Received and published: April 24, 2019

Dear Editor,

Please find our detailed responses for the comments you provided. We have made the appropriate changes in the manuscript and also attached the latex-diff file for said changes. Please do let us know if further modifications are needed.

## **1 Answers to Referee 1's remarks**

- Referee: p.4 l.29 explain "consistently respecting the underlying discretization" : You wrote: without approximations to the component field discretizations (type  $\in$  [FV,FEM] and order); please turn this mathematical sentence between the parentheses into an English one and replace FEM by FE  
Authors: The suggested change has been made in the manuscript.
- Referee: p.7 ll.30-32 in what exactly is the MBTR stack an improvement : Explain why this is an improvement as requested by the referee; just saying that

storing the connectivity is an improvement is not a satisfactory answer if you don't explain the positive impact of doing so.

Authors: Storing the connectivity of the mesh elements, the real topology of component meshes along with the parallel decomposition provides MOAB the capability to perform optimizations during mesh migration, load rebalancing with Zoltan and minimize point-to-point communications based on geometric proximity of vertices (and DoFs). p.8 l.22-l.29 details the improvements of the MBTR stack already. Let us know if these explanations are still insufficient.

- Referee: p.11 ll.2-3 state here (or anticipate) the rational for replacing MCT as a broker. Please add these arguments somewhere in the text to answer the referee's comment.

Authors: p.8 l.28 - p.9 l.6 describes the advantage of using MOAB's compact memory data structure and communication kernels over the MCT and related GSMap structures that have an  $O(p)$  complexity. Moved the reference to crystal router algorithm from p.16 l.3 to p.8. The crystal router algorithm sits at the heart of MOAB aggregated communication strategies, which are far superior in terms of scalability in comparison to MCT's M-to-N communication kernels. Additional statements have been added in p.8 to address reviewer comments.

- Referee: p.12 ll.26-29 Fig 6. is not immediate to read without some further "step to step" details in the text. Yes, the advancing front algorithm should be better explained. Give more details on the relation between the text and the figure. I suppose the source cells are in red and the target cells are in blue? What does the bottom figure represent?

Authors: Yes we have added more details here as requested. Fig 6 has been slightly modified as well and p.15 l.1-l.7 now includes some rephrasing and detailed explanation has been added to accompany the illustration. Discussions regarding determination of initial seed or starting location of the front have also been simplified.

- Referee: pp.12-13 subsection 3.3.1 does the seed determination can be fully automated or its efficiency depend on user tuning? Details on this automation should be added, as part of a better explanation of the advancing front algorithm.  
Authors: The seed or the initial cell determination proceeds through a linear search. A cell in target mesh is chosen based on local ID space, and a cell corresponding to the geometric location is identified on the source mesh. If either of these contain a hole, we need to re-seed. Hence multiple trials may be required. Page 19 I.6 has some description related to this. We have also modified description about advancing front algorithm in Page 14.
- Referee: p.14 I.7 does "to all tasks" refer to tasks (or rather processes) on the source side? I don't understand your answer ("Description in rebuttal is detailed"); please specify "target" or "source" or "coupler" tasks.  
Authors: Changes in p. 14 I.7. The "to all tasks" refers to coupler tasks since the entire remapping process, including source coverage mesh computation is performed only in coupler PEs.
- Referee: p.14 I.8 "Cells [...] are sent": how are they represented? Again, I don't understand your answer ("Description in rebuttal is detailed"). Please add the details you describe in your answer to the referee in the text or explain where they can be found if already in the text.  
Authors: Additional details have been added to p.16 I.5. Quoting original answer from rebuttal to reviewer (AC5).  
MOAB utilizes the aggregated crystal router to efficiently send small data between processes. In an all-to-all communication strategy, with  $\log(N)$  steps of communication, all the processes get access to the data they need. This is used once during the setup phase to establish point-to-point communication links, which is then used later to pack and send data directly. During the field transfer from components to coupler, we pack multiple fields together in a single array to send the data to coupler, apply weight matrices on the vectors and transmit back

the fields (in a packed and aggregated fashion) to the target component. The size of such communication is on the order of DoFs in source + target.

- Referee: p.14 l.10 please clarify the term "superset": a superset usually refers to inclusion of similar objects. Again, I don't understand your answer ("Description in rebuttal is detailed"). Please add the details you describe in your answer to the referee in the text or explain where they can be found if already in the text.

Authors: p. 16 l.9-l.10 - rephrased and removed the term superset that is causing confusion in this context.

- Referee: p.15 l.5 how expensive can be the communication of ghost intersection elements on highly distributed components? You wrote that you modified the text p.16, l.21. But beside the added references, I see no modification p.16, l.21.

Authors: In the experiments performed for scalability of remapping algorithm in Fig. 13, the ghost communication on the coverage mesh takes less than 0.1% of total time. This is a local point-to-point communication of nearest neighbors, the cost is extremely cheap. Statements have been added in p. 17 l.7 to this effect.

- Referee: p.16 l.28 "it is non-trivial to": did you find a way? Both referees asked for more details. Please add details in the text.

Authors: Refer to updates in p.18 l.28-l.32.

## 2 Answers to Referee 2's remarks

- Referee: Page 6, line 20 "oas (2018)" For OASIS3-MCT\_4.0, please cite: Valcke, S., Craig, A. and Coquart, L. (2018), OASIS3-MCT User Guide, OASIS3-MCT4.0, CECI, Université de Toulouse, CNRS, CERFACS - TR-CMGC- 18-77, Toulouse, France , Technical report XXXXX

Authors: I could not find a report number but referenced without it. Please let us know if you have an updated reference.

- Referee: Page 16, line 28, bit-for-bit capability is sometimes important to achieve Both referees asked for more details. Please add details in the text.

Authors: Refer to updates in p.18 l.28-l.32.

- Referee: Page 20, lines 18-19. For the 10243 test case, are weights being generated in 2d or 3d? Please add in the text some details about your motivation, as you detail in your reply to the referee.

Authors: P. 23 l. 3 mentions that this is a 3-d test case. Additional details have been added under P. 22 l. 27, P. 23 l. 6.

- Referee: Page 21, Figure 10, I am struggling to read the axes and other text on the plots You wrote that you have zoomed the graphs but I don't see any difference; please redo the plots with captions and axis readable for a printed article (A4 format).

Authors: Changed the layout for the sub-figures in Fig. 10 so that the axes are clearer.

- Referee: Page 25, figure 13. Is there benefit to showing the three results (colocated plus two disjoint). The manuscript diff you point to do not address the referee's question. The ones that do are p.28, l8-9. But there you only mention that "the scaling of the remapping algorithm is nearly independent of the PE layout." Please discuss a bit more as, as you state, this is very counter intuitive.

Authors: Additional comments have been added in Page 29, near line 7.

- Referee: Page 26, figure 14b. I am surprised there is so little scaling of the send/rcv at NE120 and the core counts presented. Again, the manuscript diff you point to do not address the referee's question. Please add something on the lack of scalability above 128 cores as you detail in your reply to the referee.

Authors: Page 29, Line 28. The lack of scalability has been explained and pointers to some planned future work has been discussed.

- Referee: For page 27, figure 15, maybe remind us that it's case B of Table 1 (I think that's correct) in text. Please do as suggested by the referee.

Authors: That is correct. Done.

### 3 Answers to Sophie Valcke's remarks

- Referee: p.2, l. 14: please consider changing "or include trivial linear transformations " by "or are not linked by any trivial linear transformations

Authors: Done.

- Referee: p.2, l. 17: change "need" by "needs"

Authors: Done.

- Referee: p.4, l.8: what does "nonlinearly" means in "Conservative remapping of nonlinearly coupled solution fields" ? p.4, l.17-26: Why do you split into two paragraphs "1. NC/GC" (under which you describe NC or NC/GC or GC solutions), and "2. LC/GC" (under which you have LC/GC and LC solutions)?

Authors: **explanation**

- Referee: P.4, l.22: What does L2 or H1 refer to?

Authors: These are the error norms that are standard. Brief clarifications have been added

- Referee: P.4, l.23 : define "FD" and "FV"

Authors: Expanded

- Referee: P.4, I.31: what does "locate infrastructure" mean?

Authors: Its for location of points to compute nearest neighbor or point in element computations using bounding-boxes, Kd-tree etc. Slightly modified text to clarify.
- Referee: P.5, I.5: please consider changing "the solution field projection between grids" with "the solution field projected on the target grid".

Authors: Clarified.
- Referee: P.5, I.12: define "L2"

Authors: Slightly expanded. Several references already cited that provide details on these standard mathematical notations.
- Referee: P.6, I.23: OASIS3-MCT is certainly not a climate application, it is a coupler

Authors: We do not specifically mention OASIS3-MCT as an application. It is referred to as a coupler and compared to CIME-MCT.
- Referee: P.7, I.3-4: You wrote "ESMF and SCRIP traditionally handle only cell-centered data that targets Finite Volume discretizations (FV to FV projections), with first-order conservation constraints" . This is not true as both ESMF and SCRIP offer also 2nd ordre conservative remapping. Please correct.

Authors: Corrected.
- Referee: P.7, I.6: I don't understand what "matches the areas ... to the weight ... " means. Please modify.

Authors: This is how the dual or the control-volume grid for a spectral element mesh is computed. The GLL node weights in the SE grid determine the area of the dual mesh element centered around the GLL point. Since the GLL points are not equi-spaced, it typically is a slow iterative procedure to converge the area of the dual grid element to exactly match the weights of the GLL quadrature node.

We added a reference (technical report from SNL) in P.6 l. 35 for the dual grid computation to make things clearer.

- Referee: P.7, l.30 : in "the online remapping computation uses the exact same input grids, and ...", the same input grids than what?  
Authors: Compared to the offline workflow. Updated text. P.7 l.20.
- Referee: P.8, l.14: replace "treats" by "treat" as "which" refers to the datatypes  
Authors: Done.
- Referee: P.9, l.25, please rephrase "While the MCT infrastructure only allowed for a numbering of the grid points", as MCT certainly allows for more than this!  
Authors: P.9 l.17. Rephrased sentence. Please verify.
- Referee: P.12, first paragraph and p.16, l.14-22 : Referee 1 asked you to use MPI "processes" and OpenMP "tasks" coherently through the text so please change "tasks" for "processes" in thus paragraph. Also, p.8, l.10, change "tasks" for "processes".Also p.26, l.27, change "task" for "process".  
Authors: References to task have been replaced with process where relevant. Also rephrased "remapping process" to "remapping operation" to avoid confusion.
- Referee: Figure 8, p. 17: this is almost the same than Figure 7; I don't understand what additional information does Figure 8 bring?  
Authors: Figure 7 shows the actual coverage mesh that is computed from the source mesh in coupler PEs such that the local target mesh is entirely covered. Figure 8 shows the actual intersection mesh that does not have any elements beyond the target mesh, but within the local target mesh, contains the union of source and target elements. Let me know if this is still unclear or if we should add some text in relevant section to detail the differences more.

- Referee: P.22, l.4: please consider removing "on the BlueGene-Q machine (Mira) at ANL" as this is stated l.10.

Authors: Done.

- Referee: P.22, l.10-15: Please refer more precisely to graphs a), b) and c) in Figure 10 where appropriate and discuss the results; it looks to me that only Figure 10 c is analysed/discussed.

