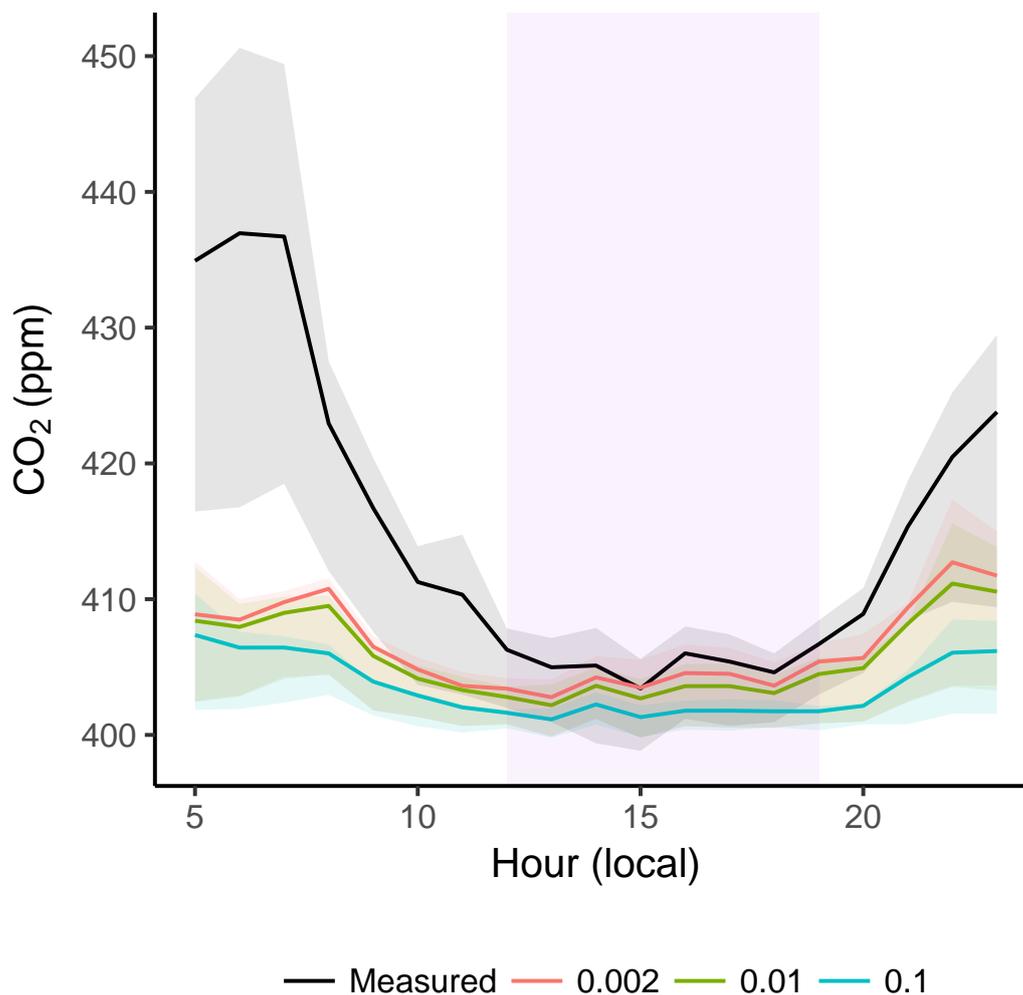

Figure 9. Modeled mole fraction at 0.002° as well as spatially degraded 0.01° and 0.1° grid resolutions by hour of day during light-rail operating hours. Purple shading indicates afternoon hours used for analyses. Solid lines represent the mean and shading represents the interquartile range. Mole fractions using finer grid resolutions (0.002° , 0.01°) agree more closely with observations than the coarser 0.1° due to the close proximity of the light-rail train to emissions sources.
