12 Abstract

13 A new module, ORACLE 2-D, simulating the organic aerosol formation and evolution in the
14 atmosphere has been developed and evaluated. The module calculates the concentrations of
15 surrogate organic species in two-dimensional space defined by volatility and oxygen-to-carbon
16 ratio. It is implemented into the EMAC global chemistry – climate model, and a comprehensive
17 evaluation of its performance is conducted using an Aerosol Mass Spectrometer (AMS) factor
18 analysis dataset derived from almost all major field campaigns that took place globally during
19 the period 2001-2010. ORACLE 2-D uses a simple photochemical aging scheme that simulates
20 efficiently the net effects of fragmentation and functionalization of the organic compounds. The
21 module predicts not only the mass concentration of organic aerosol (OA) components, but also
22 their oxidation state (in terms of O:C), which allows their classification into primary OA (POA,
23 chemically unprocessed), fresh secondary OA (SOA, low oxygen content) and aged SOA (highly
24 oxygenated). The explicit simulation of chemical OA conversion from freshly emitted
25 compounds to a highly oxygenated state during photochemical aging enables the tracking of
26 hygroscopicity changes of OA that result from these reactions. ORACLE 2-D can thus compute
27 the ability of OA particles to act as cloud condensation nuclei, and serves a tool to quantify the
28 climatic impact of OA.

29

30 1. Introduction

31 Atmospheric aerosols adversely affect human health and play a significant role in climate
32 change on regional and global scales. Depending on their composition, aerosols affect the energy
33 budget of the Earth's atmosphere by scattering and absorbing solar radiation (direct effect) and
34 by influencing the reflective properties of clouds, their lifetime, and precipitation formation
35 (indirect effects). In addition, climate change can play vital and complex role in the formation
36 and removal of atmospheric particles (Trail et al., 2013; Trail et al., 2014). Organic aerosol (OA)
37 is an important constituent of atmospheric particles contributing 20-90% to the total submicron
38 particulate mass, depending on the region (Zhang et al., 2007).

39 Primary OA has been traditionally treated as non-volatile and inert in global scale chemistry
40 climate models (CCMs). Robinson et al. (2007) demonstrated that OA emissions are semi-
41 volatile and most of the emitted OA moves to the gas phase after emission due to dilution and
42 evaporation. On the other hand, all organic vapors are subject to photochemical reactions with

43 OH in the gas phase forming organic products with lower volatility that can recondense to the
44 particulate phase as secondary organic aerosol (SOA). To describe the OA gas-aerosol
45 partitioning, Donahue et al. (2006) developed the volatility basis-set (VBS) framework, where
46 OA is assumed to be semi-volatile and photochemically reactive, and is distributed in
47 logarithmically spaced volatility bins. With this innovative approach, the semi-volatile primary
48 emissions, the chemical aging, and the SOA formation were unified within a common framework
49 that is ideally suited for regional and global chemical modeling. Since 2006, many regional
50 (Lane et al., 2008;Murphy and Pandis, 2009;Tsimpidi et al., 2010;Tsimpidi et al., 2011;Ahmadov
51 et al., 2012;Athanasopoulou et al., 2013;Koo et al., 2014;Fountoukis et al., 2014;Ciarelli et al.,
52 2017;Gao et al., 2017) and global (Pye and Seinfeld, 2010;Jathar et al., 2011;Jo et al.,
53 2013;Tsimpidi et al., 2014;Hodzic et al., 2016) modeling studies have used the VBS to account
54 for the semi-volatile nature and chemical aging of organic compounds, demonstrating
55 improvements in reproducing the OA budget and its chemical resolution.

56 The chemical aging of OA results in significant changes of its physical and chemical
57 properties due to the addition of oxygen atoms from the reaction with OH. This increase in OA
58 oxygen content is important for its impact on climate through changes in cloud condensation
59 nuclei (CCN) and ice nuclei (IN) activity. In fact, the oxygen content, expressed by the ratio of
60 oxygen to carbon atoms (O:C), influences the OA hygroscopic growth (Chang et al.,
61 2010;Lambe et al., 2011) which affects CCN activity. In addition, the phase-state changes of
62 SOA during its atmospheric lifetime, which can impact the IN activity, is also influenced by the
63 O:C of the OA (Shiraiwa et al., 2017). Donahue et al. (2011) extended the original one-
64 dimensional VBS framework to two dimensions (2-D VBS) tracking not only the saturation
65 concentration but also the oxygen content of OA during atmospheric transport. This approach
66 further improved the description of the atmospheric evolution of OA and its precursor gases that
67 become increasingly more oxidized, less volatile, and more hygroscopic during their atmospheric
68 aging. However, the large number of additional surrogate organic compounds required by the 2-
69 D VBS framework has hindered implementation in three-dimensional atmospheric models
70 (Napier et al., 2014). Therefore, the 2-D VBS approach has been mostly adopted in box and 1D
71 Lagrangian models (Murphy et al., 2011;Murphy et al., 2012;Chacon-Madrid et al., 2013;Zhao et
72 al., 2015;Paciga et al., 2016). Koo et al. (2014) introduced a hybrid VBS approach for use in
73 three dimensional chemical transport models (CTMs) which combines the simplicity of the VBS

74 with the ability to track the evolution of OA in the 2-D space of volatility and oxygen content.

75 In this work, the computationally efficient module for the description of OA composition and
76 evolution in the atmosphere (ORACLE; Tsimpidi et al., 2014) has been extended to allow for the
77 first time in a global CCM the description of both the volatility and the oxygen content of OA
78 based on the 2-D VBS approach. Similar to ORACLE v1.0, the interface of the new version
79 allows the user to have full control of the complexity of the OA scheme by adjusting the number
80 of species and reactions (i.e., number of compounds, volatility bins, O:C bins) to optimize the
81 computational cost according to the application and the desired chemical resolution. The updated
82 ORACLE module can provide valuable information about the physicochemical evolution of OA
83 during its atmospheric lifetime in support of modeling studies and help quantify the climatic
84 impact of OA.

85

86 **2. Model description**

87 **2.1 EMAC model**

88 The ECHAM/MESSy Atmospheric Chemistry (EMAC) model is a numerical chemistry
89 and climate simulation system that includes sub-models describing lower and middle
90 atmospheric processes and their interaction with oceans, land, and human influences. EMAC
91 consists of the Modular Earth Submodel System and an advanced version of the 5th generation
92 of the European Centre Hamburg (ECHAM) general circulation model. ECHAM5 (Roekner et
93 al., 2006) serves as the atmospheric dynamic core that simulates the atmospheric flow and is
94 integrated in the base model layer of MESSy. The interface structure of MESSy links the base
95 model with several atmospheric submodels that simulate online the gas-phase chemistry
96 (MECCA; Sander et al., 2011), inorganic aerosol microphysics and dynamics (GMXe; Pringle et
97 al., 2010), organic aerosol formation and growth (ORACLE; Tsimpidi et al., 2014), emissions
98 (ONLEM and OFFLEM; Kerkweg et al., 2006b), dry deposition and sedimentation (DRYDEP
99 and SEDI; Kerkweg et al., 2006a), cloud scavenging (SCAV; Tost et al., 2006), cloud
100 microphysics (CLOUD; Jöckel et al., 2006), and aerosol optical properties (AEROPT; Lauer et
101 al., 2007). EMAC has been extensively described and evaluated against ground-based and
102 satellite observations (Pozzer et al., 2012; Tsimpidi et al., 2014; Tsimpidi et al., 2016,
103 2017; Karydis et al., 2016; Karydis et al., 2017). In this study, the applied spectral resolution of
104 the EMAC model is T63L31, corresponding to a horizontal grid resolution of $1.875^{\circ} \times 1.875^{\circ}$ and

105 31 vertical layers extending to 18 km altitude (10hPa). EMAC is applied for 11 years covering
106 the period 2000-2010 and the first year is used as spin-up.

