**Abstract.** Elevated carbon dioxide (CO<sub>2</sub>) can increase plant growth, but the magnitude of this CO<sub>2</sub> fertilization effect is modified by soil nutrient availability. Predicting how nutrient availability affects plant responses to elevated CO<sub>2</sub> is a key consideration for ecosystem models, and many modelling groups have moved to, or are moving towards, incorporating nutrient limitation in their models. The choice of assumptions to represent nutrient cycling processes has a major impact on model predictions, but it can be difficult to attribute outcomes to specific assumptions in complex ecosystem simulation models. Here we revisit the quasi-equilibrium analytical framework introduced by Comins & McMurtrie (1993) and explore the consequences of specific model assumptions for ecosystem net primary productivity. We review the literature applying this framework to plant-soil models, and then analyze the effect of several

25

new assumptions on predicted plant responses to elevated CO<sub>2</sub>. Examination of alternative assumptions for plant nitrogen uptake showed that a linear function of the mineral nitrogen pool or a linear function of the mineral nitrogen pool with additional saturating function of root biomass yield similar CO<sub>2</sub> responses at longer timescales (> 5 years), suggesting that the added complexity may not be needed when these are the timescales of interest. In contrast, a saturating function of the mineral nitrogen pool with linear dependency on root biomass yields no soil nutrient feedback at the very long-term (>500 years), near-equilibrium timescale, meaning that one should expect the model to predict a full CO<sub>2</sub> fertilization effect on production. Secondly, we show that incorporating a priming effect on slow soil organic matter decomposition attenuates the nutrient feedback effect on production, leading to a strong medium-term (5-10 50 years) CO<sub>2</sub> response. Models incorporating this priming effect should thus predict a strong and persistent CO<sub>2</sub> fertilization effect over time. Thirdly, we demonstrate that using a “potential NPP” approach to represent nutrient limitation of growth yields a relatively small CO<sub>2</sub> fertilization effect across all timescales. Overall, our results highlight that the quasi-equilibrium analytical framework is effective for evaluating both the consequences and mechanisms through which different model assumptions affect 15 predictions. To help constrain predictions of the future terrestrial carbon sink, we recommend use of this framework to analyze likely outcomes of new model assumptions before introducing them to complex model structures.

**Keywords:** analytical approximation | equilibrium | CO<sub>2</sub> fertilization | nitrogen | priming | nutrient uptake

## 20 1 Introduction

Predicting how plants respond to atmospheric carbon dioxide (CO<sub>2</sub>) enrichment (eCO<sub>2</sub>) under nutrient limitation is fundamental for an accurate estimate of the global terrestrial carbon (C) budget in response to climate change. There is now ample evidence that the response of terrestrial vegetation to eCO<sub>2</sub> is modified by soil nutrient availability (Fernández-Martínez et al., 2014; Norby et al., 2010; Reich and 25 Hobbie, 2012; Sigurdsson et al., 2013). Over the past decade, land surface models have developed from

C-only models to carbon-nitrogen (CN) models (Gerber et al., 2010; Zaehle and Friend, 2010). The inclusion of C-N biogeochemistry has been shown to be essential to capture the reduction in the CO<sub>2</sub> fertilization effect with declining nutrient availability and therefore its implications for climate change (Zaehle et al., 2015). However, it has also been shown that models incorporating different assumptions predict very different vegetation responses to eCO<sub>2</sub> (Lovenduski and Bonan, 2017; Medlyn et al., 2015). Careful examination of model outputs has provided insight into the reasons for the different model predictions (De Kauwe et al., 2014; Medlyn et al., 2016; Walker et al., 2014; Walker et al., 2015; Zaehle et al., 2014), but it is generally difficult to attribute outcomes to specific assumptions in these plant-soil models that differ in structural complexity and process feedbacks (Lovenduski and Bonan, 2017; Medlyn et al., 2015; Thomas et al., 2015).

Understanding the mechanisms underlying predictions of ecosystem carbon cycle processes is fundamental for the validity of prediction across space and time. Comins and McMurtrie (1993) developed an analytical framework, the “quasi-equilibrium” approach, to make model predictions traceable to their underlying mechanisms. The approach is based on the two-timing approximation method (Ludwig et al., 1978) and makes use of the fact that ecosystem models typically represent a series of pools with different equilibration times. The method involves: 1) choosing a time interval ( $\tau$ ) such that the model variables can be divided into “fast” pools (which approach effective equilibrium at time  $\tau$ ) and “slow” pools (which change only slightly at time  $\tau$ ); 2) holding the “slow” pools constant, and calculating the equilibria of the “fast” pools (an effective equilibrium as this is not a true equilibrium of the entire system); and 3) substituting the “fast” pool effective equilibria into the original differential equations to give simplified differential equations for the slow pools at time  $\tau$ .

In a CN model, plant net primary production (NPP) can be estimated from two constraints, based on equilibration of the C balance (the “photosynthetic constraint”) and the N balance (the “nitrogen recycling constraint”) (Comins and McMurtrie, 1993). Both constraints link NPP with leaf chemistry (i.e. N:C ratio) (derivation in Section 3.1). The simulated production occurs at the intersection of these two constraint curves (shown graphically in Figure 1). To understand behaviour on medium and long-time scales (e.g.

wood, and slow and passive soil organic pools in Figure 2, 20 – 200 years), one can assume that plant pools with shorter equilibration times in the model (e.g. foliage, fine-root or active soil organic pools in Figure 2) have reached quasi-equilibrium, and model dynamics are thus driven by the behaviour of the longer timescale pools.