Authors: P.22 l.30. Description for each sub-figure has now been added.

- Referee: P.22, last paragraph: you write "The full 3-D point location and interpolation operations provided by MOAB are comparable to the implementation in Common Remapping component used in the C-Coupler Liu et al. (2013) (Liu et al., 2013) and provide relatively much stronger scalability on larger core counts Liu et al. (2014) (Liu et al., 2014) for the remapping operation" ; how do you get to that conclusion?

Authors: We looked at performance results presented in previous references for the C-Coupler before making the statement. Specific pointers are provided below.

- Please refer to results in Section 5.4.1 and Section 5.4.2 in C-Coupler1
- Also refer to results in Section 5.5 in C-Coupler2

We want to point out that the results shown with the MOAB bilinear interpolation have been shown to scale at 50% at over half a million cores on Mira, while the initialization and data transfer costs for C-Coupler as shown in the referenced papers are much higher than that of MOAB, even for much smaller resolution cases. In any case, please do let us know if we need to make the text in our manuscript a little less controversial.

- Referee: Figure 11 b: In b) how is remapped field evaluated on land point? I.e. continents seem to have a value as they are not white on the figure.

Authors: The ocean mesh does not have any elements in the land regions. So it is a mesh with holes. Hence the projection from ATM to OCN results in field data only where ocean mesh exists, and there is nothing to plot in the continent regions. This refers to Fig. 11 (b). It is possible that the confusion arises due to the solution visualization from the opposite side of the sphere that is showing through North America.

In Fig. 11 (c), the OCN mesh does not have any holes and covers the entire sphere and hence projection results in the field defined everywhere.

- Referee: P. 24, I.7: define CS (Cubed Sphere) the first time you write it in the text.  
Authors: Now CS is defined in P. 21 I.3.
- Referee: Table 1 captions: Remind the resolutions and that it is for the fully colocated PE layout  
Authors: Done.
- Referee: P.28, I.8, section 4.4: mention Figure 14-(b)  
Authors: Added reference.
- Referee: P.28, I.9, section 4.4: in "is insignificant", replace "is" by "should be" as you don't have numbers to demonstrate this here  
Authors: Done.
- Referee: P.28, I.12: the text in parentheses "(volume should remain similar to Fig. 14-(b))" seems contradictory to the rest of the sentence  
Authors: Removed.
- Referee: P.29, section 4.5, last sentence: "However, a direct comparison between these two workflows is not yet possible, but we expect the aggregated communication strategies in the crystal router algorithm Fox et al. (1989) (Fox et al., 1989) in MOAB, to provide relatively better performance at scale." Can you

explain why the two workflows are not comparable? Also why do you put this sentence here in a section on "Note on Application of Weights"?

Authors: Yes we do not use the crystal router algorithm for point-to-point communication when applying matrix weights. We have modified the description accordingly.

The two workflows are not directly comparable at the moment because for ATM (SE) to OCN (FV) projections, the offline maps generated with ESMF use the "dual" grid and online maps generated with TempestRemap use the original spectral grid, which results in very different communication graph and non-zero pattern in the weight matrix. We are still implementing a suitable infrastructure to abstract out these details so that a direct comparison can be made here. We have added some of these details to the manuscript to make the discussions clearer. Kindly let us know if the text needs to be modified further.

- Referee: P.30, l.14" replace "is" by "are" in "which is then consumed"

Authors: Done

We request you to review the updated paper and welcome other comments that would improve the scope of the manuscript.

Best regards,

Vijay Mahadevan

# Improving climate model coupling through a complete mesh representation: a case study with E3SM (v1) and MOAB (v5.x)

## Abstract.

One of the fundamental factors contributing to the spatiotemporal inaccuracy in climate modeling is the mapping of solution field data between different discretizations and numerical grids used in the coupled component models. The typical climate computational workflow involves evaluation and serialization of the remapping weights during the pre-processing step, which is then consumed by the coupled driver infrastructure during simulation to compute field projections. Tools like Earth System Modeling Framework (ESMF) (Hill et al., 2004) and TempestRemap (Ullrich et al., 2013) offer capability to generate conservative remapping weights, while the Model Coupling Toolkit (MCT) (Larson et al., 2001) that is utilized in many production climate models exposes functionality to make use of the operators to solve the coupled problem. However, such multi-step processes present several hurdles in terms of the scientific workflow, and impedes research productivity. In order to overcome these limitations, we present a fully integrated infrastructure based on the Mesh Oriented datABase (MOAB) (Tautges et al., 2004; Mahadevan et al., 2015) library, which allows for a complete description of the numerical grids, and solution data used in each submodel. Through a scalable advancing front intersection algorithm, the supermesh of the source and target grids are computed, which is then used to assemble the high-order, conservative and monotonicity preserving remapping weights between discretization specifications. The Fortran compatible interfaces in MOAB are utilized to directly link the submodels in the Energy Exascale Earth System Model (E3SM) to enable online remapping strategies in order to simplify the coupled workflow process. We demonstrate the superior computational efficiency of the remapping algorithms in comparison with other state-of-science tools and present strong scaling results on large-scale machines for computing remapping weights between the spectral-element atmosphere and finite-volume discretizations on the polygonal ocean grids.

## 1 Introduction

Understanding Earth's climate evolution through robust and accurate modeling of the intrinsically complex, coupled ocean-atmosphere-land-ice-biosphere models requires extreme-scale computational power (Washington et al., 2008). In such coupled applications, the different component models may employ unstructured spatial meshes that are specifically generated to resolve problem-dependent solution variations, which introduces several challenges in performing a consistent solution coupling. It is known that operator decomposition and unresolved coupling errors in partitioned atmosphere and ocean model simulations (Beljaars et al., 2017), or physics and dynamics components of an atmosphere, can lead to large approximation errors that cause

severe numerical stability issues. In this context, one factor contributing to the spatiotemporal accuracy is the mapping between different discretizations of the sphere used in the components of a coupled climate model. Accurate remapping strategies in such multi-mesh problems are critical to preserve higher order resolution, but are in general computationally expensive given the disparate spatial scales across which conservative projections are calculated. Since the primal solution or auxiliary derived data defined on a donor physics component mesh (source model) needs to be transferred to its coupled dependent physics mesh (target model), robust numerical algorithms are necessary to preserve discretization accuracy during these operations (Grandy, 1999; de Boer et al., 2008), in addition to conservation and monotonicity properties in the field profile.

An important consideration is that in addition to maintaining the overall discretization accuracy of the solution during remapping, global conservation, and sometimes local element-wise conservation for critical quantities (Jiao and Heath, 2004) needs to be imposed during the workflow. Such stringent requirements on key flux fields that couple components along boundary interfaces is necessary in order to mitigate any numerical deviations in coupled climate simulations. Note that these physics meshes are usually never embedded or ~~include~~are not linked by any trivial linear transformations, which render existence of exact projection or interpolation operators unfeasible, even if the same continuous geometric topology is discretized in the models. Additionally, the unique domain decomposition used for each of the component physics meshes complicates the communication pattern during intra-physics transfer, since aggregation of point location requests ~~need~~needs to be handled efficiently in order to reduce overheads during the remapping workflow (Plimpton et al., 2004; Tautges and Caceres, 2009).

Adaptive block-structured cubed-sphere or unstructured refinement of icosahedral/polygonal meshes (Slingo et al., 2009) are often used to resolve the complex fluid dynamics behavior in atmosphere and ocean models efficiently. In such models, conservative, local flux-preserving remapping schemes are critically important (Berger, 1987) to effectively reduce multimesh errors, especially during computation of tracer advection such as water vapor or  $CO_2$  (Lauritzen et al., 2010). This is also an issue in atmosphere models where physics and dynamics are computed on non-embedded grids (Dennis et al., 2012), and the improper spatial coupling between these multi-scale models could introduce numerical artifacts. Hence, the availability of different consistent and accurate remapping schemes under one flexible climate simulation framework is vital to better understand the pros and cons of the adaptive multiresolution choices (Reichler and Kim, 2008).

### 1.1 Hub-and-Spoke vs Distributed Coupling Workflow

The hub-and-spoke centralized model as shown in Fig. 1 (left) is used in the current Exascale Earth System Model (E3SM) driver, and relies on several tools and libraries that have been developed to simplify the regridding workflow within the climate community. Most of the current tools used in E3SM and the Community Earth System Model (CESM) (Hurrell et al., 2013) are included in a single package called the Common Infrastructure for Modeling the Earth (CIME), which builds on previous couplers used in CESM (Craig et al., 2005, 2012). These modeling tools approach the problem in a two-step computational process:

1. Compute the projection or remapping weights for a solution field from a source component physics to a target component physics as an offline process

**Figure 1.** E3SM Coupled Climate Solver: (a) Current model (left), (b) Newer MOAB based coupler (right).

2. During runtime, the CIME coupled solver loads the remapping weights from a file, and handles the partition-aware communication and weight matrix application to project coupled fields between components

The first task in this workflow is currently accomplished through a variety of standard state-of-science tools such as the Earth Science Modeling Framework (ESMF) (Hill et al., 2004), Spherical Coordinate Remapping and Interpolation Package (SCRIP) (Jones, 1999), TempestRemap (Ullrich et al., 2013; Ullrich and Taylor, 2015). The Model Coupling Toolkit (MCT) (Larson et al., 2001; Jacob et al., 2005a) used in the CIME solver provides data structures for the second part of the workflow. Traditionally the first workflow phase is executed decoupled from the simulation driver during a pre-processing step, and hence any updates to the field discretization or the underlying mesh resolution immediately necessitates recomputation of the remapping weight generation workflow with updated inputs. This process flow also prohibits the component solvers from performing any runtime spatial adaptivity, since the remapping weights have to be re-computed dynamically after any changes in grid positions. To overcome such deficiencies, and to accelerate the current coupling workflow, recent efforts have been undertaken to implement a fully integrated remapping weight generation process within E3SM using a scalable infrastructure provided by the topology, decomposition and data-aware Mesh Oriented datABase (MOAB) (Tautges et al., 2004; Mahadevan et al., 2015) and TempestRemap (Ullrich et al., 2013) software libraries as shown in Fig. 1 (right). Note that whether a hub-and-spoke or distributed coupling model is used to drive the simulation, a minimal layer of driver logic is necessary to compute weighted combination of fluxes, validation metrics, and other diagnostic outputs.

The paper is organized as follows. In Section. (2), we present the necessary background and motivations to develop an online remapping workflow implementation in E3SM. Section. (3) covers details on the scalable, mesh and partition aware, conservative remapping algorithmic implementation to improve scientific productivity of the climate scientists, and to simplify the overall computational workflow for complex problem simulations. Then, the performance of these algorithms are first evaluated in serial for various grid combinations, and the parallel scalability of the workflow is demonstrated on large-scale machines in Section. (4).

## 2 Background

Conservative remapping of nonlinearly coupled solution fields is a critical task to ensure consistency and accuracy in climate and numerical weather prediction simulations (Slingo et al., 2009). While there are various ways to compute a projection of a solution defined on a source grid  $\Omega_S$  to a target grid  $\Omega_T$ , the requirements related to global or local conservation in the remapped solution reduces the number of potential algorithms that can be employed for such problems.

Depending on whether (global or local) conservation is important, and if higher-order, monotone interpolators are required, there are several consistent algorithmic options that can be used (de Boer et al., 2008). All of these different remapping schemes usually have one of these characteristic traits: non-conservative (**NC**), globally-conservative (**GC**) and locally-conservative (**LC**).