107

108 **2.2 ORACLE module**

109 **2.2.1 Module description**

110 ORACLE is a computationally efficient module for the description of organic aerosol
111 composition and evolution in the atmosphere (Tsimpidi et al., 2014) that has been incorporated
112 into the EMAC model. The original version of ORACLE simulated the volatility distribution of a
113 wide variety of semi-volatile organic surrogate compounds using bins of logarithmically spaced
114 effective saturation concentrations. Organic emissions from multiple anthropogenic and natural
115 sources are taken into account using distinct surrogate species for each source category. These
116 surrogates can be subdivided into groups of organic compounds based on their volatility: Low
117 volatility organic compounds (LVOCs, $C^* \leq 10^{-2} \mu\text{g m}^{-3}$), semi-volatile organic compounds,
118 (SVOCs, $10^{-2} < C^* \leq 10^2 \mu\text{g m}^{-3}$), intermediate volatility organic compounds (IVOCs, $10^2 < C^* \leq$
119 $10^6 \mu\text{g m}^{-3}$) and volatile organic compounds (VOCs, $C^* > 10^6 \mu\text{g m}^{-3}$). These organic compounds
120 are allowed to partition between the gas and aerosol phases resulting in the formation of OA. Gas-
121 phase photochemical reactions that modify the volatility of the organics are taken into account
122 and the oxidation products of each group of precursors are simulated separately in the module to
123 keep track of their origin. The model results for the different organic components in the
124 particulate phase were compared with factor analysis results derived from a comprehensive
125 dataset of aerosol mass spectrometer (AMS) measurements from multiple field campaigns across
126 the Northern Hemisphere. The resulting good agreement between campaign average
127 concentrations and model predictions supports the capability of the model to capture the spatial
128 and temporal characteristics of OA levels. Tsimpidi et al. (2017) conducted an extensive
129 sensitivity analysis of the EMAC OA predictions to uncertain parameters in the ORACLE
130 module. One of the major conclusions of their analysis was that the model performance can be
131 improved by assuming that freshly emitted organic compounds are relatively hydrophobic and
132 become increasingly hygroscopic due to oxidation. As a first step to achieve this goal, the
133 ORACLE module has been further developed here to account for the oxidation state of the
134 organic surrogate compounds. The new version is called ORACLE 2-D.

135

136 2.2.2. Emission inventory of OA precursors

137 The emissions of biogenic VOCs (i.e., isoprene and monoterpenes) are calculated online
138 by EMAC with the ONLEM submodel. The open biomass burning emissions of LVOCs,
139 SVOCs, and IVOCs from savanna and forest fires are based on the Global Fire Emissions
140 Database (GFED version 3.1). The emissions of anthropogenic LVOCs, SVOCs, IVOCs, and
141 VOCs (i.e., aromatics, alkanes, olefins) from fossil and biofuel combustion are derived from the
142 CMIP5 emission inventory for the RCP4.5 scenario. More details about the organic compound
143 emissions used here can be found in Tsimpidi et al. (2014).

144

145 3 ORACLE 2-D description

146 3.1 Module overview

147 The original ORACLE v1.0 (called hereafter ORACLE) uses saturation concentration
148 bins to describe the volatility distribution of the major OA components. In this work, ORACLE
149 is extended to also resolve the oxygen content of OA expressed by the O:C ratio. The volatility
150 dimension is discretized in up to 10 logarithmically-spaced volatility bins separating the organic
151 compounds in low volatility (LVOCs, expressed by the volatility bins of 10^{-3} , 10^{-2} , and 10^{-1} $\mu\text{g m}^{-3}$),
152 semi-volatile (SVOCs, C^* equal to 10^0 , 10^1 , and 10^2 $\mu\text{g m}^{-3}$), and those of intermediate
153 volatility (IVOCs, C^* equal to 10^3 , 10^4 , 10^5 and 10^6 $\mu\text{g m}^{-3}$). Extremely low volatility organic
154 compounds (ELVOCs, $C^* \leq 10^{-4}$) can be formed by the ozonolysis of monoterpenes and
155 sesquiterpenes (Liggio et al., 2010; Sun et al., 2009) playing an important role for the formation
156 and growth of new particles created in situ in the atmosphere by nucleation (Ehn et al., 2014).
157 The production of ELVOCs from biogenic VOCs is not currently included in ORACLE since the
158 simulation of new particle formation is outside the scope of the current article, and part of work
159 in progress. In addition, the oxygen content dimension is discretized in up to 20 linearly spaced
160 O:C bins subdividing the organic compounds into fresh emissions (expressed by the O:C bins of
161 0.1 and 0.2), less oxygenated organic compounds (O:C equal to 0.3, 0.4, 0.5, and 0.6),
162 moderately oxygenated organic compounds (O:C equal to 0.7, 0.8, 0.9, and 1.0), and highly
163 oxygenated species with $\text{O:C} > 1$. The first bin includes also the hydrocarbons with zero oxygen.
164 The O:C range can be extended up to 2 (for CO_2). However, there are only a few atmospheric
165 organic compounds with O:C higher than unity and the observed O:C of ambient OA rarely
166 exceeds 1.1 (Ng et al., 2010; Kroll et al., 2011). The ability of ORACLE v2.0 (called hereafter

167 ORACLE 2-D) to simulate degree of oxidation of OA allows the simulation of its hygroscopicity
168 by using proposed parameterizations that link the hygroscopicity parameter kappa with the O:C
169 of OA (Chang et al., 2010; Lambe et al., 2011; Kuwata and Lee, 2017). In the current application,
170 the hygroscopicity of each OA compound is represented by a linear function of the form
171 $\kappa_{\text{org}} = 0.18 (\text{O:C}) + 0.03$ (Lambe et al., 2011). ORACLE 2-D has a flexible interface in which the
172 user can choose the resolution (number of bins used in each dimension) of the 2-D VBS space
173 through a namelist file depending on the desired application and scientific goals. In the rest of
174 this work, we employ ORACLE 2-D using the 2-D VBS at a resolution suitable for medium-term
175 simulations with global chemistry-climate models. This chemical resolution includes 164 organic
176 aerosol surrogate compounds, compared to 34 OA compounds in ORACLE, which result in a
177 16% increase of the EMAC computational burden.

178

179 **3.3 Theory: constructing the two dimensional grid**

180 For the current application, ORACLE 2-D distributes the OA surrogate species into
181 logarithmically spaced volatility bins with C^* varying from 10^{-2} to $10^6 \mu\text{g m}^{-3}$ and linearly spaced
182 oxygen content bins with O:C varying from 0.1 to 1.2 (Figure 1). Each of the OA surrogate
183 species in this C^* -O:C 2-D space is characterized by a representative number of carbon atoms
184 (n_c) and a molecular weight (MW). Donahue et al. (2011) used structure activity relationships
185 (Pankow and Asher, 2008) to express the C^* as a function of n_c and the number of oxygens per
186 molecule (n_o):

$$187 \quad \log_{10} C^* = 0.475(25 - n_c) - 2.3n_o + 0.6 \frac{n_c n_o}{n_c + n_o} \quad (1)$$

188

189 Given that n_o is a function of O:C and n_c :

190

$$191 \quad n_o = n_c (\text{O:C}) \quad (2)$$

192

193 n_c can be expressed as a function of C^* and O:C:

194
$$n_c = \frac{11.875 - \log_{10} C^*}{0.475 + 2.3(\text{O:C}) - 0.6 \frac{(\text{O:C})}{1 + (\text{O:C})}} \quad (3)$$

195

196 Assuming that the organic compounds consist entirely of carbon, oxygen, and hydrogen atoms
 197 (i.e., ignoring nitrogen and sulfur), the *MW* of each surrogate species is a function of the number
 198 of carbon (n_c), oxygen (n_o), and hydrogen (n_H) atoms per molecule and therefore it can be
 199 calculated as:

200

201
$$MW = n_H + 16n_o + 12n_c \quad (4)$$

202 where,

203

204
$$n_H = n_c(\text{H:C}) \quad (5)$$

205

206 H:C is the atomic ratio of hydrogen to carbon approximated by Heald et al. (2010) as:

207

208
$$\text{H:C} = 2 - (\text{O:C}) \quad (6)$$

209

210 Combining Equations 4, 2, and 5, we get

211

212
$$MW = (15(\text{O:C}) + 14)n_c \quad (7)$$

213

214 Given that n_c decreases as C^* increases (Eq. 3), the *MW* calculated by Eq. 7 is consistent with the
 215 molecular corridor approach (Shiraiwa et al., 2014) which suggests a tight inverse correlation
 216 between volatility and molar mass constrained by boundary lines of low and high O:C ratios.