5 The recent era of model development has seen some significant advances in representing complex plant-soil interactions, but models still diverge in future projections of CO<sub>2</sub> fertilization effect on NPP (Friend et al., 2014; Koven et al., 2015; Walker et al., 2015). A recent series of multi-model inter-comparison studies has demonstrated the importance of understanding underlying response mechanisms in determining model response to future climate change (Medlyn et al., 2015), but this can be difficult to  
10 achieve in complex global models. The quasi-equilibrium framework is a relatively simple but quantitative method to examine the effect of different assumptions on model predictions. As such, it complements more computationally expensive sensitivity analyses, and can be used as an effective tool to provide *a priori* evaluation of both the consequence and mechanism through which different new model implementations affect model predictions.

15 Here, by constructing a quasi-equilibrium framework based on the structure of the Generic Decomposition and Yield (G'DAY) model (Comins and McMurtrie, 1993), we evaluate the effects on plant responses to eCO<sub>2</sub> of some recently-developed model assumptions incorporated into ecosystem models, for example the Community Land Model (CLM)(Oleson et al., 2004), the Community Atmosphere–Biosphere Land Exchange (CABLE) model (Kowalczyk et al., 2006), the Lund-Potsdam-  
20 Jena (LPJ) model (Smith et al., 2001), the JSBACH model (Goll et al., 2017b), and the O-CN model (Zaehle et al. 2010). Specifically, we test how different functions affecting plant N uptake influence NPP responses to eCO<sub>2</sub> at various quasi-equilibrium time steps. The present study is a continuation of the series of the quasi-equilibrium studies as reviewed in Section 2, with a general aim of helping to understanding the similarities and differences of predictions made by different process-based models, as demonstrated  
25 in Section 3.

## 2. Literature Review

Many of the assumptions currently being incorporated into CN models have previously been explored using the quasi-equilibrium framework; here we provide a brief literature review describing the outcomes of this work (Table 1). Firstly, the flexibility of plant and soil stoichiometry has recently been highlighted as a key assumption (Stocker et al., 2016; Zaehle et al., 2014). A key finding from early papers applying the quasi-equilibrium framework was that model assumptions about the flexibility of the plant wood N:C ratio (Comins, 1994; Comins and McMurtrie, 1993; Dewar and McMurtrie, 1996; Kirschbaum et al., 1994; Kirschbaum et al., 1998; McMurtrie and Comins, 1996; Medlyn and Dewar, 1996) and soil N:C ratio (McMurtrie and Comins, 1996; McMurtrie et al., 2001; Medlyn et al., 2000) were critical determinants of the magnitude of the transient (10 to > 100 years) plant response to eCO<sub>2</sub> (Figure 1). Different to the effect of foliar N:C ratio flexibility, which has an instantaneous effect on photosynthesis, the flexibility of the wood N:C ratio controls the flexibility of nutrient storage per unit biomass accumulated in the slow turnover pool. Therefore, a constant wood N:C ratio, such as was assumed in CLM4 (Thornton et al., 2007; Yang et al., 2009), means that effectively a fixed amount of N is locked away from the active processes such as photosynthesis on the timescale of the lifespan of the woody tissue. In contrast, a flexible wood N:C ratio, such as was tested in O-CN (Meyerholt and Zaehle, 2015), allows variable N storage in the woody tissue, and consequently more nutrient available for C uptake at the transient timescale. Similarly, flexibility in the soil N:C ratio determines the degree of the soil N cycle feedback (e.g. N immobilization and mineralization) and therefore its effect on plant response to eCO<sub>2</sub>. A large response to eCO<sub>2</sub> occurs when the soil N:C ratio is allowed to vary, whereas there could be little or no response if the soil N:C ratio is assumed to be inflexible (McMurtrie and Comins, 1996).

Changes in plant allocation with eCO<sub>2</sub> are also a source of disagreement among current models (De Kauwe et al. 2014). The quasi-equilibrium framework has been used to investigate a number of different plant C allocation schemes (Comins and McMurtrie, 1993; Kirschbaum et al., 1994; Medlyn and Dewar, 1996). For example, Medlyn and Dewar (1996) suggested that plant long-term growth responses to eCO<sub>2</sub> depend strongly on the extent to which stem and foliage allocations are coupled. With no coupling (i.e.

fixed allocation of C and N to stemwood), plant growth was not responsive to eCO<sub>2</sub>; with linear coupling (i.e. allocation to stemwood proportional to foliage allocation), a significant long-term increase in total growth following eCO<sub>2</sub> was found (Figure S1). The reason for this is similar to the argument behind wood N:C ratio flexibility, that decreasing C allocation to wood decreases the rate of N removal per unit of C invested in growth. In contrast, Kirschbaum et al. (1994) found that changes in allocation between different parts of plant only marginally changed the CO<sub>2</sub> sensitivity of production at different timescales. The fundamental difference between the two allocation schemes was that Kirschbaum et al. (1994) assumed that the root allocation coefficient was determined by a negative relationship with the foliar N:C ratio, meaning that the increase in foliar N:C ratio would lead to a decreased root allocation and increased wood and foliage allocation, whereas Medlyn and Dewar (1996) investigated stem-foliage allocation coupling without introducing a feedback via the foliar N:C ratio. The comparison of the two allocation schemes is indicative of the underlying causes of model prediction divergence in recent inter-model comparisons (De Kauwe et al., 2014; Walker et al., 2015).

Another hypothesis currently being explored in models is the idea that increased belowground allocation can enhance nutrient availability under elevated CO<sub>2</sub> (Dybzinski et al., 2014; Guenet et al., 2016). Comins (1994) argued that the N deficit induced by CO<sub>2</sub> fertilization could be eliminated by stimulation of N fixation. This argument was explored in more detail by McMurtrie et al. (2000), who assumed that eCO<sub>2</sub> led to a shift in allocation from wood to root exudation, which resulted in enhanced N fixation. They showed that, although the increase in N fixation could induce a large eCO<sub>2</sub> response in NPP over the long-term, a slight decrease in NPP was predicted over the medium-term. This decrease occurred because increased exudation at eCO<sub>2</sub> increased soil C input, causing increased soil N sequestration and lowering the N available for plant uptake. Over the long-term, however, both NPP and C storage were greatly enhanced because the sustained small increase in N input led to a significant build-up in total ecosystem N on this timescale.