### 1. NC/GC: Solution interpolation approximations

- **NC**: (Approximate or exact) nearest neighbor interpolation
- **NC/GC**: Radial Basis Function (RBF) (Flyer and Wright, 2007) interpolators and patch-based Least Squares reconstructions (Zienkiewicz and Zhu, 1992; Fleishman et al., 2005)
- **GC**: Consistent Finite Element (FE) interpolation and area re-normalization

### 2. LC/GC: Mass ( $L_2$ -~~er~~) and gradient-preserving ( $H_1$ ~~projection~~-) projections

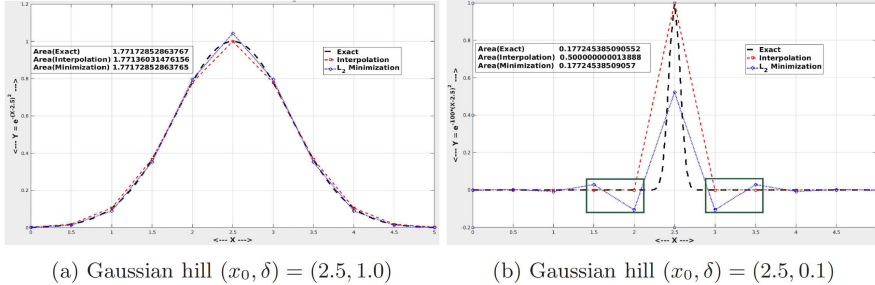

- **LC/GC**: Embedded ~~FE/FD/FV~~ Finite Element (FE), Finite Difference (FD), and Finite Volume (FV) meshes in adaptive computations
- **LC**: Intersection-based field integrators with consistent higher-order discretization (Jones, 1999)
- **LC**: Constrained projections to ensure conservation (Berger, 1987; Aguerre et al., 2017) and monotonicity (Rančić, 1995)

Typically in climate applications, flux fields are interpolated using first-order (locally) conservative interpolation, while other scalar fields use non-conservative but higher-order interpolators (e.g. bilinear or biquadratic). For scalar solutions that do not need to be conserved, consistent FE interpolation, patch-wise reconstruction schemes (Fornberg and Piret, 2008) or even nearest neighbor interpolation (Blanco and Rai, 2014) can be performed efficiently using Kd-tree based ~~search-and-locate~~ search-and-locate point infrastructure. Vector fields like velocities or wind stresses are interpolated using these same routines by separately tackling each Cartesian-decomposed component of the field. However, conservative remapping of flux fields require computation of a supermesh (Farrell and Maddison, 2011), or a global intersection mesh that can be viewed as  $\Omega_S \cup \Omega_T$ , which is then used to compute projection weights that contain additional conservation and monotonicity constraints embedded in them.

In general, remapping implementations have three distinct steps to accomplish the ~~solution field projection between grids~~ projection of solution fields from a source to a target grid. First, the target points of interest are identified and located in the source grid,

such that, the target cells are a subset of the covering (source) mesh. Next, an intersection between this covering (source) mesh and the target mesh is performed, in order to calculate the individual weight contribution to each target cell, without approximations to the component field discretizations (~~(type  $\in [FV, FEM]$  and order)~~ that can be defined with arbitrary-order FV or FE basis). Finally, application of the weight matrix yields the projection required to conservatively transfer the data onto the target grid.

- 5 To illustrate some key differences between some **NC** to **GC** or **LC** schemes, we show a 1-D Gaussian hill solution, projected onto a coarse grid through linear basis interpolation and weighted Least-Squares ( $L_2$ ) minimization, as shown in Fig. 2. While the point-wise linear interpolator is computationally efficient, and second-order accurate (Fig. 2-(a)) for smooth profiles, it does not preserve the exact area under the curve. In contrast, the  $L_2$  minimizer conserves the global integral area, but can exhibit spurious oscillatory modes as shown in Fig. 2-(b), when dealing with solutions with strong gradients (Gibbs
- 10 phenomena (Gottlieb and Shu, 1997)). This demonstration confirms that even for the simple 1-D example, a conservative and monotonic projector is necessary to preserve both stability and accuracy for repeated remapping operator applications, in order to accurately transfer fields between grids with very different resolutions. These requirements are magnified manifold when dealing with real-world climate simulation data.

**Figure 2.** An illustration: comparing point interpolation vs  $L_2$  minimization; impact on conservation and monotonicity properties.

- While there is a delicate balance in optimizing the computational efficiency of these operations without sacrificing the
- 15 numerical accuracy or consistency of the procedure, several researchers have implemented algorithms that are useful for a variety of problem domains. In the recent years, the growing interest to rigorously tackle coupled multiphysics applications has led to research efforts focused on developing new regridding algorithms. The Data Transfer Kit (DTK) (Slattery et al., 2013) from Oak Ridge National Labs was originally developed for Nuclear engineering applications, but has been extended for other problem domains through custom adaptors for meshes. DTK is more suited for non-conservative interpolation of scalar
- 20 variables with either mesh-aware (using consistent discretization bases) or RBF-based meshless (point-cloud) representations (Slattery, 2016) that can be extended to model transport schemes on a sphere (Flyer and Wright, 2007). The Portage library

(Herring et al., 2017) from Los Alamos National Laboratory also provides several key capabilities that are useful for geology and geophysics modeling applications including porous flow and seismology systems. Using advanced clipping algorithms to compute the intersection of axis-aligned squares/cubes against faces of a triangle/tetrahedron in 2-d and 3-d respectively, general intersections of arbitrary convex polyhedral domains can be computed efficiently (Powell and Abel, 2015). Support for conservative solution transfer between grids and bound-preservation (to ensure monotonicity) (Certik et al., 2017) has also been recently added. While Portage does support hybrid level parallelism (MPI + OpenMP), demonstrations on large-scale machines to compute remapping weights for climate science applications has not been pursued previously. Based on the software package documentation, support for remapping of vector fields with conservation constraints in DTK and Portage is not directly available for use in climate workflows. Additionally, unavailability of native support for projection of high-order spectral-element data on a sphere onto a target mesh restricts the use of these tools for certain component models in E3SM.

In earth science applications, the state-of-science regridding tool that is often used by many researchers is the ESMF library, and the set of utility tools that are distributed along with it (Collins et al., 2005; Dunlap et al., 2013), to simplify the traditional offline-online computational workflow as described in Section. (1.1). ESMF is implemented in a component architecture (Zhou, 2006) and provides capabilities to generate the remapping weights for different discretization combinations on the source and target grids in serial and parallel. ESMF provides a standalone tool, ESMF\_REGRIDWEIGHTGEN, to generate *offline* weights that can be consumed by climate applications such as E3SM and OASIS3-MCT. ESMF also exposes interfaces that enable drivers to directly invoke the remapping algorithms in order to enable the fully-online workflow as well.

Currently, the E3SM components are integrated together in a hub-and-spoke model (Fig. 1 (left)), with the inter-model communication being handled by the Model Coupling Toolkit (MCT) (Larson et al., 2001; Jacob et al., 2005a) in CIME. The MCT library consumes the offline weights generated with ESMF or similar tools, and provides the functionality to interface with models, decompose the field data, and apply the remapping weights loaded from a file during the setup phase. Hence, MCT serves to abstract the communication of data in the E3SM ecosystem. However, without the offline remapping weight generation phase for fixed grid resolutions and model combinations, the workflow in Fig. 1 (a) is incomplete.

Similar to the CIME-MCT driver used by E3SM, OASIS3-MCT (Valcke, 2013; Craig et al., 2017) is a coupler used by many European climate models, where the interpolation weights can be generated offline through SCRIP (included as part of OASIS3-MCT). An option to call SCRIP in an online mode is also available. The OASIS team have recently parallelized SCRIP to speed up its calculation time (Valcke et al., 2018). OASIS3-MCT also supports application of global conservation operations after interpolation, and does not require a strict hub-and-spoke coupler. Similar to the coupler in CIME, OASIS3-MCT utilizes MCT to perform both the communication of fields between components and for application of the pre-computed interpolation weights in parallel.

ESMF and SCRIP traditionally handle only cell-centered data that targets Finite Volume discretizations (FV to FV projections), with ~~first-order~~ first or second order conservation constraints. Hence, generating remapping weights for atmosphere-ocean grids with a Spectral Element (SE) source grid definition requires generation of an intermediate and spectrally equivalent, ‘*dual*’ grid, which matches the areas of the polygons to the weight of each Gauss-Lobatto-Legendre (GLL) nodes (Mundt et al., 2016). Such procedures add more steps to the offline process and can degrade the accuracy in the remapped

solution since the original spectral order is neglected (transformation from  $p$ -order to first order). These procedures may also introduce numerical uncertainty in the coupled solution that could produce high solution dispersion (Ullrich et al., 2016).

To calculate remapping weights directly for high-order Spectral Element grids, E3SM uses the TempestRemap C++ library (Ullrich et al., 2013). TempestRemap is a uni-process tool focused on the mathematically rigorous implementations of the remapping algorithms (Ullrich and Taylor, 2015; Ullrich et al., 2016) and provides higher order conservative and monotonicity preserving interpolators with different discretization basis such as (Finite Volume (FV), the spectrally equivalent continuous Galerkin FE with GLL basis (cGLL), and dis-continuous Galerkin FE with GLL basis (dGLL)). This library was developed as part of the effort to fill the gap in generating consistent remapping operators for non-FV discretizations without a need for intermediate dual meshes. Computation of conservative interpolators between any combination of these discretizations (FV, cGLL, dGLL) and grid definitions are supported by TempestRemap library. However, since this regridding tool can only be executed in serial, the usage of TempestRemap prior to the work presented here has been restricted primarily to generating the required mapping weights in the offline stage.

Even though ESMF and OASIS3-MCT have been used in online remapping studies, weight generation as part of a pre-processing step currently remains the preferred workflow for many production climate models. While this decoupling provides flexibility in terms of choice of remapping tools, the data management of the mapping files for different discretizations, field constraints and grids can render provenance, reproducibility and experimentation a difficult task. It also precludes the ability to handle moving or dynamically adaptive meshes in coupled simulations. However, it should be noted that the shift of the remapping computation process from a pre-processing stage in the workflow, to the simulation stage, imposes additional onus on the users to better understand the underlying component grid properties, their decompositions, the solution fields being transferred and the preferred options for computing the weights. This also raises interesting workflow modifications to ensure verification of the online weights such that consistency, conservation and dissipation of key fields are within user-specified constraints. In the implementation discussed here, the online remapping computation uses the exact same input grids, and specifications [like the offline workflow](#), along with ability to write the weights to file, which can be used to run ~~offline checks~~ [detailed verification studies](#) as needed.