217 Organic compound emissions from anthropogenic fuel combustion and open biomass
 218 burning include LVOCs (with C^* at 298 K equal to $10^{-2} \mu\text{g m}^{-3}$) SVOCs (with C^* at 298 K equal
 219 to 10^0 and $10^2 \mu\text{g m}^{-3}$) and IVOCs (with C^* at 298 K equal to 10^4 and $10^6 \mu\text{g m}^{-3}$). Their
 220 corresponding emissions are estimated using the emission factors of Tsimpidi et al. (2016).

221 Freshly emitted LVOCs, SVOCs, and IVOCs from anthropogenic and open biomass burning
222 sources are assigned an initial O:C of 0.1 (Figure 1a) and 0.2 (Figure 1b), respectively (Donahue
223 et al., 2011). We distinguish anthropogenic and biogenic VOCs, and their first generation
224 oxidation products are distributed in four volatility bins (with C^* at 298 K equal to 10^0 , 10^1 , 10^2 ,
225 and $10^3 \mu\text{g m}^{-3}$) by using the aerosol mass yields by Tsimpidi et al. (2014). The O:C distributions
226 of the first generation VOC oxidation products are given by Murphy et al. (2011) and vary with
227 volatility (Figures 1c and 1d).

228

229 3.4 New photochemical aging scheme

230 Similar to ORACLE, multiple generations of homogeneous gas-phase reactions with OH
231 are simulated for all OA compounds treated by ORACLE 2-D. After each oxidation step, oxygen
232 atoms are added to the reacting organic gas resulting in an increase of oxygen content and a
233 change of volatility due to functionalization (reducing the volatility) or fragmentation (increasing
234 the volatility). To minimize the computational cost and at the same time simulate the net effect
235 of both fragmentation and functionalization, ORACLE 2-D uses an approach similar to the aging
236 scheme proposed by Murphy et al. (2011). ORACLE 2-D assumes a net average decrease in
237 volatility of aSOA-v reacting with OH by a factor of 10 and the addition of one or two oxygen
238 atoms with the same probability of 50% (Figure 1c). The same addition of oxygen atoms is
239 assumed for bSOA-v, however, its volatility remains unchanged due to a balancing of
240 fragmentation and functionalization effects (Murphy et al., 2012) (Figure 1d). The OH reaction
241 rate constant for both aSOA-v and bSOA-v is $1 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Tsimpidi et al., 2010).
242 The reaction of SOA-sv and SOA-iv with OH with a rate constant of $2 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$
243 (Tsimpidi et al., 2014) results in the addition of two or three oxygen atoms (with equal
244 probability) and the reduction of their volatilities by a factor of 100 (Figure 1a, 1b). The number
245 of added oxygen atoms (n_{o+}) due to the reaction with OH is then expressed as an increase of
246 O:C in the 2-D space. Each of the OA surrogate compounds in the 2-D space described in
247 Section 3.3 has a representative number of carbon per molecule (n_c). Assuming that carbon is
248 conserved during the reaction with OH, the O:C of the product is calculated as follows:

249

250
$$(\text{O}:\text{C})_{\text{product}} = (\text{O}:\text{C})_{\text{reactant}} + \frac{n_{\text{O}_2}}{n_{\text{C}}} \quad (8)$$

251

252 If the $(\text{O}:\text{C})_{\text{product}}$ has more than one decimal places, then is distributed between the two adjacent
 253 O:C bins of the 2-D space by using linear interpolation. Finally, since carbon is conserved, the
 254 increase in mass due to the added oxygen after each oxidation reaction is calculated as:

255

256
$$\frac{OM_{\text{product}}}{OM_{\text{reactant}}} = \frac{\left(\frac{OM}{OC}\right)_{\text{product}}}{\left(\frac{OM}{OC}\right)_{\text{reactant}}} \quad (9)$$

257

258 where, following Murphy et al. (2011),

259

260
$$\left(\frac{OM}{OC}\right) = 1 + 16(\text{O}:\text{C}) + \frac{1}{12}(\text{H}:\text{C}) \quad (10)$$

261

262 3.5 Phase partitioning calculations

263 ORACLE 2-D uses the core layer of the ORACLE module to calculate the partitioning of
 264 organic compounds between the gas and particle phases by assuming bulk equilibrium (Tsimpidi
 265 et al., 2014). However, the computational time required for the phase partitioning increases
 266 super-linearly with the number of species. As the condensation/evaporation of organic
 267 compounds depends only on their saturation concentration and not their O:C ratio, only one
 268 equilibrium calculation is performed per volatility bin of each category (i.e., fuel combustion,
 269 biomass burning, anthropogenic VOC products, and biogenic VOC products). This approach
 270 reduces significantly the number of equation to be solved and the corresponding computational
 271 cost of the phase partitioning calculations.

272 The ORACLE core layer calculates the aerosol composition at equilibrium by solving the
 273 following set of n nonlinear equations:

274

275
$$C_{a,i} = C_{t,i} - x_i C_i^* \text{ for } i = 1, n \quad (11)$$

276

277
$$x_i = \frac{C_{a,i}/M_i}{\sum_{i=1}^n C_{a,i}/M_i} \quad (12)$$

278

279 where $C_{t,i}$ and $C_{a,i}$ are the total and aerosol-phase concentrations of product i in $\mu\text{g m}^{-3}$,
 280 respectively, C_i^* is the effective saturation concentration of species i , x_i is the mole fraction of
 281 product i in the absorbing organic phase, and M_i is the molecular weight of product i which
 282 corresponds to the weighted average molecular weight of the species with the same saturation
 283 concentration.

284 Assuming that the distribution of the species of the same volatility bin in the different O:C
 285 bins does not change due to the condensation or evaporation, the gas and aerosol concentrations
 286 of each compound in the 2-D space after the phase partitioning calculations are given by:

287

288
$$SOG_{i,j}(t + \Delta t) = \left(\sum_{j=1}^m SOG_{i,j}(t + \Delta t) \right) \frac{SOG_{i,j}(t) + SOA_{i,j}(t)}{\sum_{j=1}^m SOG_{i,j}(t) + \sum_{j=1}^m SOA_{i,j}(t)} \quad (13)$$

289

290 and

291

292
$$SOA_{i,j}(t + \Delta t) = \left(\sum_{j=1}^m SOA_{i,j}(t + \Delta t) \right) \frac{SOG_{i,j}(t) + SOA_{i,j}(t)}{\sum_{j=1}^m SOG_{i,j}(t) + \sum_{j=1}^m SOA_{i,j}(t)} \quad (14)$$

293

294 where, SOG and SOA are the gas and aerosol concentrations of each compound, respectively, i
 295 and j are the volatility and O:C bins index in the 2-D space, respectively, m is the total number of
 296 O:C bins, and t and $t+\Delta t$ are the times before and after the phase partitioning calculations,
 297 respectively.

298

299

300 4. Model results

301 4.1 Total OA and O:C

302 Simulated total OA concentrations are high over regions affected by anthropogenic fuel
303 combustion and open biomass burning (Figure 2). The highest annual average OA concentrations
304 at the surface are predicted over the densely populated areas of Eastern China, Northern India
305 and Bangladesh ($10\text{--}28\ \mu\text{g m}^{-3}$), as well as over the tropical forest in the Congo Basin ($12\text{--}22\ \mu\text{g}$
306 m^{-3}). Considerably high OA concentrations are also predicted over the tropical forests of
307 Southeast Asia and the Amazon ($6\text{--}17\ \mu\text{g m}^{-3}$). Strong fossil fuel combustion sources over the
308 Arabian Peninsula result in annual average OA concentrations of $6\text{--}10\ \mu\text{g m}^{-3}$. Over Europe,
309 predicted OA annual average concentrations at the ground level are in the $3\text{--}7\ \mu\text{g m}^{-3}$ range. Over
310 North America, the highest OA concentration is simulated over Southern California, and also
311 over the Mexico City metropolitan area, and the Southeastern USA ($2\text{--}8\ \mu\text{g m}^{-3}$). OA
312 concentrations in the $0.5\text{--}1\ \mu\text{g m}^{-3}$ range are predicted over parts of the oceans due to the long-
313 range transport of OA from the adjacent continental sources. The calculated total tropospheric
314 OA burden is $3.3\ \text{Tg}$, which is higher compared to the calculated tropospheric burden of
315 ORACLE v1.0 ($2\ \text{Tg}$; Tsimpidi et al., 2016) but is within the range of OA tropospheric burdens
316 (0.7 to $3.8\ \text{Tg}$) from 31 global CTMs reported by Tsigaridis et al. (2014).