The interaction between rising CO<sub>2</sub> and warming under nutrient limitation is of key importance for future simulations. Medlyn et al. (2000) demonstrated that short-term plant responses to warming, such as

physiological acclimation, are over-ridden by the positive effects of warming on soil nutrient availability in the medium to long term. Similarly, McMurtrie et al. (2001) investigated how the flexibility of the soil N:C ratio affects predictions of the future C sink under elevated temperature and CO<sub>2</sub>. They showed that assuming an inflexible soil N:C ratio with elevated temperature would mean a release of nitrogen with enhanced decomposition, leading to a large plant uptake of N to enhance growth. In contrast, an inflexible soil N:C ratio would mean that the extra N mineralized under elevated temperature is largely immobilized in the soil and hence a smaller increase in C storage. This effect of soil N:C stoichiometry on the response to warming is opposite to the effect on eCO<sub>2</sub> described above. Therefore, under a scenario where both temperature and CO<sub>2</sub> increase, the C sink strength is relatively insensitive to soil N:C variability, but the relative contributions of temperature and CO<sub>2</sub> to this sink differ under different soil N:C ratio assumptions (McMurtrie et al., 2001). This outcome may explain the results observed by Bonan and Levis (2010) when comparing coupled carbon cycle-climate simulations. The TEM (Sokolov et al., 2008) and CLM models (Thornton et al., 2009), which assumed inflexible stoichiometry, had a large climate-carbon feedback but a small CO<sub>2</sub> concentration-carbon feedback, contrasting with the O-CN model (Zaehle et al., 2010), which assumed flexible stoichiometry and had a small climate-carbon feedback and a large CO<sub>2</sub> concentration-carbon feedback. Variations among models in this stoichiometric flexibility assumption could potentially also explain the trade-off between CO<sub>2</sub> and temperature sensitivities observed by Huntzinger et al. (2017).

### 3. Methods and Results

This section combines both methods and results together, because equation derivation is fundamental to the analytical and graphic interpretation of the model performance within the quasi-equilibrium framework. Below we first describe the baseline simulation model and derivation of the quasi-equilibrium constraints (Section 3.1), then follow with analytical evaluations of new model assumptions using the quasi-equilibrium framework (Section 3.2). Within each subsection (Section 3.2.1 to 3.2.3), we first provide key equations for each assumption and the derivation of the quasi-equilibrium constraints with

these new assumptions, then provide our graphic interpretations and analyses to understand the effect of the model assumption on plant NPP responses to eCO<sub>2</sub>.

More specifically, we tested alternative model assumptions for three processes that affect plant carbon-nitrogen cycling: (1) section 3.2.1 evaluates different ways of representing plant N uptake, namely plant N uptake as a fixed fraction of the mineral N pools, as a saturating function of the mineral N pool and linearly depends on root biomass (Zaehle and Friend, 2010), or as a saturating function of root biomass and linearly depends on mineral N pool (McMurtrie et al., 2012); (2) section 3.2.2 tests the effect the “potential NPP” approach that downregulates potential NPP to represent N limitation (Oleson et al., 2004); and (3) section 3.2.3 evaluates root exudation and its effect on soil organic matter decomposition rate (i.e. priming effect). The first two assumptions have been incorporated into some existing land surface model structures (e.g. CLM, CABLE, O-CN, LPJ), whereas the third is a framework proposed following the observation that models did not simulate some key characteristic observations of the DukeFACE experiment (Walker et al., 2015; Zaehle et al., 2014), and therefore could be of importance in addressing some model limitations in representing soil processes (van Groenigen et al., 2014; Zaehle et al., 2014). It is our purpose to demonstrate how one can use this analytical framework to provide *a priori* and generalizable understanding of the likely impact of new model assumption on model behaviour without having to run a complex simulation model. Here we do not target specific ecosystems to parameterize the model but anticipate that the analytical interpretation of quasi-equilibrium framework is of general applicability for woody-dominated ecosystems. One could potentially adopt the quasi-equilibrium approach to provide case-specific evaluations of model behaviour against observations (e.g. constraining the likely range of wood N:C ratio flexibility).

### **3.1 Baseline model and derivation of the quasi-equilibrium constraints**

Our baseline simulation model is similar in structure to G'DAY (Generic Decomposition And Yield, Comins & McMurtrie 1993), a generic ecosystem model that simulates biogeochemical processes (C, N,

and H<sub>2</sub>O) at daily or sub-daily time steps. A simplified G'DAY model version that simulates plant-soil C-N interactions at a weekly timestep was developed for this study (Figure 2). In G'DAY, plants are represented by three stoichiometrically flexible pools: foliage, wood and roots. Each pool turns over at a fixed rate. Litter enters one of four litter pools (metabolic and structural above- and below-ground) and decomposes at a rate dependent on the litter N:C ratio, soil moisture and temperature. Soil organic matter (SOM) is represented as active, slow and passive pools, which decay according to first order decay functions with different rate constants. Plants access nutrients from the mineral N pool, which is an explicit pool supplied by SOM decomposition and an external input, which is assumed to be constant, as a simplified representation of fixation and atmospheric deposition.