There are several challenges in scalably computing the regridding operators in parallel, since it is imperative to have both a mesh- and partition-aware datastructure to handle this part of the regridding workflow. A few climate models have begun to calculate weights online as part of their regular operation. The ICON GCM (Wan et al., 2013) uses YAC (Hanke et al., 2016) and FGOALS (Li et al., 2013) uses the C-Coupler (Liu et al., 2014, 2018) framework. These codes expose both offline and online remapping capabilities with parallel decomposition management similar to the ongoing effort presented in the current work for E3SM. Both of these packages provide algorithmic options to perform in-memory search and locate operations, interpolation of field data between meshes with first order conservative remapping, higher-order patch-recovery (Zienkiewicz and Zhu, 1992) and RBF schemes and the NC nearest-neighbor queries. The use of non-blocking communication for field data in these packages align closely with scalable strategies implemented in MCT (Jacob et al., 2005b). While these capabilities are used routinely in production runs for their respective models, the motivation for the work presented here is to tackle coupled high-resolution runs on next generation architectures with scalable algorithms (the high resolution E3SM coupler routinely runs on

13,000 mpi tasks), without sacrificing numerical accuracy for all discretization descriptions (FV, cGLL, dGLL) on unstructured grids.

In the E3SM workflow supported by CIME, the ESMF-regridder understands the component grid definitions, and generates the weight matrices (offline). The CIME driver loads these operators at runtime and places them in MCT datatypes, which ~~treates~~treat them as discrete operators to compute the interpolation or projection of data on the target grids. Additional changes in conservation requirements or monotonicity of the field data cannot be imposed as a runtime or post-processing step in such a workflow. In the current work, we present a new infrastructure with scalable algorithms implemented using the MOAB mesh library and TempestRemap package to replace the ESMF-E3SM-MCT remapper/coupler workflow. A detailed review of the algorithmic approach used in the MOAB-TempestRemap (MBTR) workflow, along with the software interfaces exposed to E3SM is presented next.

### 3 Algorithmic approach

Efficient, conservative and accurate multi-mesh solution transfer workflows (Jacob et al., 2005b; Tautges and Caceres, 2009) are a complex process. This is due to the fact that in order to ensure conservation of critical quantities in a given norm, exact cell intersections between the source and target grids have to be computed. This is complicated in a parallel setting since the domain decompositions between the source and target grids may not have any overlaps, making it a potentially all-to-all collective communication problem. Hence, efficient implementations of regridding operators need to be mesh, resolution, field and decomposition aware in order to provide optimal performance in emerging architectures.

Fully online remapping capability within a complex ecosystem such as E3SM requires a flexible infrastructure to generate the projection weights. In order to fulfill these needs, we utilize the MOAB mesh datastructure combined with the TempestRemap libraries in order to provide an in-memory remapping layer to dynamically compute the weight matrices during the setup phase of the simulations for static source-target grid combinations. For dynamically adaptive and moving grids, the remapping operator can be recomputed at runtime as needed. The introduction of such a software stack allows higher order conservation of fields while being able to transfer and maintain field relations in parallel, within the context of the fully decomposed mesh view. This is an improvement to the E3SM workflow where MCT is oblivious to the underlying mesh datastructure in the component models. Having a fully mesh-aware implementation with element connectivity and adjacency information, along with parallel ghosting and decomposition information also provides opportunities to implement dynamic load-balancing algorithms to gain optimal performance on large-scale machines. Without the mesh topology, MCT is limited to performing trivial decompositions based on global ID spaces during mesh migration operations. YAC interpolator (Hanke et al., 2016) and the multidimensional Common Remapping software (CoR) in C-Coupler2 (Liu et al., 2018) provide similar capabilities to perform a parallel tree-based search for point location and interpolation through various supported numerical schemes.

MOAB is a fully distributed, compact, array-based mesh datastructure, and the local entity lists are stored in ranges along with connectivity and ownership information, rather than explicit lists, thereby leading to a high degree of memory compression. The memory constraints per process scales well in parallel Tautges and Caceres (2009), and is only proportional to the

number of entities in the local partition, which reduces as number of processes increases (strong scaling limit). This is similar to the Global Segment Map (GSM) in MCT, which in contrast is stored in every processor, leading to  $O(N_x)$  memory requirements. The parallel communication infrastructure in MOAB is heavily leveraged (Tautges et al., 2012) to utilize the scalable, crystal router algorithm (Fox et al., 1989; Schliephake and Laure, 2015) in order to scalably communicate the covering cells  
5 to different processors. This parallel mesh infrastructure in MOAB provides the necessary algorithmic tools for optimally executing the online remapping and coupler processes to replace MCT in E3SM.

In order to illustrate the online remapping algorithm implemented with the MOAB-TempestRemap infrastructure, we define the following terms. Let  $N_{c,S}$  be the component processes for source mesh,  $N_{c,T}$  be the component processes for target mesh and  $N_x$  be the coupler processes where the remapping operator is computed. More generally, the problem statement can be  
10 defined as: transfer a solution field  $U$  defined on the domain  $\Omega_S$  and processes  $N_{c,S}$ , to the domain  $\Omega_T$  and processes  $N_{c,T}$ , through a centralized coupler with domain information  $\Omega_S \cup \Omega_T$  defined on  $N_x$  processes. Such a complex online remapping workflow for projecting the field data from a source to target mesh follows the algorithm shown in Algorithm. 1.

In the following sections, the new E3SM online remapping interface implemented with a combination of the MOAB and TempestRemap libraries is explained. Details regarding the algorithmic aspects to compute conservative, high-order remapping  
15 weights in parallel, without sacrificing discretization accuracy on next generation hardware are presented.

### 3.1 Interfacing to Component Models in E3SM

Within the E3SM simulation ecosystem, there are multiple component models (atmosphere-ocean-land-ice-runoff) that are coupled to each other. While the MCT infrastructure only allowed for a numbering of the grid points primarily manages the global Degree-of-Freedom (DoF) partitions without a notion of the underlying mesh, the new MOAB-based coupler infrastructure provides the ability to natively interface to the underlying component mesh, and intricately understand the field Degree of Freedom (DoF) DoF data layout associated with each model. MOAB can understand recognize the difference between values on a cell center and values on a cell edge or corner. In the current work, the MOAB mesh database has been used to create the relevant integration abstraction for the HOMME atmosphere model (Thomas and Loft, 2005; Taylor et al., 2007) (cubed-sphere SE grid) and the Model for Prediction Across Scales (MPAS) ocean model (Ringler et al., 2013; Petersen et al., 2015) (polygonal  
25 meshes with holes representing land and ice regions). Since details of the mesh are not available at the level of the coupler interface, additional MOAB (Fortran) calls via the `iMOAB` interface are added to HOMME and MPAS component models to describe the details of the unstructured mesh to MOAB with explicit vertex and element connectivity information, in contrast to MCT coupler that is oblivious to the underlying grid. The atmosphere-ocean coupling requires the largest computational effort in the coupler (since they cover about 70% of the coupled domain), and hence bulk of discussions in the current work  
30 will focus on remapping and coupling between these two component models.

MOAB can handle the finite-element zoo of elements on a sphere (triangles, quadrangles, and polygons) making it an appropriate layer to store both the mesh layout (vertices, elements, connectivity, adjacencies) and the parallel decomposition for the component models along with information on shared and ghosted entities. While having a uniform partitioning methodology across components may be advantageous for improving the efficiency of coupled climate simulations, the parallel partition of

**Figure 3.** MOAB representation of partitioned component meshes.

the meshes are chosen according to the requirements in individual component solvers. Fig. 3 shows examples of partitioned SE and MPAS meshes, visualized through the native MOAB plugin for VisIt (VisIt, 2005).

The coupled field data that is to be remapped from the source grid to the target grid also needs to be serialized as part of the MOAB mesh database in terms of an internally contiguous, MOAB data storage structure named a ‘Tag’ (Tautges et al., 2004). For E3SM, we use element-based tags to store the partitioned field data that is required to be remapped between components. Typically, the number of DoF per element ( $nDoF_e$ ) is determined based on the underlying discretization;  $nDoF_e = p^2$  values in HOMME where  $p$  is the order of SE discretization, and  $nDoF_e = 1$  for the FV discretization in MPAS ocean. With this complete description of the mesh and associated data for each component model, MOAB contains the necessary information to proceed with the remapping workflow.

### 3.2 Migration of Component Mesh to Coupler

E3SM’s driver supports multiple modes of partitioning the various components in the global processor space. This is usually fine tuned based on the estimated computational load in each physics, according to the problem case definition. A sample process-execution (PE) layout for a E3SM run on 9000 processes with ATM on 5400 and OCN on 3600 ~~tasks~~ processes is shown in Fig. 4. In the case shown in the schematic,  $N_{e,ATM} = 5400$ ,  $N_{e,OCN} = 3600$  and  $N_x = 4800$ . In such a PE layout, the atmosphere component mesh from HOMME, distributed on  $N_{e,ATM}$  (5400) ~~tasks~~ processes needs to be migrated and redistributed on  $N_x$  (4800) ~~tasks~~ processes. Similarly, from  $N_{e,OCN}$  (3600) to  $N_x$  (4800) ~~tasks~~ processes for the MPAS ocean

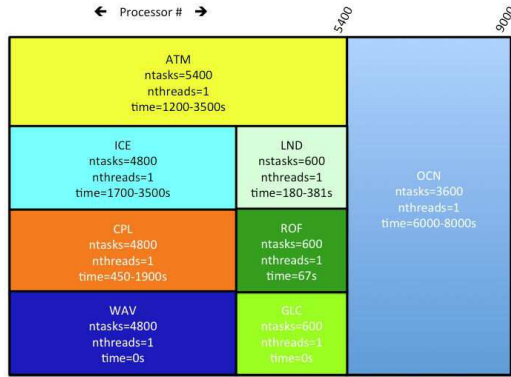

Figure 4. Example E3SM process execution layout for a problem case

mesh. In the hub-and-spoke coupling model as shown in Fig. 1, the remapping computation is performed only in the coupler processors. Hence, inference of a communication pattern becomes necessary to ensure scalable data transfers between the components and the coupler. In the existing implementation, MCT handles such communication, which is being replaced by point-to-point communication kernels in MOAB to transfer mesh and data between different components or component-coupler

PEs. Note that in a distributed coupler, source and target components can communicate directly, without any intermediate transfers (through the coupler). Under the unified infrastructure provided by MOAB, minimal changes are required to enable either the hub-and-spoke or the distributed coupler for E3SM runs, which offers opportunities to minimize time to solution without any changes in spatial coupling behavior.

For illustration, let  $N_c$  be the number of component ~~processing-process~~ elements, and  $N_x$  be the number of coupler ~~processing-process~~ elements. In order to migrate the mesh and associated data from  $N_c$  to  $N_x$ , we first compute a trivial partition of elements that map directly in the partition space, the same partitioning as used in the CIME-MCT coupler. In MOAB, we have exposed parallel graph and geometric repartitioning schemes through interfaces to Zoltan (Devine et al., 2002) or ParMetis (Karypis et al., 1997), in order to evaluate optimized migration patterns to minimize the volume of data communicated between component and coupler. We intend to analyze the impact of different migration schemes on the scalability of the remapping ~~process-operation~~ in Section. (4). These optimizations have the potential to minimize data movement in the MOAB-based remapper, and to make it a competitive data broker to replace the current MCT (Jacob et al., 2005a) coupler in E3SM.