317 Figure 3a depicts the annual average simulated O:C ratio of total OA at the surface.
318 Lower values of O:C are predicted close to OA sources, i.e., over the industrialized areas of the
319 Northern Hemisphere, and over the tropical and boreal forests. The lowest average values occur
320 over the boreal forests (as low as 0.3) due to the limited photochemical activity over these
321 regions, in contrast to the tropical forests, where O:C is around 0.5. Over the densely populated
322 areas of Asia, Europe and North America, the O:C is about 0.3-0.4, i.e., close to the
323 anthropogenic sources. O:C levels increase rapidly (in excess of 0.6) downwind of the sources
324 due to photochemical aging of the transported OA. The highest O:C values are calculated over
325 the Sahara Desert and the remote Atlantic and Pacific Oceans ($0.8\text{--}1$), however, over these
326 regions, OA concentrations are low (Figure 2). O:C ratios increase significantly with altitude
327 according to the model (Figure 3b) since organic vapors transported vertically react with OH,
328 forming products with higher oxygen content. Over the mid-latitudes of the Northern
329 Hemisphere, the average O:C ratio near the surface is 0.55, and increases as the air masses are
330 transported aloft by approximately 0.05 for every 100 hPa (Figure 3b).

331

332 **4.2 POA and SOA**

333 Figure 4a depicts the decadal average simulated POA concentrations at the surface. POA
334 concentrations are high over the densely populated areas of the Northern Hemisphere due to
335 strong fuel combustion emissions from the industrial, energy, residential and transport sectors.
336 The highest concentrations are calculated over Eastern China ($3\text{--}13\ \mu\text{g m}^{-3}$), Bangladesh ($2\text{--}8\ \mu\text{g m}^{-3}$)
337 m^{-3}), and Eastern Europe ($1\text{--}3\ \mu\text{g m}^{-3}$). Open biomass burning emissions from forest, woodland,
338 peatland and savannah fires result in high POA concentrations over the tropics ($3\text{--}8\ \mu\text{g m}^{-3}$ over
339 the Congo Basin) and the boreal forests ($1\text{--}6\ \mu\text{g m}^{-3}$ over Russia). However, a large fraction of
340 POA evaporates due to dilution as the air masses travel downwind from the sources, resulting in
341 significant reduction of the concentration (Figure 4a). Then, the material that is transferred to the
342 gas phase can be oxidized and recondense to the aerosol phase forming SOA that persists even
343 far from the sources (Figure 4b). This results in a relatively homogeneous regional distribution
344 of SOA with a continental background of $2\ \mu\text{g m}^{-3}$ and high concentrations even far downwind
345 from anthropogenic (e.g., $7\text{--}22\ \mu\text{g m}^{-3}$ over South and Eastern Asia) and open biomass burning
346 (e.g., $9\text{--}17\ \mu\text{g m}^{-3}$ over Central Africa) sources. Lower concentrations are predicted over the
347 boreal forests ($\sim 1\ \mu\text{g m}^{-3}$) due to minor photochemical activity.

348 The calculated tropospheric burden of POA and SOA is 0.25 Tg and 3.05 Tg,
349 respectively. While the value of POA is very similar to the corresponding tropospheric burden of
350 ORACLE v1.0 (0.24 Tg), the tropospheric burden of SOA has increased significantly (1.74 Tg in
351 ORACLE v1.0). The tropospheric burden of POA calculated by ORACLE 2-D is much lower
352 than most global CTMs in the AEROCOM intercomparison study (mean value of 0.85 Tg)
353 (Tsigaridis et al., 2014). This difference is due to the evaporation of POA and its conversion into
354 SOA in ORACLE 2-D, given that this dynamic behavior of POA is not taken into account by
355 most of the global CTMs. On the other hand, the ORACLE 2-D calculated SOA tropospheric
356 burden is higher than most CTMs from the AEROCOM intercomparison study (mean value of 1
357 Tg) (Tsigaridis et al., 2014) due to its stronger chemical production. As indicated by Tsimpidi et
358 al. (2016), the POA burden is underestimated by our model, especially in the urban environment
359 in the winter, because our emission inventory does not yet account for residential wood burning
360 (Denier van der Gon et al., 2015).

361

362 **4.3 Fresh and Aged SOA**

363 The major advantage, at least in this initial phase, of extending the ORACLE module to
364 describe the oxygen content of OA is the model's ability to quantify the degree of photochemical
365 processing of the OA. The model can distinguish the fresh SOA that is relatively less oxygenated
366 and the highly aged and oxygenated SOA. As a first approximation, OA compounds with $O:C \leq$
367 0.6 are considered "fresh SOA" and OA compounds with $O:C > 0.6$ are considered as "aged
368 SOA".

369 Figure 5 depicts the average concentrations of fresh and aged SOA and their fractional
370 contributions to total SOA at the surface. Fresh SOA exceeds aged SOA close to the source areas
371 (Figures 5c). On the other hand, the spatial distribution of aged SOA extends further from the
372 sources with relatively high concentrations even over remote continental (e.g., Sahara) and
373 oceanic (e.g., North Pacific) regions (Figure 5b). The fraction of aged SOA is higher over the
374 industrialized regions (0.4-0.7), where IVOCs comprise 70% of total fuel combustion emissions,
375 and lower over the tropics (0.1-0.5), where IVOCs represent 40% of total open biomass burning
376 emissions (Figure 5d). Overall, the tropospheric burden of fresh SOA is 1.26 Tg and of aged
377 SOA 1.79 Tg.

378 The simulated vertical profiles of fresh and aged SOA are quite different (Figure 6). Both
379 fresh and aged SOA concentrations are high near the surface with zonal averages of 0.9-1.7 $\mu\text{g m}^{-3}$
380 m^{-3} over the northern mid-latitudes and the tropics. However, at higher altitudes the oxidation of
381 fresh SOA continues, which leads to the transformation into aged SOA. Therefore, above 960
382 hPa altitude the zonal average concentrations of fresh SOA decrease gradually (below 1 $\mu\text{g m}^{-3}$)
383 and that of aged SOA increase, exceeding in some cases 1.5 $\mu\text{g m}^{-3}$ at 850 hPa altitude. Further
384 aloft in the atmosphere (above 700 hPa altitude) the levels of both fresh and aged SOA are
385 reduced significantly due to dilution and removal.

386

387 **4.3 2-D space distribution**

388 In this section, we present a new feature that comes along with the upgraded ORACLE 2-D.
389 Since ORACLE 2-D explicitly describes the concentration of organic surrogate species in two
390 dimensional space, defined by their volatility and O:C ratio, it can also provide as output their
391 distribution in this 2-D space. As an example, Figure 7 depicts the 2-D distribution of the
392 average total OA concentrations during the years 2001-2010 over central Europe and the

393 Amazon basin. The first left column represents all the species with $C^* \leq 10^{-2} \mu\text{g m}^{-3}$, while the top
394 line represents all the species with $\text{O:C} \geq 1.2$.