10 The baseline simulation model further assumes that: 1) gross primary production (GPP) is function of a light-use efficiency (LUE), which depends on the foliar N:C ratio ( $n_f$ ) and atmospheric CO<sub>2</sub> concentration ( $C_a$ ) (Appendix A1), 2) carbon use efficiency (the ratio of NPP:GPP) is constant; 3) allocation of newly fixed carbon among foliage ( $a_f$ ), wood ( $a_w$ ) and root ( $a_r$ ) pools is constant; 4) foliage ( $n_f$ ), wood ( $n_w$ ) and root N:C ( $n_r$ ) ratios are flexible; 5) wood and root N:C ratios are proportional to the

15 foliar N:C ratio, with constants of proportionality  $r_w$  and  $r_r$ , respectively; 6) a constant proportion ( $t_f$ ) of foliage N is retranslocated before leaves senesce; 7) active, slow and passive SOM pools have fixed N:C ratios; and 8) an N uptake constant determines the plant N uptake rate. Definitions of parameters and forcing variables are summarized in Table 2. For all simulations, ambient CO<sub>2</sub> concentration (aCO<sub>2</sub>) was set at 400 ppm and eCO<sub>2</sub> at 800 ppm.

20 We now summarize the key derivation of the two quasi-equilibrium constraints, the photosynthetic constraint and the nutrient cycling constraint, from our baseline simulation model (details provided in Appendix A1 and A2). The derivation follows Comins and McMurtrie (1993), which is further elaborated in work by (McMurtrie et al., 2000; Medlyn and Dewar, 1996), and evaluated Comins (1994). First, the photosynthetic constraint is derived by assuming that the foliage C pool ( $C_f$ ) has equilibrated. Following

the GPP and CUE assumptions (see above) and the detailed derivations made in Appendix A1, an implicit relationship between NPP and  $n_f$  exists:

$$NPP = LUE(n_f, C_a) \cdot I_0 \cdot (1 - e^{-k\sigma a_f NPP/s_f}) \cdot CUE \quad (\text{Eq. 1})$$

where  $I_0$  is the incident radiation,  $k$  is the canopy light extinction coefficient, and  $\sigma$  is the specific leaf area. This equation is the photosynthetic constraint, which relates NPP with  $n_f$ .

- 5 Secondly, the nitrogen cycling constraint is derived by assuming that nitrogen inputs to, and outputs from, the equilibrated pools, are equal. Based on the assumed residence times of the passive SOM (~400 years), slow SOM (15 years) and woody biomass (50 years) pools, we can calculate the nutrient recycling constraint at three different timescales (conceptualized in Figure 3): very long (VL, > 500 years, all pools equilibrated), long (L, 100 – 500 years, all pools equilibrated except the passive pool), or medium (M, 5-  
10 50 years, all pools equilibrated except slow, passive and wood pools). At the VL-term, we have:

$$N_{in} = N_{loss} \quad (\text{Eq. 2})$$

where  $N_{in}$  is the total N input into the system, and  $N_{loss}$  is the total N lost from the system via leaching and volatilisation. Analytically, with some assumptions about plant N uptake (Appendix A2), we can transform Eq. 2 into a relationship between NPP and  $n_f$ , expressed as:

$$NPP = \frac{N_{in}(1 - l_n)}{l_n(a_f n_{fl} + a_w n_w + a_r n_r)} \quad (\text{Eq. 3})$$

- 15 where  $l_n$  is the fraction of N mineralization that is lost  $a_f$ ,  $a_w$  and  $a_r$  are the allocation coefficients for foliage, wood and roots, respectively, and  $n_{fl}$ ,  $n_w$  and  $n_r$  are the N:C ratios for foliage litter, wood and roots, respectively. Since  $n_w$  and  $n_r$  are assumed proportional to  $n_f$  (Table 2), the nutrient recycling constraint also links NPP and  $n_f$ . The intersection with the photosynthetic constraint yields the very-long term equilibria of both NPP and  $n_f$ . Similarly, we can write the nitrogen recycling constraint at the L-term  
20 and M-term as a function between NPP and  $n_f$  (details explained in Appendix A2). Their respective

interaction with the photosynthetic constraint yields the L-term and M-term equilibria points of both NPP and  $n_f$  (Figure 1 and 3). Essentially, at each timescale, there are two unknowns (NPP and  $n_f$ ) to be resolved via both the nitrogen recycling constraint and the photosynthetic constraint equations. Based on this set of analytical equations, one can evaluate how different assumptions affect the behaviour of the model quantitatively. Below, we describe how different new model assumptions affect the predicted plant response to a doubling of CO<sub>2</sub> concentration at various timescales.

## 3.2 Evaluations of new model assumptions based on the quasi-equilibrium framework

### 3.2.1 Explicit plant N uptake

- 10 We now move to considering new model assumptions. We first consider different representations of plant N uptake. In the baseline model, the mineral N pool ( $N_{min}$ ) is implicit, as we assumed that all mineralized N in the soil is either taken up by plants ( $N_U$ ) or lost from the system ( $N_{loss}$ ). Here, we evaluate three alternative model representations where plant N uptake depends on an explicit  $N_{min}$  pool, and their effects on plant responses to eCO<sub>2</sub>. We consider plant N uptake as 1) a fixed coefficient of the mineral N pool,
- 15 2) a saturating function of root biomass and a linear function of the mineral N pool (McMurtrie et al., 2012), and 3) a saturating function of the mineral N pool and a linear function of root biomass. The last function has been incorporated into some land surface models, for example, O-CN (Zaehle and Friend, 2010) and CLM (Ghimire et al., 2016), while the first two have been incorporated into G'DAY (Corbeels et al., 2005).
- 20 A mineral N pool was made explicit by specifying a constant coefficient ( $u$ ) to regulate the plant N uptake rate (i.e.  $N_U = u \cdot N_{min}$ ). N lost from the system is a function of mineral N pool ( $N_{min}$ ), regulated by a loss rate ( $l_{n,rate}, yr^{-1}$ ). For the VL term equilibrium, we have  $N_{in} = N_{loss}$ , which means  $N_{min} = \frac{N_{in}}{l_{n,rate}}$ , hence:

$$N_{loss} = \frac{l_{n,rate}}{u} \cdot NPP \cdot (a_f n_{fl} + a_w n_w + a_r n_r) \quad (\text{Eq. 4})$$

Where  $n_{fl}$  is the foliage litter N:C ratio, which is proportional to  $n_f$  (Table 2). At the VL equilibrium, we can re-arrange the above equation to relate NPP to  $n_f$ :

$$NPP = \frac{u N_{in}}{l_n \cdot (a_f n_{fl} + a_w n_w + a_r n_r)} \quad (\text{Eq. 5})$$

which indicates that the N-cycling constraint for NPP is inversely dependent on  $n_f$ .