(a) Component mesh on 2 tasks  
(b) Migrated mesh on 4 tasks (Trivial partitioner)  
(c) Migrated mesh on 4 tasks (Zoltan partitioner)

**Figure 5.** Migration strategies to repartition from  $N_c \rightarrow N_x$

We show an example of a decomposed ocean mesh (polygonal MPAS mesh) that is replicated in a E3SM problem case run on two processes in Fig. 5. Fig. 5-(a) is the original decomposed mesh on 2 ~~tasks-processes~~  $\in N_c$ , while Fig. 5-(b) and Fig. 5-  
 15 (c) show the impact of migrating a mesh from 2  $N_c$  ~~tasks-processes~~ to 4 ~~tasks-processes~~  $\in N_x$  with a trivial linear partitioner and a Zoltan based geometric online partitioner. The decomposition in Fig. 5-(b) shows that the element ID based linear partitioner can produce bad data locality, which may require large number of nearest neighbor communications when computing a source coverage mesh. The resulting communication pattern can also make the migration, and coverage computation process non-scalable on larger core counts. In contrast, in Fig. 5-(c), the Zoltan partitioners produce much better load balanced decom-  
 20 positions with Hypergraph (PHG), Recursive Coordinate Bisection (RCB) or Recursive Inertial Bisection (RIB) algorithms to reduce communication overheads in the remapping workflow. In order to better understand the impact of online decomposition strategies on the overall remapping ~~process~~ operation, we need to better understand the impact of the repartitioner on two communication-heavy steps.

1. Mesh migration from component to coupler involving communication between  $N_{c,s/t}$  and  $N_x$ ,
- 25 2. Computing the coverage mesh requiring gather/scatter of source mesh elements to cover local target elements.

In a hub-and-spoke model with online remapping, the best coupler strategy will require a simultaneous partition optimization for all grids such that mesh migration includes constraints on geometric coordinates of component pairs. While such extensions can be implemented within the infrastructure presented here, the performance discussions in Section 4 will only focus on the trivial and Zoltan-based partitioners. It is also worth noting that in a distributed coupler, pair-wise migration optimizations can  
 30 be performed seamlessly using a master(*target*)-slave(*source*) strategy to maximize partition overlaps.

### 3.3 Computing the Regridding Operator

Standard approaches to compute the intersection of two convex polygonal meshes involve the creation of a Kd-tree (Hunt et al., 2006) or BVH-tree datastructure (Ize et al., 2007) to enable fast element location of relevant target points. In general, each target point of interest is located on the source mesh by querying the tree datastructure, and the corresponding (source) element is then marked as a contributor to the remapping weight computation of the target DoF. This process is repeated to form a list of source elements that interact directly according to the consistent discretization basis. TempestRemap, ESMF and YAC use variations of this search-and-clip strategy tailored to their underlying mesh representations.

#### 3.3.1 Advancing Front Intersection – A Linear Complexity Algorithm

The intersection algorithm used in this paper follows the ideas from (Löhner and Parikh, 1988; Gander and Japhet, 2013), in which two meshes are covering the same domain. At the core is an advancing front method that aims to traverse through the source and target meshes to compute a union (super) mesh. First, two convex cells from the source coverage mesh and the target meshes that intersect are identified by using an adaptive Kd-tree search tree datastructure. This process also includes determination of the seed (the starting cell) for the advancing front in each of the partitions independently. Advancing in both meshes using face adjacency information, incrementally all possible intersections are computed (Březina and Exner, 2017) accurately to a user defined tolerance (default =  $1e - 15$ ) in linear time.

While the advancing front algorithm is not restricted to convex cells, the intersection computation is simpler if they are strictly convex. If concave polygons exist in the initial source or target meshes, they are recursively decomposed into simpler convex polygons, by splitting along interior diagonals. Note that the intersection between two convex polygons results in a strictly convex polygon. Hence, the underlying intersection algorithm remains robust to resolve even arbitrary non-convex meshes covering the same domain space.

Fig. 6 illustrates how the algorithm advances. ~~Each target cell is resolved by building a local queue of source~~ In each local partition of the coupler PEs, a pair of source (blue) and target (red) cells that intersect ~~the target cell. Source cells is found Fig. 6 (A). Using face adjacency queries for the source mesh, as shown in Fig. 6 (B), all source cells that intersects the current target cell are found. New possible pairs between cells adjacent to the current target cell and other source cells are added to a local queue incrementally, using adjacency information. At the same time, a global queue with seeds is formed, containing pairs of source/target cells that have the probability to intersect. When there are no more source cells in the local queue, the algorithm advances to.~~ After the current target cell is resolved, a pair from the queue is considered next. Fig. 6 (C) shows the resolving of a second target cell, which is intersecting here with 3 source cells. If both meshes are contiguous, this algorithm guarantees to compute all possible intersections between source and target cells. Fig. 6 (D) shows the colormap representation of the progression in which the intersection polygons were found, from blue (low count) towards red. This advance/progression is also illustrated through videos in both the next seed from the global queue, and the algorithm repeats. This workflow has been illustrated in both ~~serial (Mahadevan et al., 2018a) and in parallel with partitioned meshes (Mahadevan et al., 2018b) parallel (Mahadevan et al., 2018b) contexts on partitioned meshes.~~

**Figure 6.** Illustration of the advancing front intersection algorithm.

This flooding-like advancing front needs a stable and robust methodology of intersecting edges/segments in two cells that belong to different meshes. Any pair of segments that intersect can appear in four different pairs of cells. A list of intersection points is maintained on each target edge, so that the intersection points are unique. Also, a geometric tolerance is used to merge intersection points that are close to each other, or if they are proximal to the original vertices in both meshes. Decisions regarding whether points are inside, outside or at the boundary of a convex enclosure are handled separately. If necessary, more robust techniques such as adaptive precision arithmetic procedures used in *Triangle* (Shewchuk, 1996), can be employed to resolve the fronts more accurately. Note that the advancing front strategy can be employed for meshes with topological holes (e.g. ocean meshes, in which the continents are excluded) without any further modifications by using a new **seed-pair** for each disconnected region in the target mesh.

#### **Note on Gnomonic Projection for Spherical Geometry**

Meshes that appear in climate applications are often on a sphere. Cell edges are considered to be great circle arcs. A simple gnomonic projection is used to project the edges on one of the six planes parallel to the coordinate axis, and tangent to the sphere (Ullrich et al., 2013). With this projection, all curvilinear cells on the sphere are transformed to linear polygons on a gnomonic plane, which simplifies the computation of intersection between multiple grids. Once the intersection points and cells

are computed on the gnomonic plane, these are projected back on to the original spherical domain without approximations. This is possible due to the fact that intersection can be computed to machine precision as the edges become straight lines in a gnomonic plane (projected from great circle arcs on a sphere). If curves on a sphere are not great circle arcs (splines, for example), the intersection between those curves have to be computed using some nonlinear iterative procedures such as Newton Raphson (depending on the representation of the curves).

### 3.4 Parallel Implementation Considerations

Existing Infrastructure from MOAB (Tautges et al., 2004) was used to extend the advancing front algorithm in parallel. The expensive intersection computation can be carried out independently, in parallel, once we redistribute the source mesh to envelope the target mesh areas fully, in a step we refer to as ‘source coverage mesh’ computation.

#### 3.4.1 Computation of a Source Coverage Mesh

We select the target mesh as the driver for redistribution of the source mesh. On each task, we first compute the bounding box of the local target mesh. This information is then gathered and communicated to all tasks, and used for redistributing the local source mesh. Cells that intersect the bounding boxes of other processors are sent to the corresponding owner task using the aggregating crystal router algorithm that is particularly efficient in performing all-to-all strategies with  $O(\log(N_s))$  complexity. This graph is computed once during the setup phase to establish point-to-point communication patterns, which is then used to pack and send/receive mesh elements or data at runtime.

This workflow guarantees that the target mesh on each processor is completely enveloped by the covering mesh repartitioned from its original source mesh decomposition, as shown in Fig. 7. In other words, the covering mesh is a superset of fully encompasses and bounds the target mesh in each task. It is important to note that some source coverage cells might be sent to multiple processors during this step, depending on the target mesh resolution and decomposition. The parallel infrastructure in MOAB is heavily leveraged (Tautges et al., 2012) to utilize the scalable, crystal router algorithm (Fox et al., 1989; Schliephake and Laurs, 2015) in order to scalably communicate the covering cells to different processors.

**Figure 7.** Source coverage mesh fully covers local target mesh; local intersection proceeds between atmosphere (Quadrangle) and ocean (Polygonal) grids.

**Figure 8.** Intersection mesh computed with the coverage and target mesh in a single process.

Once the relevant covering mesh is accumulated locally on each process, the intersection computation can be carried out in parallel, completely independently, using the advancing front algorithm (Section. (3.3.1)), as shown in Fig. 8. After computation of the local intersection polygons, the vertices on the shared edges between processes are communicated to avoid duplication. In order to ensure consistent local conservation constraints in the weight matrix in the parallel setting, there might be a need for additional communication of ghost intersection elements to nearest neighbors. This extra communication step is only required for computing interpolators for flux variables, and can generally be avoided when transferring scalar fields with non-conservative bilinear or higher-order interpolations. Note that this ghost exchange on the intersection mesh only requires nearest-neighbor communications within the coupler PEs, since the communication graph has been established a-priori.

The parallel advancing front algorithm presented here to globally compute the intersection supermesh can be extended to expose finer grained parallelism using hybrid-threaded (OpenMP) programming or a task-based execution model, where each task handles a unique front in the computation queue. Such task or hybrid threaded parallelism can be employed in combination with the MPI-based mesh decompositions. Using local partitions computed with Metis and through standard coloring approaches, each thread or task can then proceed to compute the intersection elements until the front collides with another, and until all the overlap elements have been computed in each process. Such a parallel hybrid algorithm has the potential to scale well even on heterogeneous architectures and provides options to improve the computational throughput of the regridding process (Löhner, 2014).

### 3.5 Computation of Remapping operator with TempestRemap

For illustration, consider a scalar field  $U$  discretized with standard Galerkin FEM on source  $\Omega_1$  and target  $\Omega_2$  meshes with different resolutions. The projection of the scalar field on the target grid is in general given as follows.

$$U_2(\Omega_2) = \Pi_1^2 U_1(\Omega_1) \quad (1)$$

where,  $\Pi_1^2$  is the discrete solution interpolator of  $U$  defined on  $\Omega_1$  to  $\Omega_2$ . This interpolator  $\Pi_1^2$  in Eq. (1) is often referred to as the remapping operator, which is pre-computed in the coupled climate workflows using ESMF and TempestRemap. For embedded meshes, the remapping operator can be calculated exactly as a restriction or prolongation from the source to target grid. However, for general unstructured meshes and in cases where the source and target meshes are topologically different, the numerical integration to assemble  $\Pi_1^2$  needs to be carried out on the supermesh (Ullrich and Taylor, 2015). Since a unique source and target parent element exists for every intersection element belonging to the supermesh  $\Omega_1 \cup \Omega_2$ ,  $\Pi_1^2$  is assembled as the sum of local mass matrix contributions on the intersection elements, by using the consistent discretization basis for the source and target field descriptions (Ullrich et al., 2016). The intersection mesh typically contains arbitrary convex polygons and hence subsequent triangulation may be necessary before evaluating the integration. This global linear operator directly couples source and target DoFs based on the participating intersection element parents (Ullrich et al., 2009).