395 Over Europe, approximately 50% of OA has $C^* = 1 \mu\text{g m}^{-3}$. About 10% of the OA is
396 emitted directly in this volatility bin as POA with $\text{O:C} = 0.1$, while the rest, 40%, is SOA with
397 higher O:C from the aging of more volatile compounds. The volatility bin with $C^* = 10^{-2} \mu\text{g m}^{-3}$
398 is also important, containing 18% of the total OA. On the other hand, volatility bins with $C^* >$
399 10^2 contain less than 1% of total OA since organic species in these high volatility bins exist
400 mainly in the gas phase. Furthermore, about 30% of the total OA over Europe has $\text{O:C} \leq 0.2$,
401 mainly from direct emissions of POA from fuel combustion sources with $\text{O:C} = 0.1$ (20% of total
402 OA). Organic species with $\text{O:C} = 0.4$ are also important, representing 15% of the total OA.
403 Overall, 40% of OA over Europe has $0.3 \leq \text{O:C} \leq 0.6$ and 30% is highly oxidized with $\text{O:C} \geq 0.7$.

404 Over the Amazon, similar to Europe, approximately 50% of total OA has $C^* = 1 \mu\text{g m}^{-3}$
405 while bins with $C^* > 10^2$ contain only 2% of total OA. However, volatility bins with $10^2 \leq C^*$
406 $\leq 10^3$ are more important compared to Europe containing about 30% of the total OA
407 concentrations. This discrepancy can be attributed to the high bSOA-v concentrations over the
408 Amazon rainforest, which remain within higher volatility bins during their photochemical aging
409 compared to aSOA-v. Furthermore, similar to Europe, about 30% of total OA over the Amazon
410 has $\text{O:C} \leq 0.2$, mainly affected by the direct aerosol emissions from biomass burning with $\text{O:C} =$
411 0.2 (~20% of total OA). OA species with $0.3 \leq \text{O:C} \leq 0.6$ represent 55% of the total OA with
412 mostly $\text{O:C} = 0.4$ (35% of total OA). On the other hand, only 15% of the total OA is highly
413 oxidized with $\text{O:C} \geq 0.7$. Comparing these results to Europe shows that OA over biomass
414 burning areas (e.g., the Amazon) are estimated to be less oxidized than OA over anthropogenic
415 areas (e.g., Europe).

416

417 5. Model performance evaluation

418 The mean absolute gross error (MAGE), mean bias (MB), normalized mean error (NME),
419 normalized mean bias (NMB), and the root mean square error (RMSE) are used to assess the
420 model performance of the simulations of OA components (i.e., POA, fresh and aged SOA) and
421 O:C :

422

$$MAGE = \frac{1}{N} \sum_{i=1}^N |P_i - O_i| \quad (15) \qquad MB = \frac{1}{N} \sum_{i=1}^N (P_i - O_i) \quad (16)$$

424

$$NME = \frac{\sum_{i=1}^N |P_i - O_i|}{\sum_{i=1}^N O_i} \quad (17) \qquad NMB = \frac{\sum_{i=1}^N (P_i - O_i)}{\sum_{i=1}^N O_i} \quad (18)$$

426

$$RMSE = \left[\frac{1}{N} \sum_{i=1}^N (P_i - O_i)^2 \right]^{\frac{1}{2}} \quad (19)$$

428

429 where O_i is the observed campaign average value of the i^{th} OA component or O:C, P_i is the
 430 corresponding modelled value during the same period, and N is the total number of comparisons
 431 used for the evaluation.

432

433 5.1 Organic aerosol concentrations

434 The simulated POA and SOA can be compared against AMS factor analysis results from
 435 61 field campaigns performed during the period 2001–2010 over urban-downwind and rural
 436 environments in the Northern Hemisphere (Figure 8). Information for each of these campaigns is
 437 given in Tsimpidi et al. (2016). Factor-analysis techniques classify OA into hydrocarbon-like OA
 438 (HOA), biomass burning OA (BBOA), and oxygenated OA (OOA). HOA is assumed to
 439 correspond to POA from fossil fuel combustion, and BBOA corresponds to POA from biomass
 440 burning (Crippa et al., 2014). Therefore, simulated POA is compared here against the sum of
 441 AMS HOA and BBOA (Table 1). OOA corresponds to modelled SOA (Table 2) and can be
 442 further classified into two subtypes, semi-volatile OOA (SVOOA) and low volatility OOA
 443 (LVOOA) (Crippa et al., 2014). Recent studies have suggested that the main difference between
 444 these two OOA types is often not so much their volatility, but mostly their oxygen content
 445 (Kostenidou et al., 2016; Louvaris et al., 2017). These two OOA types represent distinct
 446 oxidation states with O:C of 0.33-0.67 for SVOOA and 0.67-1.00 for LVOOA (Donahue et al.,
 447 2012). Therefore, SVOOA can be compared at least as a zero-order approximation against the
 448 simulated fresh SOA (Table 3) and LVOOA against the simulated aged SOA (Table 4).

449 The model reproduces the observed campaign average POA concentrations well in most cases
450 over both the urban downwind and rural locations (Table 1, Figure 8a). The average simulated
451 POA concentration over the urban downwind regions is around $0.65 \mu\text{g m}^{-3}$ and it decreases
452 further after continued transport from the sources to $0.45 \mu\text{g m}^{-3}$ over the rural areas. Compared
453 to AMS HOA concentrations, modelled POA is unbiased over rural environments, however, it is
454 underestimated downwind of urban areas, as indicated in Sect. 4.2 ($\text{MB}=-0.17 \mu\text{g m}^{-3}$). The
455 model has the best performance during summer with $\text{MB}=-0.05 \mu\text{g m}^{-3}$ and $\text{RMSE} = 0.40 \mu\text{g m}^{-3}$.
456 Compared to ORACLE (Tsimpidi et al., 2016), ORACLE 2-D produces almost identical
457 concentrations of POA, hence the model performance is unchanged.

458 Calculated SOA concentrations are higher than POA both downwind of major urban
459 centers ($2.76 \mu\text{g m}^{-3}$) and rural locations ($2.53 \mu\text{g m}^{-3}$). Simulated average SOA concentrations
460 are slightly low-biased compared to AMS OOA measurements downwind of urban areas ($\text{MB}=-$
461 $0.22 \mu\text{g m}^{-3}$) and over rural areas ($\text{MB}=-0.18 \mu\text{g m}^{-3}$). While the model performs well during
462 spring ($\text{NMB}=10\%$), summer ($\text{NMB}=-10\%$), and autumn ($\text{NMB}=0\%$), it strongly underestimates
463 SOA concentrations during winter ($\text{NMB}=-76\%$). This underestimation of SOA by the model is
464 mostly due to missing LVOOA. For the 41 campaigns in which both OOA types were identified,
465 EMAC reproduces the fresh SOA concentrations well (compared to SVOOA) with a MB of 0.41
466 and $0.32 \mu\text{g m}^{-3}$ downwind of urban and in rural locations, respectively (Table 4). Furthermore,
467 except during winter, the model is also able to capture the seasonal variations of the fresh SOA
468 concentration (Table 4). However, the model underpredicts the aged SOA concentrations
469 (compared to AMS measured LVOOA) with a MB of -0.95 and $-0.70 \mu\text{g m}^{-3}$ over urban
470 downwind and rural locations, respectively. This aged SOA underestimation is also evident
471 during the four seasons of the year and especially during winter ($\text{NMB} = -93\%$). This result may
472 indicate that the model underestimates the atmospheric aging rate of SOA or misses processes
473 forming highly oxidized OA, e.g., highly oxidized ELVOCs from the ozonolysis of terpenes
474 (Ehn et al., 2014; Jokinen et al., 2016). Another useful feature of ORACLE 2-D is that detailed
475 AMS measurements can be used to gain further insights into what causes biases and errors in its
476 OA predictions. Compared to ORACLE (Tsimpidi et al., 2016), ORACLE 2-D tends to produce
477 higher fresh SOA concentrations and slightly lower aged SOA concentrations. However, this
478 discrepancy may be partially due to the fact that in ORACLE fresh SOA is assumed to
479 correspond only to first generation oxidation products, while in ORACLE 2-D fresh SOA is

480 defined based on the O:C ratio, and includes higher generation oxidation products as well.
481 Overall, the simulated average total SOA concentrations in ORACLE 2-D ($2.59 \mu\text{g m}^{-3}$) are
482 higher than ORACLE ($1.91 \mu\text{g m}^{-3}$) reducing the gap with the corresponding AMS OOA (2.78
483 $\mu\text{g m}^{-3}$).