The second function represents plant N uptake as a saturating function of root biomass ( $C_r$ ), and a linear function of the mineral N pool (McMurtrie et al., 2012), expressed as:

$$N_U = \frac{C_r}{C_r + K_r} \cdot N_{min} \quad (\text{Eq. 6})$$

where  $K_r$  is a constant. At the VL equilibrium, we have  $N_{in} = N_{loss} = l_{n,rate} N_{min}$ , and  $C_r = \frac{NPP \cdot a_r}{s_r}$ , where  $s_r$  is the lifetime of root. Substituting for  $C_r$  in Eq. 6, we relate  $N_u$  with NPP:

$$N_U = \frac{NPP \cdot a_r}{NPP \cdot a_r + K_r \cdot s_r} \cdot \frac{N_{in}}{l_{n,rate}} \quad (\text{Eq. 7})$$

Since  $N_U$  is also a function of NPP, we can re-arrange and get:

$$NPP = \frac{N_{in}}{l_{n,rate} (a_f n_{fl} + a_w n_w + a_r n_r)} - \frac{K_r s_r}{a_r} \quad (\text{Eq. 8})$$

Comparing with Eq. 5, here NPP is also inversely dependent on  $n_f$ , but with an additional negative offset of  $\frac{K_r s_r}{a_r}$ . The third approach to represent N uptake (e.g. O-CN and CLM) expresses N uptake as a saturating

function of mineral N, and also linearly depends on root biomass (Zaehle and Friend, 2010), according to:

$$N_U = \frac{N_{min}}{N_{min} + K} \cdot C_r \cdot V_{max} \quad (\text{Eq. 9})$$

where  $K$  is a constant coefficient, and  $V_{max}$ , the maximum root N uptake capacity, is simplified as a constant here. Since  $N_U$  is also a function of NPP, we get

$$N_{min} = K \cdot \frac{(a_f n_{fl} + a_w n_w + a_r n_r)}{V_{max} \cdot \frac{a_r}{s_r} - (a_f n_{fl} + a_w n_w + a_r n_r)} \quad (\text{Eq. 10})$$

5 This equation sets a limit to possible values of  $n_f$ . In equilibrium, for  $N_{min}$  to be non-zero, we need  $(a_f n_{fl} + a_w n_w + a_r n_r) < V_{max} \frac{a_r}{s_r}$ . The N loss rate is still proportional to the mineral N pool, so  $N_{loss}$  is given by

$$N_{loss} = l_{n,rate} \cdot K \cdot \frac{(a_f n_{fl} + a_w n_{wl} + a_r n_{rl})}{V_{max} \cdot \frac{a_r}{s_r} - (a_f n_{fl} + a_w n_{wl} + a_r n_{rl})} \quad (\text{Eq. 11})$$

The above equation provides a  $N_{loss}$  term that no longer depends on NPP, but only on  $n_f$ . If the N leaching loss is the only system N loss, the VL-term nutrient constraint no longer involves NPP, implying  
 10 that the full photosynthetic CO<sub>2</sub> fertilization effect is realized. The L- and M-term nutrient recycling constraints, however, are still NPP-dependent, due to feedbacks from the slowly recycling wood and SOM pools (e.g. Eq. A11 – A15).

The impacts of these alternative representations of N uptake are shown in Figure 4. First, the explicit  
 15 consideration of the mineral N pool with a fixed uptake constant ( $u$ ) of 1 yr<sup>-1</sup> has little impact on the transient response to eCO<sub>2</sub> when compared to the baseline model (Figure 4a, Figure 1a, Table 3). Varying  $u$  does not strongly (<5%) affect plant responses to CO<sub>2</sub> fertilization at different time steps (Figure S2).

This is because  $u$  is only a scaling factor of NPP, meaning it affects NPP but not its response to eCO<sub>2</sub> (Table 4), as depicted by Eq. 5.

Moreover, the approach that assumes N uptake as a saturating function of root biomass and linearly depends on mineral P pool (McMurtrie et al., 2012) has comparable eCO<sub>2</sub> effects on production to the baseline and the fixed uptake coefficient models (Figure 4b, Table 3). Essentially, if  $\frac{K_r s_r}{a_r}$  is small, we can approximate NPP by  $\frac{N_{in}}{l_{n,rate}(a_f n_{f1} + a_w n_w + a_r n_r)}$ , which shares a similar structure to the baseline and fixed uptake coefficient models (Eq. 8, Eq. 5, and Eq. A10). Furthermore, Eq. 8 also depicts that increase in  $a_r$  should lead to higher NPP and increase in  $s_r$  or  $K_r$  should lead to decreased NPP. However, these predictions depend on assumptions of  $l_{n,rate}$  and  $n_f$ . If  $l_{n,rate}$  or  $n_f$  is small, NPP would be relatively less sensitive to  $a_r$ ,  $K_r$  or  $s_r$ .