MOAB supports point-wise FEM interpolation (bilinear and higher-order spectral) with local or global subset normalization (Tautges and Caceres, 2009), in addition to a conservative first-order remapping scheme. But higher order conservative

monotone weight computations are currently unsupported natively. To fill this gap for climate applications, and to leverage existing developments in rigorous numerical algorithms to compute the conservative weights, interfaces to TempestRemap in MOAB were added to scalably compute the remap operator in parallel, without sacrificing field discretization accuracy. The MOAB interface to the E3SM component models provides access to the underlying type and order of field discretization, along with the global partitioning for the DoF numbering. Hence the projection or the weight matrix can be assembled in parallel by traversing through the intersection elements, and associating the appropriate source and target DoF parent to columns and rows respectively. The MOAB implementation uses a sparse matrix representation using the Eigen3 library (Guennebaud et al., 2010) to store the local weight matrix. Except for the particular case of projection onto a target grid with cGLL description, the matrix rows do not share any contributions from the same source DoFs. This implies that for FV and dGLL target field descriptions, the application of the weight matrix does not require global collective operations and sparse ~~matrix-vector~~ matrix-vector (SpMV) applications scale ideally (still memory bandwidth limited). In the cGLL case, we perform a reduction of the parallel vector along the shared DoFs to accumulate contributions exactly. However, it is non-trivial to ensure full bit-for-bit (BFB) reproducibility during such reductions ~~and currently, the MBTR workflow does not support exact reproducibility. Requirements for rigorous bitwise reproduction for online remapping needs careful implementation to enforce that the advancing-front intersection and weight matrix is computed in the exact same global element order, in addition to ensuring that the parallel SpMV products are reduced identically, independent of the parallel mesh decompositions.~~

It is also possible to use the transpose of the remapping operator computed between a particular source and target component combination, to project the solution back to the original source grid. Such an operation has the advantage of preserving the consistency and conservation metrics originally imposed in finding the remapping operator and reduces computation cost by avoiding recomputation of the weight matrix for the new directional pair. For example, when computing the remap operator between atmosphere and ocean models (with holes), it is advantageous to use the atmosphere model as the source grid, since the advancing front seed computation may require multiple ~~iterations if the trials if the initial~~ front begins within a hole ~~in the source mesh. Given that the seed or the initial cell determination on the target mesh is chosen at random, the corresponding intersecting cell on the source mesh found through a linear search could be contained within a hole in the source mesh. In such a case, a new target cell is then chosen and the source cell search is repeated. Hence multiple trials may be required for the advancing front algorithm to start propagating, depending on the mesh topology and decomposition. Note that the linear search in the source mesh can easily be replaced with a Kd-tree datastructure to provide better computational complexity for cases where both source and target meshes have many holes.~~ Additionally, such transpose vector applications can also make the global coupling symmetric, which may have favorable implications when pursuing implicit temporal integration schemes.

### 3.6 Note on MBTR Remapper Implementation

The remapping algorithms presented in the previous section are exposed through a combination of implementations in MOAB and TempestRemap libraries. Since both the libraries are written in C++, direct inheritance of key datastructures such as the GridElements (mesh) and OfflineMap (projection weights) are available to minimize data movement between the libraries. Additionally, Fortran codes such as E3SM can invoke computations of the intersection mesh and the remapping weights through

specialized language-agnostic interfaces in MOAB: iMOAB (Mahadevan et al., 2015). These interfaces offer the flexibility to query, manipulate and transfer the mesh between groups of processes that represent the component and coupler processing elements.

5 Using the iMOAB interfaces, the E3SM coupler can coordinate the online remapping workflow during the setup phase of the simulation, and compute the projection operators for component and scalar or vector coupled field combinations. For each pair of coupled components, the following sequence of steps are then executed to consistently compute the remapping operator and transfer the solution fields in parallel.

1. iMOAB\_SendMesh and iMOAB\_ReceiveMesh: Send the component mesh (defined on  $N_{c,l}$  processes), and receive  
10 the complete unstructured mesh copy in the coupler processes ( $N_x$ ). This mesh migration undergoes an online mesh repartition either through a trivial decomposition scheme or with advanced Zoltan algorithms (geometric or graph partitioners)
2. iMOAB\_ComputeMeshIntersectionOnSphere: The advancing front intersection scheme is invoked to compute the overlap mesh in the coupler processes
- 15 3. iMOAB\_CoverageGraph: Update the parallel communication graph based on the (source) coverage mesh association in each process
4. iMOAB\_ComputeScalarProjectionWeights: The remapping weight operator is computed and assembled with discretization-specific (FV, SE) calls to TempestRemap, and stored in Eigen3 SparseMatrix object

Once the remapping operator is serialized in-memory for each coupled scalar and flux fields, this operator is then used at  
20 every timestep to compute the actual projection of the data.

1. iMOAB\_SendElementTag and iMOAB\_ReceiveElementTag: Using the coverage graph computed previously, direct one-to-one communication of the field data is enabled between  $N_{c,l}$  and  $N_x$ , before and after application of the weight operator
2. iMOAB\_ApplyScalarProjectionWeights: In order to compute the field interpolation or projection from the  
25 source component to the target component, a matvec product of the weight matrix and the field vector defined on the source grid is performed. The source field vector is received from source processes  $N_{c,s}$  and after weight application, the target field vector is sent to target processes  $N_{c,t}$

Additionally, to facilitate offline generation of projection weights, a MOAB based parallel tool `mbtempest` has been written in C++, similar to ESMF and TempestRemap (serial) standalone tools. `mptempest` can load the source and target  
30 meshes from files, in parallel, and compute the intersection and remapping weights through TempestRemap. The weights can then be written back to a SCRIP-compatible file format, for any of the supported field discretization combinations in source and destination components. Added capability to apply the weight matrix onto the source solution field vectors, and native

visualization plugins in VisIt for MOAB, simplify the verification of conservation and monotonicity for complex remapping workflows. This workflow allows users to validate the underlying assumptions for remapping solution fields across unstructured grids, and can be executed in both a serial and parallel setting.

## 4 Results

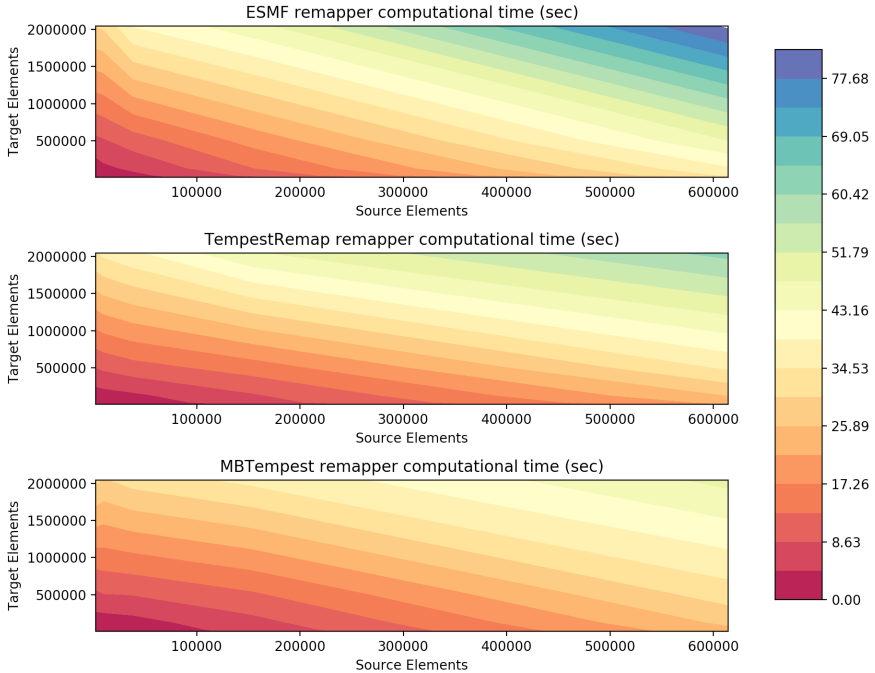

Evaluating the performance of the in-memory, MOAB-TempestRemap (MBTR) remapping infrastructure requires recursive profiling and optimization to ensure scalability for large-scale simulations. In order to showcase the advantage of using the mesh-aware MOAB datastructure as the MCT coupler replacement, we need to understand the per task performance of the regridded in addition to the parallel point locator scalability, and overall time for remapping weight computation. Note that except for the weight application for each solution field from a source grid to a target grid, the in-memory copy of the component meshes, migration to coupler PEs, computation of intersection elements and remapping weights are done only once during the setup phase in E3SM, per coupled component model pair.

### 4.1 Serial Performance

We compare the total cost for computing the supermesh and the remapping weights for several source and target grid combinations through three different methods to determine the serial computational complexity.

1. ESMF: Kd-tree based regridded and weight generation for first/second order FV→FV conservative remapping
  2. TempestRemap: Kd-tree based supermesh generation and conservative, monotonic, high-order remap operator for FV→FV, SE→FV, SE→SE projection
  3. MBTempest: Advancing front intersection with MOAB and conservative weight generation with TempestRemap interfaces
- Fig. 9 shows the serial performance of the remappers for computing the conservative interpolator from Cubed-Sphere (CS) grids to polygonal MPAS grids of different resolutions for a FV→FV field transfer. This total time includes the computation of intersection mesh or supermesh, in addition to the remapping weights with field conservation specifications. These serial runs were executed on a machine with 8x Intel Xeon(R) CPU E7-4820 @ 2.00GHz (total of 64 cores) and 1.47 TB of RAM. As the source grid resolution increases, the advancing front intersection with linear complexity outperforms the Kd-tree intersection algorithms used by TempestRemap and ESMF. The time spent in the remapping task, including the overlap mesh generation, provides an overall metric on the single task performance when memory bandwidth or communication concerns do not dominate in a parallel run. In this comparison with three remapping software libraries, the total computational time in the fine resolution limit as  $\frac{n_{ele}(source)}{n_{ele}(target)} \approx 1$  consistently increases (going diagonally from left to right in Fig. 9). We note that the serial version of TempestRemap is comparable to ESMF and can even provide better timings on the highly refined cases, while the MBTempest remapper consistently outperforms both the tools, with a 2x speedup on average. The relatively

**Figure 9.** Comparison of serial regridding computation (supremesh and projection weight generation) between ESMF, TempestRemap, and MBTempest

better performance in MBTempest is accomplished through the linear complexity advancing front algorithm, which further offers avenues to incorporate finer grain task or thread level parallelism to accelerate the on-node performance on multicore and GPGPU architectures.

#### 4.2 Scalability of the MOAB Kd-tree Point Locator

- 30 In addition to being able to compute the supremesh between  $\Omega_S$  and  $\Omega_T$ , MOAB also offers datastructures to query source elements containing points that correspond to the target DoFs locations. This operation is critical in evaluating bilinear and

biquadratic interpolator approximations for scalar variables when conservative projection is not required by the underlying coupled model. The solution interpolation for the multi-mesh case involves two distinct phases.

1. Setup phase: Use Kd-tree to build the search datastructure to locate points corresponding to vertices in the target mesh on the source mesh
2. Run phase: Use the elements containing the located points to compute consistent interpolation onto target mesh vertices

Studies were performed ~~on the BlueGene-Q machine (Mira) at ANL~~ to evaluate the strong and weak scalability of the parallel Kd-tree point search implementation in MOAB. The scalability results were generated with the CIAN2 coupling mini-app (Morozov and Peterka, 2016), which links to MOAB to handle traversal of the unstructured grids and transfer of solution fields between the grids. For this case, a series of hexahedral and tetrahedral meshes were used to interpolate an analytical solution. By changing the basis interpolation order, and mesh resolutions, the convergence of the interpolator was verified to provide theoretical accuracy orders of convergence in the asymptotic fine limit.