484

485 **5.2 O:C ratio**

486 The simulated O:C ratio of total OA and SOA is compared against observed O:C of OA
487 and OOA from 30 and 58 field campaigns, respectively, performed during the period 2001–2010
488 in the Northern Hemisphere (Tables 5, 6). Given that global models, including EMAC,
489 underestimate concentrations of POA and SOA over urban locations (Tsigaridis et al., 2014;
490 Tsimpidi et al., 2016), AMS data from these locations is not included for the statistical
491 evaluation of the calculated O:C (Figure 9, Tables 7, 8). In fact, the model tends to overestimate
492 the O:C of total OA compared to observations from urban locations (e.g., Mexico City,
493 Barcelona, New York, Riverside, Paris; Table 5). This overprediction can be attributed to the
494 coarse spatial resolution and the difficulty to represent freshly emitted (or formed) OA on a local
495 scale. On the other hand, the model performs remarkably well in reproducing the O:C ratio of
496 both total OA (NMB=7%, RMSE=0.13) and SOA (NMB=5%, RMSE=0.12) in non-urban areas.

497 The model tends to overestimate the O:C ratio of total OA compared to observations
498 from field campaigns close to the coasts (e.g., western coast of Chile, Mace Head). The model
499 reproduces very well the low O:C ratios of total OA during winter and the higher values during
500 spring and autumn (Table 7). On the other hand, it overestimates the O:C of total OA during
501 summer (MB=0.14). However, there are only 4 field campaigns conducted during the summer
502 months that provide O:C of total OA with surprisingly low O:C values for this time of the year
503 (0.3-0.4) which are not captured by the model. Overall, the O:C of total OA is slightly
504 overestimated by the model (MB=0.04).

505 Simulated O:C of SOA is relatively high (0.5-0.7) at most observational sites, which
506 agrees well with measurements. The model also captures the very high O:C values (larger than
507 0.7) observed over very remote areas (e.g., Okinawa, Finokalia). On the other hand, low O:C
508 ratios (lower than 0.5), reported by a few field campaigns, are overestimated by the model (Duke
509 forest, Rhine Valley, Jiaying). Remarkably, the model performance during winter is unbiased for
510 the O:C ratio of SOA (Table 8). This is in contrast to its inability to reproduce SOA

511 concentrations during winter (Tsimpidi et al., 2016). During the other seasons the model slightly
512 overestimates the O:C ratio of SOA with an MB ranging from 0.02 (during spring) to 0.07
513 (during summer and autumn).

514

515 **6. Conclusions**

516 The ORACLE module for the description of OA composition and evolution in the
517 atmosphere (Tsimpidi et al., 2014) has been extended to simultaneously simulate the volatility
518 and the oxygen content of OA that results from atmospheric aging. Similar to ORACLE v1.0, the
519 new version is implemented in the EMAC CCM, and considers the formation of OA from the
520 emissions and chemical aging of LVOCs, SVOCs and IVOCs from fossil fuel, biofuel and
521 biomass burning related sources, as well as from the oxidation of anthropogenic and biogenic
522 VOC precursors. The updated ORACLE module employs the 2-D VBS framework that uses
523 logarithmically spaced effective saturation concentration bins to describe the volatility of organic
524 compounds, and linearly spaced oxygen per carbon ratio bins to describe their oxygenation state.

525 The simulated concentrations of OA and its components (i.e., POA and SOA) are similar
526 to ORACLE v1.0 with relatively high concentrations over the industrialized areas in the
527 Northern Hemisphere and the biomass burning areas in the tropics. The tropospheric burdens of
528 POA and SOA are calculated to be 0.25 and 3.05 Tg respectively, the latter being higher than
529 with ORACLE v1.0. The new ORACLE 2-D module additionally allows calculation of the
530 oxidation state of OA (in terms of O:C), and therefore, its classification into fresh SOA (with
531 O:C lower than 0.6) and aged SOA (with O:C higher than 0.6). O:C is calculated to be relatively
532 low close to source regions and at high latitudes. The predicted O:C ratio is as low as 0.3 over
533 the boreal forests, 0.3-0.4 close to the anthropogenic sources in the Northern Hemisphere, 0.5
534 over the tropical forests and higher than 0.6 downwind of source areas and at altitudes aloft.
535 Accordingly, fresh SOA concentrations are higher close to sources while aged SOA increases as
536 the air masses are transported away from the sources and to higher altitudes. The estimated
537 tropospheric burden of fresh SOA is 1.26 Tg and of aged SOA 1.79 Tg. The analysis of model
538 results regarding the distribution of OA in the 2-D space of volatility and oxygen content showed
539 that half of OA has $C^* = 1 \mu\text{g m}^{-3}$ over both anthropogenic areas (e.g., Europe) and tropical
540 forests (e.g., Amazon). Furthermore, over Europe OA compounds are more strongly oxidized
541 than over the Amazon, and consist of 40% fresh OA and 30% aged SOA (compared to 55% and

542 15%, respectively, over the Amazon). The remainder 30% in both areas consists of POA or very
543 low oxidized material with $O:C \leq 0.2$.

544 The simulated OA components (POA, fresh, aged and total SOA) have been compared
545 with observed subtypes of OA (sum of HOA and BBOA, SVOOA, LVOOA and OOA) derived
546 from AMS factor analysis results from 61 field campaigns, performed during the period 2001–
547 2010 over urban-downwind and rural environments in the Northern Hemisphere. The model
548 reproduces the POA concentrations over both types of environment with low bias. While the
549 model appears to capture the fresh SOA concentrations reasonably well, it underestimates the
550 concentrations of aged SOA, resulting in an overall underprediction of total SOA. The
551 underestimation of aged SOA by the model emphasizes the need to better describe chemical
552 aging processes and further explore the effect of ELVOCs on the formation of SOA.
553 Furthermore, the model realistically reproduces the observed O:C ratio of total OA (NMB=7%)
554 and OOA (NMB=5%) from 50 field campaigns over urban-downwind and rural areas.

555 ORACLE 2-D is a flexible module that efficiently describes the organic aerosol
556 composition and evolution in the atmosphere by simulating the changes in OA volatility and
557 oxygen content throughout its lifetime in the atmosphere. The ability of ORACLE 2-D to
558 simulate the degree of OA oxidation can help determine the changing OA hygroscopicity during
559 atmospheric aging. ORACLE 2-D can potentially provide valuable insights into the composition
560 and reactivity of OA and the physicochemical evolution during atmospheric transport of OA,
561 which can help reduce aerosol-related uncertainties that persist in global atmospheric chemistry
562 and climate modeling.

563

564 **Code and Data Availability**

565 To use ORACLE 2-D as part of EMAC, please first apply for an ECHAM5 and a MESSy
566 license. The GCM ECHAM5 has been developed at the Max Planck Institute for Meteorology in
567 Hamburg (see: www.mpimet.mpg.de/en/wissenschaft/modelle/echam/echam5.html). The
568 Modular Earth Submodel System (MESSy) is developed and applied by a consortium of
569 institutions, initiated by the Max Planck Institute for Chemistry. The usage of MESSy and access
570 to the source code is licensed to all affiliates of institutions that are members of the MESSy
571 Consortium. Institutions can be a member of the MESSy Consortium by signing the MESSy
572 Memorandum of Understanding. More information can be found on the MESSy Consortium

573 Website (www.messy-interface.org). The measurement data used for the evaluation of the model
574 can be found in Tables 5 and 6 of this manuscript and Tables S6 and S7 in the supplement of
575 Tsimpidi et al. (2016) (available online at [https://doi.org/10.5194/acp-16-8939-2016-](https://doi.org/10.5194/acp-16-8939-2016-supplement)
576 [supplement](https://doi.org/10.5194/acp-16-8939-2016-supplement)).

944 **Table 8.** Statistical evaluation of EMAC O:C ratio of OOA against observations from 18 data

945 sets worldwide during 2001-2010.