By comparison, representing N uptake as a saturating function of mineral N and linearly depends on root biomass (Ghimire et al., 2016; Zaehle and Friend, 2010) no longer involves the VL-term nutrient recycling constraint on production (Figure 4c), which is predicted by Eq. 11. Actual VL-term NPP is determined only by  $n_f$  along the photosynthetic constraint, meaning that the full CO<sub>2</sub> fertilization effect on production is realized with the increase in CO<sub>2</sub>. The magnitudes of the CO<sub>2</sub> fertilization effect at other time steps are comparable to those of the baseline model (Table 3), because the  $N_{loss}$  term is smaller than  $N_w$ ,  $N_{Sp}$  or  $N_{Ss}$  terms, meaning it has a relatively smaller effect on NPP at equilibrium. However, steeper nutrient recycling constraint curves are observed (Figure 4c), indicating a stronger sensitivity of the NPP response to changes in  $n_f$ .

20

### 3.2.2 Potential NPP

In several vegetation models, including CLM-CN, CABLE and JSBACH, potential (non-nutrient limited) NPP is calculated from light, temperature and water limitations. Actual NPP is then calculate by down-regulating the potential NPP to match nutrient supply. Here we term this the “potential NPP” approach.

We examine this assumption in the quasi-equilibrium framework following the implementation of this approach adopted in CLM-CN (Bonan and Levis, 2010; Thornton et al., 2007). The potential NPP is reduced if mineral N availability cannot match the demand from plant growth:

$$P_{dem} = NPP_{pot}(a_f n_{fl} + a_w n_w + a_r n_r) \quad (\text{Eq. 12})$$

where  $P_{dem}$  is the plant N demand, and  $NPP_{pot}$  the potential NPP of the plant. Writing  $(a_f n_f + a_w n_w + a_r n_r)$  as  $n_{plant}$ , the whole-plant N:C ratio, and the whole-soil N:C ratio as  $n_{soil}$ , we can calculate the immobilization N demand as:

$$I_{dem} = f C_{lit} s_t (n_{soil} - n_{plant}) \quad (\text{Eq. 13})$$

where  $f$  is the fraction of litter C that becomes soil C,  $C_{lit}$  is the total litter C pool, and  $s_t$  is the turnover time of the litter pool. Actual plant N uptake is expressed as:

$$P_{act} = \min\left(\frac{N_{min} P_{dem}}{I_{dem} + P_{dem}}, P_{dem}\right) \quad (\text{Eq. 14})$$

Actual NPP is expressed as:

$$NPP_{act} = NPP_{pot} \frac{P_{act}}{P_{dem}} \quad (\text{Eq. 15})$$

10 For the VL constraint, we have  $N_{in} = N_{loss}$ . We can calculate  $NPP_{pot}$  as:

$$NPP_{pot} = \frac{N_{in} (1 - l_n)}{l_n n_{plant}} \quad (\text{Eq. 16})$$

For an actual NPP, we need to consider the immobilization demand. Re-arranging the above, we get:

$$NPP_{act} = \frac{N_{in} (1 - l_n)}{l_n [n_{plant} + f(n_{soil} - n_{plant})]} \quad (\text{Eq. 17})$$

This equation removes the  $NPP_{act}$  dependence on  $NPP_{pot}$ . It can be shown that the fraction of  $P_{dem}/(I_{dem} + P_{dem})$  depends only on the N:C ratios and  $f$ , not on  $NPP_{pot}$ . This means that there will be no eCO<sub>2</sub> effect on  $NPP_{act}$ .

As shown in Figure 5a, the potential NPP approach results in relatively flat nutrient recycling constraint curves, suggesting that the CO<sub>2</sub> fertilization effect is only weakly influenced by soil N availability. Despite a sharp instantaneous NPP response, CO<sub>2</sub> fertilization effects on  $NPP_{act}$  are small at the M-, L- and VL-term timescales (Table 3). This outcome can be understood from the governing equation for the nutrient recycling constraint, which removes  $NPP_{act}$  dependence on  $NPP_{pot}$  (Eq. 17). Although in the first instance, the plant can increase its production, over time the litter pool increases in size proportion to  $NPP_{pot}$ , meaning that immobilisation demand increases to match the increased plant demand, which leads to no overall change in the relative demands from the plant and the litter. This pattern is similar under alternative wood N:C ratio assumptions (Figure 5b, Table 3).

### 3.2.3 Root exudation to prime N mineralisation

The priming effect is described as the stimulation of the decomposition of native soil organic matter, caused by larger soil carbon input under eCO<sub>2</sub> (van Groenigen et al., 2014). Experimental studies suggest that this phenomenon is widespread and persistent (Dijkstra and Cheng, 2007), but this process has not been incorporated by most land surface models (Walker et al., 2015). Here we introduce a novel framework to induce priming effect on soil decomposition, and test its effect on plant production response to eCO<sub>2</sub> within the quasi-equilibrium framework.

To account for the effect of priming on decomposition of SOM, we first introduce a coefficient to determine the fraction of root growth allocated to exudates,  $a_{rhizo}$ . Here we assumed that N:C ratio of the rhizodeposition is the same as the root N:C ratio. The coefficient  $a_{rhizo}$  is estimated by a function dependent on foliar N:C:

$$a_{rhizo} = a_0 + a_1 \cdot \frac{1/n_f - 1/n_{ref}}{1/n_{ref}} \quad (\text{Eq. 18})$$

where  $n_{ref}$  is a reference foliar N:C ratio to induce plant N stress (0.04), and  $a_0$  and  $a_1$  are tuning coefficients (0.01 and 1, respectively). Within the quasi-equilibrium framework, for the VL soil constraint we now have:

$$NPP = \frac{N_{in}}{[a_f n_{fl} + a_w n_w + a_r a_{rhizo} n_r + a_r (1 - a_{rhizo}) n_r]} \frac{l_n}{1 - l_n} \quad (\text{Eq. 19})$$

To introduce an effect of root exudation on the turnover rate of slow SOM pool, rhizodeposition is transferred into the active SOM pool according to a microbial use efficiency parameter ( $f_{cue,rhizo} = 0.3$ ). The extra allocation of NPP into the active SOM is therefore:

$$C_{rhizo} = NPP \cdot a_r \cdot a_{rhizo} \cdot f_{cue,rhizo} \quad (\text{Eq. 20})$$

The increased active SOM pool N demand is associated with the degradation rate of the slow SOM pool, expressed as:

$$k_{slow,new} = k_{slow} \cdot (1 + k_m) \cdot \frac{C_{rhizo}}{C_{rhizo} + k_m} \quad (\text{Eq. 21})$$

where  $k_{slow}$  is the original decomposition rate of the slow SOM pool, and  $k_m$  is a sensitivity parameter.