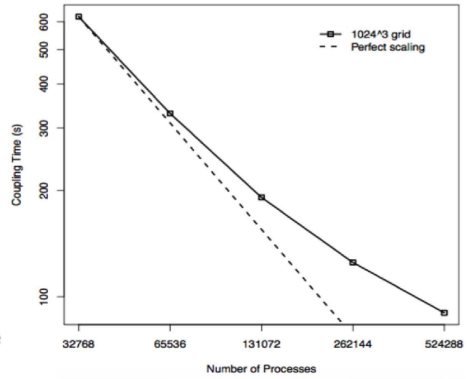

The performance tests were executed on the IBM BlueGene/Q Mira at 16 MPI ranks per node, with 2GB RAM per MPI rank, at up to 500K MPI processes. The strong scaling results and error convergence were computed with a grid size of  $1024^3$ . The solution interpolation on varying mesh resolutions were performed by projecting an analytical solution from a Tetrahedral→Hexahedral→Tetrahedral grid, with total number of points/rank varied between [2K, 32K] in the study. Note that the total DoFs in this study is much larger than typical climate production runs, and hence we use these experiments to showcase the strong scaling of the bilinear interpolation operation at the high-res limit.

First, the root-mean-square (RMS) error was measured in the bilinearly interpolated solution against the analytical solution, and plotted for different source and target mesh resolutions. Fig. 10 ~~shows a~~ (a) demonstrates that the error convergence of the interpolants match the expected theoretical second order rates, and that the error constant is proportional to ratio of source to target mesh resolution. Next, the Fig. 10(b) shows the strong scaling efficiency of around 50% is achieved on a maximum of 512K cores (66% of Mira). We note that the computational complexity of the Kd-tree data structure scales as  $O(n \log(n))$  asymptotically, and the point location phase during initial search setup dominates the total cost on higher core counts. This is evident in the timing breakdown for each phase shown in Fig. 10-(c). Since the point location is performed only once during simulation startup, while the interpolation is performed multiple times per timestep during the run, we expect the total cost of the projection for scalar variables to be amortized over transient climate simulations with fixed grids. Further investigations with optimal BVH-tree (Larsen et al., 1999) or R-tree implementations for these interpolation cases could help reduce the overall cost.

The full 3-D point location and interpolation operations provided by MOAB are comparable to the implementation in Common Remapping component used in the C-Coupler (Liu et al., 2013) and provide relatively much stronger scalability on larger core counts (Liu et al., 2014) for the remapping operation. Such higher-order interpolators for multicomponent physics variables can provide better performance in atmospheric chemistry calculations. Additionally, as component mesh resolutions are increased to sub-Km regimes, the expectations from remapping libraries such as MOAB to provide scalable search and location of points becomes important. Currently, only the NC bilinear or biquadratic interpolation of scalar fields with subset normaliza-

(a) Tet→Hex RMS Error

(b) Strong Scaling

(c) Strong Scaling by Component

**Figure 10.** MOAB 3-d Kd-tree Point Location: Strong scaling on Mira (BG/Q)

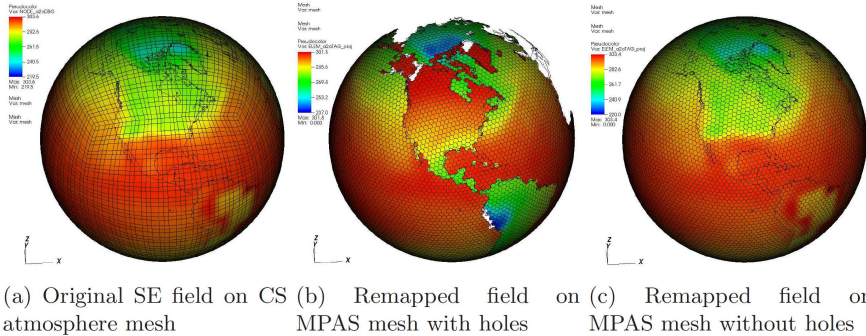

tion (Tautges and Caceres, 2009) is supported directly in MOAB (via Kd-tree point location and interpolation), and advancing front intersection algorithm does not make use of these data-structures. In contrast, TempestRemap and ESMF use a Kd-tree search to not only compute the location of points, but also to evaluate the supersmesh  $\Omega_S \cup \Omega_T$ , and hence the computational

complexity for the intersection mesh determination scales as  $O(n \log(n))$ , in contrast to the linear complexity ( $O(n)$ ) of the advancing front intersection algorithm implemented in MOAB.

### 4.3 The Parallel MBTR Remapping Algorithm

The MBTR online weight generation workflow within E3SM was employed to verify and test the projection of real simulation data generated during the coupled atmosphere-ocean model runs. A choice was made to use the model-computed temperature on the lowest level of the atmosphere, since the heat fluxes that nonlinearly couples the atmosphere and ocean models are directly proportional to this interface temperature field. By convention, the fluxes are computed on the ocean mesh, and hence the atmosphere temperature must be interpolated onto MPAS polygonal mesh. We use this scenario as a test case for demonstrating the strong scalability results in this section.

The atmosphere run with approximately 4 degree grid size and 11 elements per edge on a cubed-sphere (NE11) in E3SM, and the projection of its lowest level temperature onto two different MPAS meshes (with approximate grid size of 240km) are shown in Fig. 11. The conservative projection from SE→FV on a mesh with holes (Fig. 11-(b)) and without holes (Fig. 11-(c)) corresponding to land regions, is presented here to show the difference in the remapped solutions.

**Figure 11.** Projection of the NE11 SE bottom atmospheric temperature field onto the MPAS ocean grid

#### 4.3.1 Scaling Comparison of Conservative Remappers (FV→FV)

The strong scaling studies for computation of remapping weights to project a FV solution field between CS grids of varying resolutions was performed on the Blues large-scale cluster (with 16 Sandy Bridge Xeon E5-2670 2.6GHz cores and 32 GB RAM per node) at ANL, and the Cori supercomputer at NERSC (with 64 Haswell Xeon E5-2698v3 2.3GHz cores and 128 GB RAM per node). Fig. 12 shows that the MBTR workflow consistently outperforms ESMF on both the machines as the number

of processes used by the coupler is increased. The timings shown here represent the total remapping time i.e., cumulative computational time for generating the super mesh and the (conservative) remapping weights.

**Figure 12.** CS (E=614400 quads)  $\rightarrow$  CS (E=153600 quads) remapping (-m conserve) on LCRC/ALCF and NERSC machines

- 15 The relatively better scaling for MOAB on the Blues cluster is due to faster hardware and memory bandwidth compared to the Cori machine. The strong scaling efficiency approaches a plateau on Cori Haswell nodes as communication costs for the coverage mesh computation start dominating the overall remapping processes, especially in the limit of  $\frac{nele}{process} \rightarrow 1$  at large node counts.

#### 4.3.2 Strong Scalability of Spectral Projection (SE $\rightarrow$ FV)

- To further evaluate the characteristics of in-memory remapping computation, along with cost of application of the weights during a transient simulation, a series of further studies were executed on the NERSC Cori system to determine the spectral projection of a real dataset between atmosphere and ocean components in E3SM. The source mesh contains 4th order spectral  
 5 element temperature data defined on Gauss-Lobatto quadrature nodes (cGLL discretization) of the CS mesh, and the projection is performed on a MPAS polygonal mesh with holes (FV discretization). A direct comparison to ESMF was unfeasible in this study since the traditional workflow requires the computation of a dual mesh transformation of the spectral grid. Hence, only timings for MBTR workflow is shown here.

Two specific cases were considered for this SE $\rightarrow$ FV strong scaling study with conservation and monotonicity constraints.

- 10
1. **Case A (NE30):** 1-degree CS (30 edges per side) SE mesh (nele=5400 quads) with  $p = 4$  to MPAS mesh (nele=235160 polygons)
  2. **Case B (NE120):** 0.25-degree CS (120 edges per side) SE mesh (nele=86400 quads) with  $p = 4$  to MPAS mesh (nele=3693225 polygons)

The performance tests for each of these cases were launched with three different process execution layouts for the atmosphere, ocean components and the coupler.

- (a) Fully colocated PE layout:  $N_{atm} = N_x$  and  $N_{ocn} = N_x$
- (b) Disjoint-ATM model PE layout:  $N_{atm} = N_x/2$  and  $N_{ocn} = N_x$
- (c) Disjoint-OCN model PE layout:  $N_{atm} = N_x$  and  $N_{ocn} = N_x/2$

**Table 1.** Strong scaling on Cori for SE→FV projection with two different resolutions [on a fully colocated PE layout](#)

| Number of  | Case A (NE30)         |                          | Case B (NE120)        |                          |
|------------|-----------------------|--------------------------|-----------------------|--------------------------|
| processors | Intersection<br>(sec) | Compute<br>Weights (sec) | Intersection<br>(sec) | Compute<br>Weights (sec) |
| 16         | 0.936846              | 0.64983                  | 145.623               | 9.732                    |
| 32         | 0.449022              | 0.429028                 | 53.1244               | 5.78093                  |
| 64         | 0.377767              | 0.373476                 | 22.7167               | 4.92151                  |
| 128        | 0.255154              | 0.270574                 | 6.70485               | 2.79397                  |
| 256        | 0.180136              | 0.18272                  | 2.26435               | 1.71835                  |
| 512        | 0.162388              | 0.104737                 | 1.25471               | 0.928622                 |
| 1024       | 0.203354              | 0.0932475                | 0.680122              | 0.618943                 |

A breakdown of computational time for key tasks on Cori with up to 1024 processes for both the cases is tabulated in Table 1 on a fully colocated decomposition i.e.,  $N_{ocn} = N_{atm} = N_x$ . It is clear that the computation of parallel intersection mesh strong scales well for these production cases, especially for larger mesh resolutions (Case B). For the smaller source and target mesh resolution (Case A), we notice that the intersection time hits a lower bound that is dominated by the computation of the coverage mesh to enclose the target mesh in each task. It is important to stress that this one time setup call to compute remap operator, per component pair, is relatively much cheaper compared to individual component and solver initializations and get amortized over longer transient simulations. It is also worth noting that as the I/O bandwidth in emerging architectures are not scaling in line with the compute throughput, such an online workflow can generally be faster than parallel I/O for reading the weights from file at scale. The MBTR implementation is also flexible to allow loading the weights from file directly in order to preserve the existing coupler process with MCT. In comparison to the computation of the intersection mesh, the time to assemble the remapping weight operator in parallel is generally smaller. Even though both of these operations are performed only once during the setup phase of the E3SM simulation, the weight operator computation involves several validation checks that utilize collective MPI operations, which do destroy the embarrassingly parallel nature of the calculation, once appropriate coverage mesh is determined in each task.