Season	Number of datasets	Mean Observed ($\mu\text{g m}^{-3}$)	Mean Predicted ($\mu\text{g m}^{-3}$)	MAGE ($\mu\text{g m}^{-3}$)	MB ($\mu\text{g m}^{-3}$)	NME (%)	NMB (%)	RMSE ($\mu\text{g m}^{-3}$)
Winter	7	0.58	0.56	0.14	-0.02	23	-4	0.17
Spring	12	0.63	0.65	0.08	0.02	13	4	0.10
Summer	10	0.58	0.65	0.09	0.07	15	12	0.11
Autumn	3	0.58	0.65	0.10	0.07	17	11	0.10
Total	32	0.60	0.63	0.10	0.03	16	5	0.12

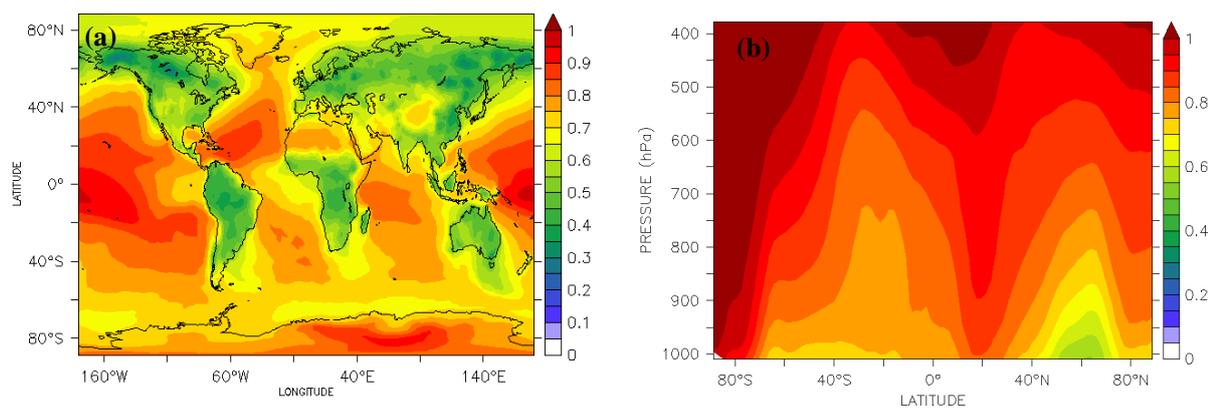

946 **Figure 1:** The 2-D grid space in ORACLE 2-D module with saturation concentration (in $\mu\text{g m}^{-3}$) on the x-axis and the O:C ratio on the y-axis. For each cell an organic surrogate compound
 947 m^{-3}) on the x-axis and the O:C ratio on the y-axis. For each cell an organic surrogate compound
 948 is defined with a specific carbon number calculated as a function of effective saturation
 949 concentration and O:C ratio. The formation and evolution of SOA from: (a) fuel combustion
 950 SVOCs and IVOCs, (b) biomass burning SVOCs and IVOCs, (c) anthropogenic VOCs and, (d)
 951 biogenic VOCs are shown. The arrows correspond to the aging reactions and the grey grids to
 952 the initial chemical state of the species prior to aging.

953 **Figure 2:** Predicted average surface concentration of total OA ($\mu\text{g m}^{-3}$) during the years 2001-
954 2010.

960

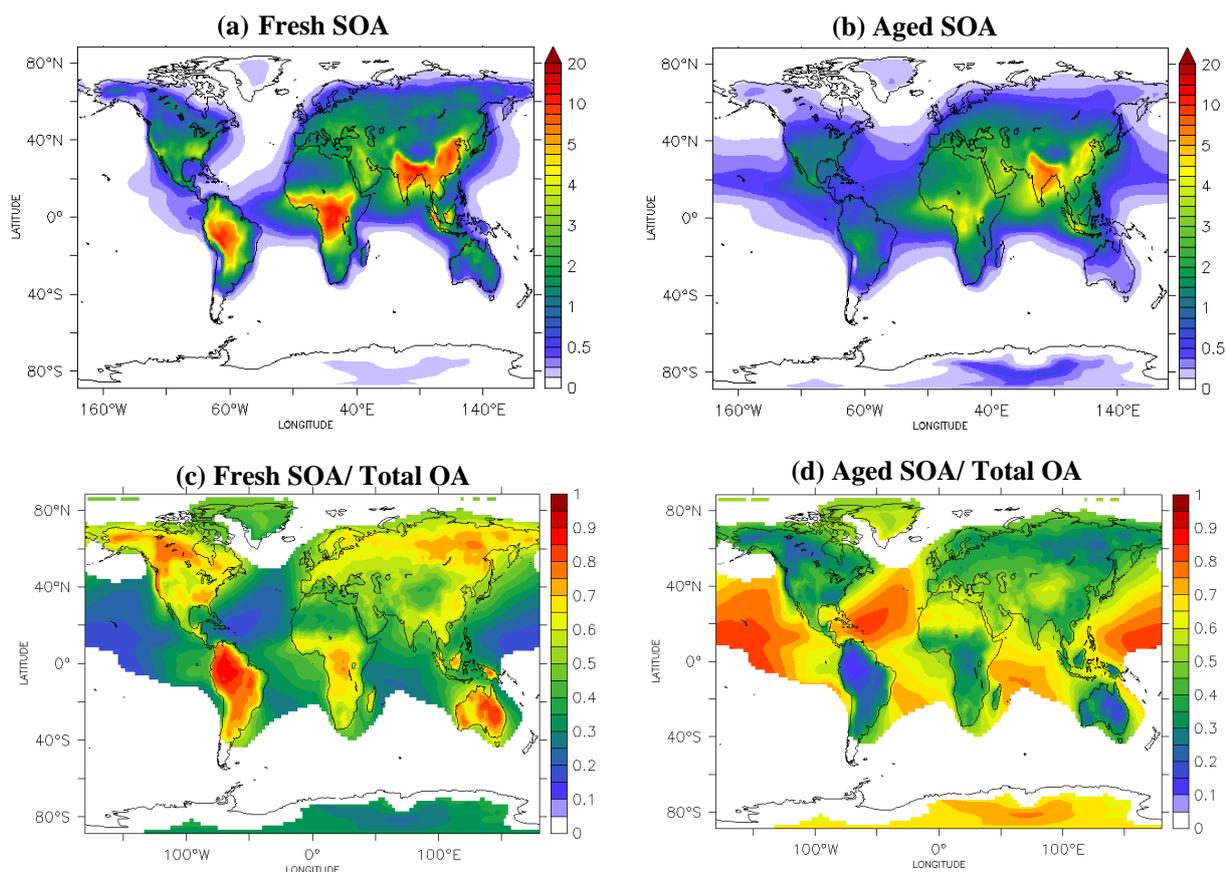

961 **Figure 3:** Predicted (a) average surface and (b) average zonal concentrations of total O:C during

962

the years 2001-2010.

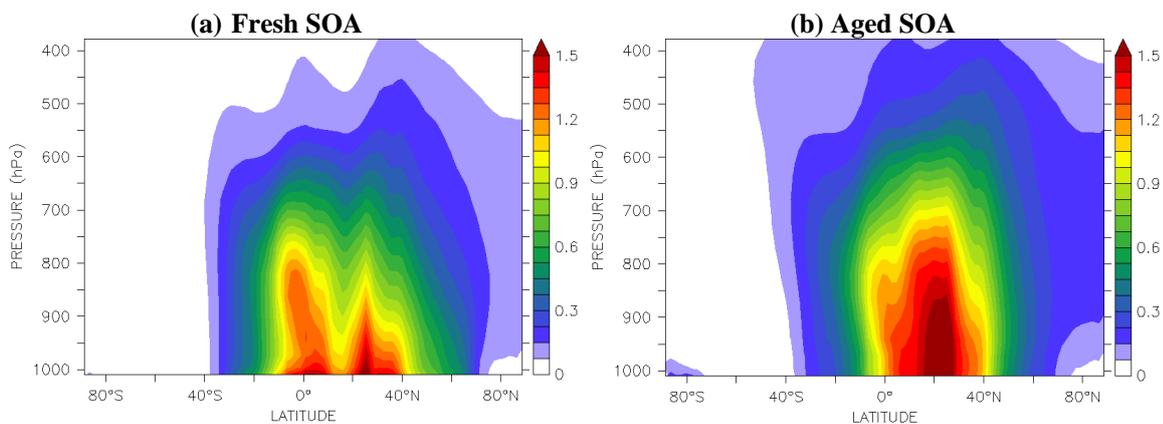

963 **Figure 4:** Predicted average surface concentration of (a) POA ($\mu\text{g m}^{-3}$) and (b) SOA ($\mu\text{g m}^{-3}$)
964 during the years 2001-2010.