10 The decomposition rate of the slow SOM pool affects  $N_{Rs}$ , the amount of N released from the slow SOM pools, as:

$$N_{Rs} = k_{slow,new} C_s [n_s (1 - \Omega_{ss}) - n_p \Omega_{ps}] \quad (\text{Eq. 22})$$

where  $C_s$  is the slow SOM pool, and  $\Omega_{ss}$  and  $\Omega_{ps}$  are the proportion of C released through decomposition of slow and passive SOM pools that subsequently enters slow SOM pool, respectively.

Root exudation and the associated priming effect results in a strong M-term plant response to eCO<sub>2</sub> when compared to the baseline model (Figure 6a in comparison to Figure 4a). In fact, the magnitude of the priming effect on M-term NPP response to eCO<sub>2</sub> is comparable to its L- and VL-term NPP responses, indicating a persistent eCO<sub>2</sub> effect over time (Table 3). A faster decomposition rate and therefore a smaller pool size of the slow SOM pool are observed (Table 5). With a fixed wood N:C ratio assumption, NPP response to eCO<sub>2</sub> is drastically reduced at the M-term as compared to the model with a variable wood N:C assumption (Figure 6b), but is comparable to its corresponding baseline fixed wood N:C model (Table 3). Varying parameter coefficients ( $a_0$ ,  $a_1$ ,  $f_{cue,rhizo}$  and  $k_m$ ) affects the decomposition rates of slow soil organic pool and hence could lead to variation of the priming effect on M-term CO<sub>2</sub> response (Figure S3). Further experimental studies are needed to better constrain these parameters. Adding root exudation without influencing slow SOM pool decomposition rate (Eq. 21) leads to a smaller predicted M-term CO<sub>2</sub> response than the model with the direct effect on the slow SOM pool. However, it also leads to a higher predicted M-term CO<sub>2</sub> response than the baseline model (Figure 7), because  $a_r$  and  $n_r$  affect the reburial fraction of the slow SOM pool, as shown in McMurtrie et al. (2000). Finally, the model with a variable wood N:C assumption indicates that there is no increase in NUE (Table 2) at the M-term as compared to its L- and VL-term responses (Figure 6c). In comparison, the fixed wood N:C ratio assumption means that there is a decreased wood “quality” (reflected via decreased N:C ratio), and therefore faster decomposition of slow SOM pool does not release much extra N to support the M-term CO<sub>2</sub> response, leading to a significant rise of NUE at the M-term (Figure 6d).

## 20 4 Discussion

### 4.1 Influence of alternative N uptake assumptions on predicted CO<sub>2</sub> fertilization

The quasi-equilibrium analysis of the time-varying plant response to eCO<sub>2</sub> provides a quantitative framework to understand the relative contributions of different model assumptions governing the supply of N to plants in determining the magnitude of the CO<sub>2</sub> fertilization effect. Here, we evaluated how plant responses to eCO<sub>2</sub> are affected by widely used model assumptions relating to plant N uptake, soil

decomposition, and immobilization demand under alternative wood N:C coupling strategies (variable and fixed wood N:C ratios). These assumptions have been adopted in land surface models such as O-CN (Zaehle and Friend, 2010), CABLE (Wang et al., 2007), LPJ-Guess N (Wårlind et al., 2014), JASBACH-CNP (Goll et al., 2012), ORCHIDEE-CNP (Goll et al., 2017a), and CLM4 (Thornton et al., 2007). In line with previous findings (Comins and McMurtrie, 1993; Dewar and McMurtrie, 1996; Kirschbaum et al., 1998; McMurtrie and Comins, 1996; Medlyn and Dewar, 1996), our results show that assumptions related to wood stoichiometry have a very large impact on estimates of plant responses to eCO<sub>2</sub>. More specifically, models incorporating a fixed wood N:C ratio consistently predicted smaller CO<sub>2</sub> fertilization effects on production than models using a variable N:C ratio assumption (Table 3). Examples of models assuming constant (Thornton et al., 2007; Weng and Luo, 2008) and variable (Zaehle and Friend, 2010) plant tissue stoichiometry are both evident in the literature, and therefore, assuming all other model structure and assumptions are similar, prediction differences could potentially be attributed to the tissue stoichiometric assumption incorporated into these models, as suggested in some previous simulation studies (Medlyn et al., 2016; Medlyn et al., 2015; Meyerholt and Zaehle, 2015; Zaehle et al., 2014). Together with more appropriate representation of the trade-offs governing tissue C-N coupling (Medlyn et al., 2015), further tissue biochemistry data is necessary to constrain this fundamental aspect of ecosystem model uncertainty (Thomas et al., 2015).