**Strong scaling study for the NE30 and NE120 cases for spectral projection with Zoltan repartitioner on Cori**

- 5 The component-wise breakdown for the advancing front intersection mesh, the parallel communication graph for sending and receiving data between component and coupler, and finally, the remapping weight generation for the SE→FV setup for NE30 and NE120 cases are shown in Fig. 13. The cumulative time for this remapping process is shown to scale linearly for NE120 case, even if the parallel efficiency decreases significantly in the NE30 case, as expected based on the results in Table 1. Note that the MBTR workflow provides a unique capability to consistently and accurately compute SE→FV projection weights
- 10 in parallel, without any need for an external pre-processing step to compute the dual mesh (as required by ESMF) or running the entire remapping process in serial (TempestRemap). ~~Also note that-~~

- Another key aspect of the results shown in Fig. 13 confirms that there is the relative indifference in performance of the algorithms to the type of PE layout used to partition the component process space. Theoretically, we expect the fully disjoint case to perform the worst, and a full colocated case with maximal overlap to perform the best, since the layout directly affects
- 15 the total amount of data communicated for both the mesh and field data. However, in practice, with online repartitioning strategies exposed through Zoltan (PHG and RCB), overall scaling of the remapping algorithm is nearly independent of the PE layout for the simulation. This is especially evident from the timings for the coverage mesh computation for the NE120 case for all three PE layouts.

(a) NE30 component-wise strong scaling

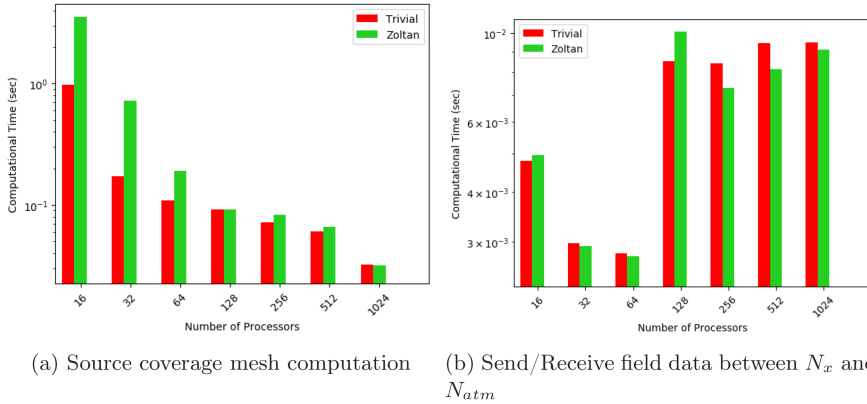

(b) NE120 component-wise strong scaling

#### 4.4 Effect of partitioning strategy

- 20 In order to determine the effect of partitioning strategies described in Fig. 5, the NE120 case with the trivial decomposition and Zoltan geometric partitioner (RCB) were tested in parallel. Fig. 14 compares the two strategies for optimizing the mesh migration from the component to coupler. These strategies play a critical role in task mapping and data locality for the source coverage mesh computation, in addition to determining the communication graph complexity between the components and the coupler. This comparison highlights that the coverage mesh cost reduces uniformly at scale, while the trivial partitioning
- 5 scheme behaves better on lower core counts as shown in Fig. 14-(a). The communication of field data between the atmosphere component and the coupler resulting from the partitioning strategy is a critical operation during the transient simulation, and generally stays within network latency limits in Cori ~~, as the message size reduces (shown in Fig. 14-(b)).~~ Even though the communication kernel does not show ~~good~~ ideal scaling on increasing node counts, the relative cost of the operation ~~is~~ should be insignificant in comparison to total time spent in individual component solvers. Note that production climate model solvers
- 10 require multiple data fields to be remapped at every rendezvous timestep, and hence the size of the packed messages may be larger for such simulations ~~(volume should remain similar to Fig. 14 (b)).~~ We also note that there is a factor of 3 increase in the communication time to send and receive data, which occurs after the 64 process count on Cori in Fig. 14-(b). This is an artifact of the additional communication latency due to the transition from an intra-node (each Haswell node in Cori accommodates 64 processes) to inter-node nearest neighbor data transfer when using multiple nodes. In this strong scaling study, the net data size being transferred reduces with increasing core counts, and hence the point-to-point communication beyond 128 processes is primarily dominated by network latency and task placement. As part of future extensions, we will further explore task mapping strategies with the Zoltan2 (Leung et al., 2014) library, in addition to online partition rebalancing to maximize geometric overlap, and minimize communication time during remapping.

**Figure 14.** Scaling of the communication kernels driven with the parallel graph computed with a trivial redistribution and the Zoltan geometric (RCB) repartitioner for the NE120 case with  $N_{ocn} = N_x$  and  $N_{atm} = N_x/2$  on Cori

#### 5 4.5 Note on Application of Weights

Generally, operations involving Sparse Matrix-Vector (SpMV) products are memory bandwidth limited (Bell and Garland, 2009), and occur during the application of remapping weights operator on to the source solution field vector, in order to compute the field projection onto the target grid. In addition to the communication of field data shown in Fig. 14-(b), the cost of remapping weight application in parallel (presented in Fig. 15) determines the total cost of the remapping operation during runtime. Except for the case of cGLL target discretizations, the parallel SpMV operation during the weight application do not involve any global collective reductions. In the current E3SM and OASIS3-MCT workflow, these operations are handled by the MCT library. In high resolution simulations of E3SM, the total time for the remapping operation in MCT is primarily dominated by the communication costs based on the communication graph, similar to the MBTR workflow. However, a direct comparison between of the communication kernels in these two workflows is not yet possible, but we expect the aggregated communication strategies in the crystal router algorithm (Fox et al., 1989) in MOAB, to provide relatively better performance at scale since the offline maps for MCT that are generated with ESMF use the "dual" grid, while the online maps generated with MBTR utilize the original spectral grid with no approximations, which results in very different communication graph and non-zero pattern in the remap weight matrices.

Figure 15. SE→FV remapping weight operator application [for the NE120 case](#) on Cori

## 5 Conclusion

Understanding and controlling primary sources of errors in a coupled system dynamically, will be key to achieving predictable and verifiable climate simulations on emerging architectures. Traditionally, the computational workflow for coupled climate simulations has involved two distinct steps, with an offline pre-processing phase using remapping tools to generate solution field projection weights (ESMF, TempestRemap, SCRIP), which ~~are~~ [are](#) then consumed by the coupler to transfer field data between the component grids.

The offline steps include generating grid description files and running the offline tools with the problem-specific options. Additionally many of state-of-science tools such as ESMF and SCRIP require additional steps to specially handle interpolators from SE grids. Such workflows create bottlenecks that do not scale, and can inhibit scientific research productivity. When experimenting with refined grids, a goal for E3SM, this tool chain has to excercised repeatedly. Additionally, when component meshes are dynamically modified, either through mesh adaptivity or dynamical mesh movement to track moving boundaries, the underlying remapping weights must be recomputed on the fly.

To overcome some of these limitations, we have presented scalable algorithms and software interfaces to create a direct component coupling with online regridding and weight generation tools. The remapping algorithms utilize the numerics exposed by TempestRemap, and leverage the parallel mesh handling infrastructure in MOAB to create a scalable in-memory remapping infrastructure that can be integrated with existing coupled climate solvers. Such a methodology invalidates the need for dual grids, preserves higher-order spectral accuracy, and locally conserves the field data, in addition to monotonicity constraints, when transferring solutions between grids with non-matching resolutions.

- 5 The serial and parallel performance of the MOAB advancing front intersection algorithm with linear complexity ( $O(n)$ ) was demonstrated for a variety of source and target mesh resolution combinations, and compared with the current state-of-science regridding tools such as ESMF (serial/parallel) and TempestRemap (serial) that have a  $O(n \log(n))$  complexity using the Kd-tree datastructure. The MOAB-TempestRemap (MBTR) software infrastructure yields a balance of both the scalable performance on emerging architectures without sacrificing discretization accuracy for component field interpolators.
- 10 There are also several optimizations in the MBTR algorithms that can be implemented to improve finer-grained parallelism on heterogeneous architectures, and to minimize data movement with better partitioning in combination with load rebalancing strategies. Such a software infrastructure provides a foundation to build a new coupler to replace the current offline-online, hub-and-spoke MCT-based coupler in E3SM, and offer extensions to enable a fully distributed coupling paradigm (without the need for a centralized coupler) to minimize computational bottlenecks in a task-based workflow.
- 15 *Code availability.* Information on the availability of source code for the algorithmic infrastructure and models featured in this paper is tabulated below.

| Short name          | Code availability   |
|---------------------|---|
| <b>E3SM</b>         | E3SM Project (2018) is under active development funded by the US Department of Energy. E3SM version 1.1 has been publicly released under an open-source 3-clause BSD license in August 2018, and available at GitHub.   |
| <b>MOAB</b>         | MOAB Tautges et al. (2004) is an open-source library under the umbrella of the SIGMA toolkit (2014) Mahadevan et al. (2015), and is publicly available under the Lesser GNU Public License (v3) on BitBucket. v5.1.0 was released on Jan 07, 2019 and available <a href="#">here</a> . DOI: 10.5281/zenodo.2584863. |
| <b>TempestRemap</b> | The TempestRemap Ullrich and Taylor (2015); Ullrich et al. (2016) source code is available under a BSD open-source license and hosted in GitHub. v2.0.2 was released on Dec 19, 2018 and available <a href="#">here</a> .   |

*Video supplement.* The video supplements for the serial and parallel advancing front mesh intersection algorithm to compute the supermesh ( $\Omega_S \cup \Omega_T$ ) of a source ( $\Omega_S$ ) and target ( $\Omega_T$ ) grid is demonstrated.

| Short name  |  |  | Video description and availability   |
|---|--|--|--|
| <b>Serial advancing front mesh intersection</b>   |  |  | Intersection between CS and MPAS grids on a single task is illustrated.<br>DOI:10.6084/m9.figshare.7294901   |
| <b>Parallel advancing front mesh intersection</b> |  |  | Simultaneous parallel Intersection between CS and MPAS grids on two different tasks are illustrated side by side.<br>DOI:10.6084/m9.figshare.7294919 |

*Author contributions.* VM and RJ wrote the paper (with comments from IG and JS). VM and IG designed and implemented the MOAB integration with TempestRemap library, along with exposing the necessary infrastructure for online remapping through iMOAB interfaces. IG and JS configured the MOAB-TempestRemap remapper within E3SM, and verified weight generation to transfer solution fields between atmosphere and ocean component models. VM conducted numerical verification studies and executed both the serial and parallel scalability studies on Blues and Cori LCF machines to quantify performance characteristics of the remapping algorithms. The broader project idea was conceived by Andy Salinger (SNL), RJ, VM, and IG.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* Support for this work was provided by the Climate Model Development and Validation - Software Modernization project, and partially by the SciDAC Coupling Approaches for Next Generation Architectures (CANGA) project, which are funded by the US Department of Energy (DOE), Office of Science Biological and Environmental Research Program. CANGA is also funded by the DOE Office of Advanced Scientific Computing Research. This research used resources of the Argonne Leadership Computing Facility at Argonne National Laboratory, which is supported by the Office of Science of the U.S. Department of Energy under contract DE-AC02-06CH11357, and resources of the National Energy Research Scientific Computing Center, a DOE Office of Science User Facility supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. We gratefully acknowledge the computing resources provided on Blues, a high-performance computing cluster operated by the Laboratory Computing Resource Center at Argonne National Laboratory. We would also like to thank Dr. Paul Ullrich at University of California, Davis for several helpful discussions regarding remapping schemes and, in particular, implementations in TempestRemap. We would also like to thank the anonymous reviewers for their indepth comments that helped clarify and improve the manuscript.