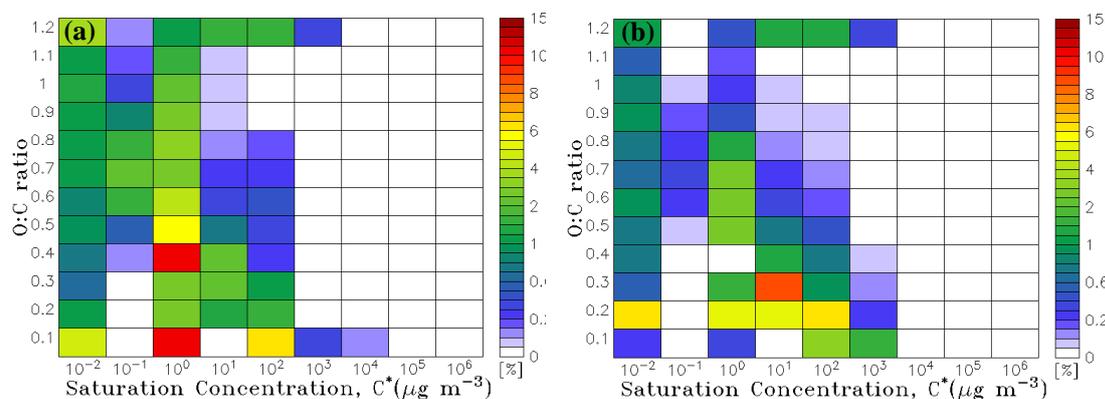

965

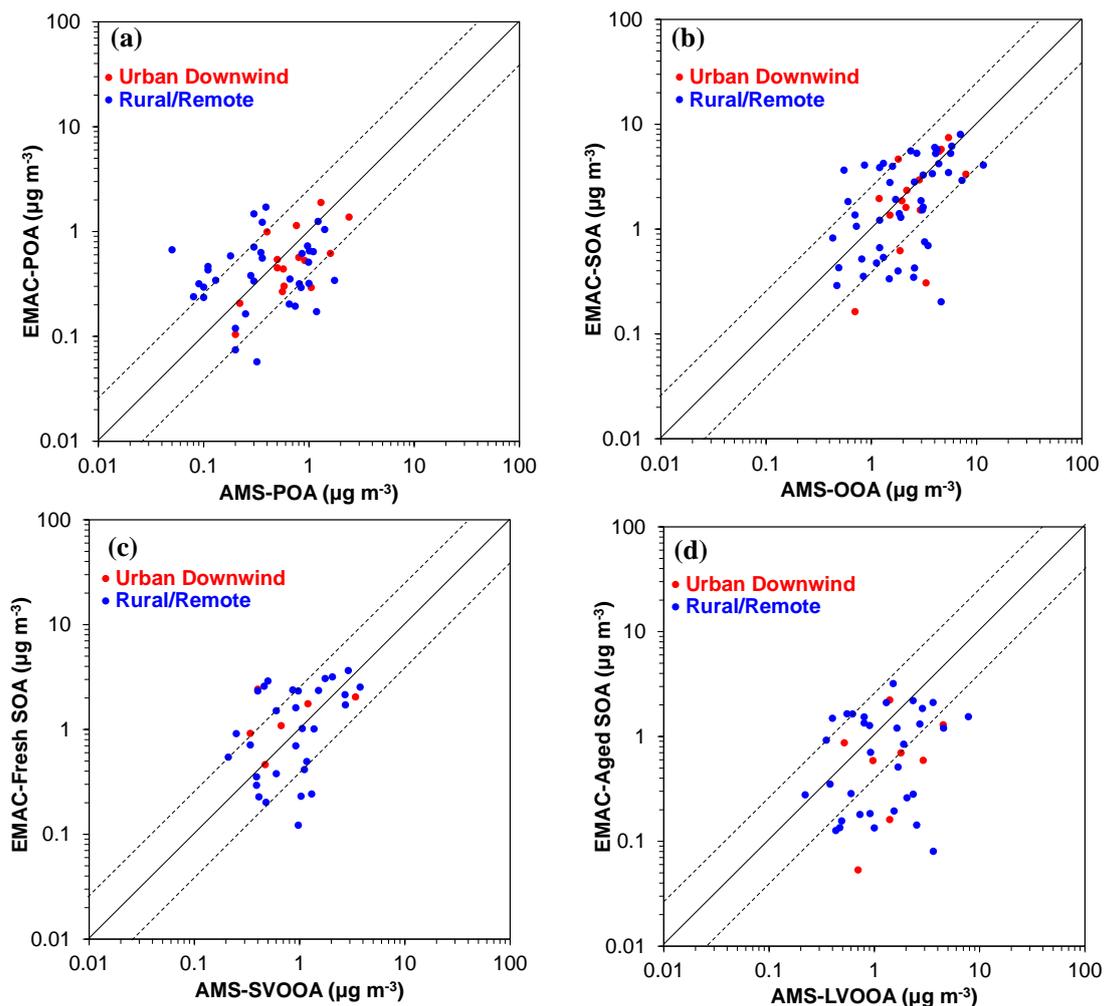

966 **Figure 5:** Predicted average surface concentration (in $\mu\text{g m}^{-3}$) of (a) fresh SOA and (b) aged
967 SOA and surface fraction of (c) fresh SOA and (d) aged SOA to total OA during the years 2001-
968 2010.

969 **Figure 6:** Predicted average zonal concentration (in $\mu\text{g m}^{-3}$) of (a) fresh SOA and (b) aged SOA
970 during the years 2001-2010.

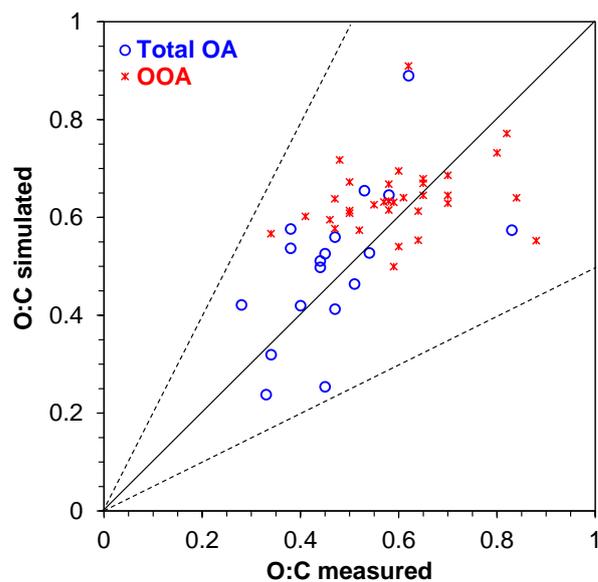

971 **Figure 7:** The average predicted fraction of OA concentration in each cell of the ORACLE 2-D
972 grid space to total OA concentration over (a) Europe and (b) the Amazon basin during the years
973 2001-2010.

974

975 **Figure 8:** Scatterplots comparing model predictions to AMS measurements and their PMF
 976 analysis for: (a) POA, (b) OOA, (c) SV-OOA, and (d) LV-OOA concentrations (in $\mu\text{g m}^{-3}$) in
 977 the Northern Hemisphere during 2001-2010. Each point represents the data set average value
 978 over urban downwind (in red) and rural/remote (in blue) sites. Also shown are the 1:1, 2:1, and
 979 1:2 lines.

980

981 **Figure 9:** Scatterplot comparing model predictions to measurements for O:C ratio of total OA
982 (in blue) and OOA (in red) over non-urban areas in the Northern Hemisphere during 2001-2010.
983 Each point represents the data set average value over a specific measurement site. Also shown
984 are the 1:1, 2:1, and 1:2 lines.