C-N coupled simulation models generally predict that the CO<sub>2</sub> fertilization effect on plant production is progressively constrained by soil N availability over time: the progressive nitrogen limitation hypothesis (Luo et al., 2004; Norby et al., 2010; Zaehle et al., 2014). Here we showed similar temporal patterns in a model with different plant N uptake assumptions (Figure 4) and the potential NPP assumption (Figure 5). In particular, the progressive N limitation effect on NPP is shown as a down-regulated M-term CO<sub>2</sub> response after the sharp instantaneous CO<sub>2</sub> fertilization effect on production is realized. However, the model incorporating a priming effect of C on soil N availability with a flexible wood N:C ratio assumption induced a strong M-term CO<sub>2</sub> response (13% increase in NPP), thereby introducing a persistent CO<sub>2</sub> effect over time (Figure 6a). This strong M-term CO<sub>2</sub> response is due to an enhanced decomposition rate of soil

organic matter, consistent with a series of recent observations and modelling studies (Finzi et al., 2015; Guenet et al., 2018; Sulman et al., 2014; van Groenigen et al., 2014). However, as a previous quasi-equilibrium study showed, a significant increase in the M-term CO<sub>2</sub> response can occur via changes in litter quality into slow SOM pool or increased N input into the system (McMurtrie et al., 2000). Our study  
5 differs from McMurtrie et al. (2000) in that we introduced an explicit effect of C priming on  $k_{slow}$  – the decomposition rate of slow SOM pool – via extra rhizodeposition (Eq. 21). As such, a faster decomposition rate of slow SOM is observed (Table 5), equivalent to adding extra N for mineralization to support the M-term CO<sub>2</sub> response (Figure 6c). More complex models for N uptake, incorporating a carbon cost for nitrogen acquisition, are being proposed (Fisher et al., 2010; Ghimire et al., 2016; Shi et  
10 al., 2015a); we suggest that the likely effects of introducing these complex sets of assumptions into large-scale models could usefully be explored with the quasi-equilibrium framework.

Processes regulating the progressive nitrogen limitation under eCO<sub>2</sub> were evaluated by Liang et al. (2016) based on a meta-analysis, which bridged the gap between theory and observations. It was shown that the expected diminished CO<sub>2</sub> fertilization effect on plant growth was not apparent at the ecosystem scale due  
15 to extra N supply through increased biological N fixation and decreased leaching under eCO<sub>2</sub>. Here, our baseline assumption assumed fixed N input into the system, and therefore plant available N is progressively depleted through increased plant N sequestration under eCO<sub>2</sub>, as depicted by the progressive N limitation hypothesis (Luo et al., 2004). A function that allows N fixation parameter to vary could provide further assessment of the tightness of the ecosystem N cycle process and its impact to  
20 plant response to eCO<sub>2</sub>. Furthermore, given the significant role wood N:C ratio plays in plant N sequestration, matching modelled range of wood tissue stoichiometry with observations can provide addition level of evaluation of model performance. Our study provides a generalizable evaluation based on the assumption that wood N:C ratio, when allowed to vary in a model, is proportional to leaf N:C ratio. Case-specific, more realistic evaluations can be performed based on the quasi-equilibrium framework to  
25 bridge models with observations.

A strong M-term and persistent CO<sub>2</sub> fertilization effects over time was also found by some models in Walker et al. (2015), but without introducing a priming effect. In models such as CLM, N losses from the system are concentration dependent, and plant N uptake is a function of both N supply and plant demand. Increased plant N demand in models where N uptake is a function of plant N demand, reduces soil solution N concentration and therefore system N losses. This means that over time N can accumulate in the system in response to eCO<sub>2</sub> and sustain an eCO<sub>2</sub> response. Here, our quasi-equilibrium framework considers N lost as a fixed rate that depends linearly on the mineral N pool, and the mineral N pool changes at different equilibrium time points. For example, as shown in Table S1, M-term N loss rate is significantly reduced under eCO<sub>2</sub> as compared to the VL-term N lost rate under aCO<sub>2</sub>. This suggests a positive relationship between N lost and NPP, as embedded in Eq. 4.

We also showed that the magnitude of the CO<sub>2</sub> fertilization effect is significantly reduced at all time-scales when models incorporate the potential NPP approach (Figure 5). Among all model assumptions tested, the potential NPP approach induced the smallest M- to VL-term responses (Table 3). It can be shown from equation derivation (Eq. 17) that the fraction  $P_{dem}/(P_{dem} + I_{dem})$  depends only on the N:C ratios and  $f$  (fraction of litter C become soil C), implying that models incorporating the potential NPP assumption should show no response of NPP to CO<sub>2</sub>. Both our study and simulation-based studies showed small CO<sub>2</sub> responses (Walker et al., 2015; Zaehle et al., 2014), possibly because the timing of  $P_{dem}$  and  $I_{dem}$  differs due to the fluctuating nature of GPP and N mineralization at daily to seasonal time steps, such that N is limiting at certain times of the year but not at others. Additionally, models such as CLM have volatilization losses (not leaching) that are reduced under eCO<sub>2</sub>, which may lead to production not limited by N availability, meaning that full CO<sub>2</sub> fertilization effect may be realized. Finally, leaching is simplified here, treated as a fixed fraction of the mineral N pool. In models such as CLM or JASBACH, it is a function of soil soluble N concentration, implying a dependency on litter quality (Zaehle et al., 2014).

## 4.2 Implications for probing model behaviours

Model-data intercomparisons have been shown as a viable means to investigate how and why models differ in their predicted response to eCO<sub>2</sub> (De Kauwe et al., 2014; Walker et al., 2015; Zaehle et al., 2014). Models make different predictions because they have different model structures (Lombardozzi et al., 2015; Meyerholt et al., 2016; Shi et al., 2018; Xia et al., 2013; Zhou et al., 2018), parameter uncertainties (Dietze et al., 2014; Wang et al., 2011), response mechanisms (Medlyn et al., 2015), and numerical implementations (Rogers et al., 2016). It is increasingly difficult to diagnose model behaviours from the multitude of model assumptions incorporated into the model. Furthermore, while it is true that the models can be tuned to match observations within the domain of calibration, models may make correct predictions but based on incorrect or simplified assumptions (Medlyn et al., 2005; Medlyn et al., 2015; Walker et al., 2015). As such, diagnosing model behaviours can be a challenging task in complex plant-soil models. In this study, we showed that the effect of a model assumption on plant response to eCO<sub>2</sub> can be analytically predicted by solving together the photosynthetic and nutrient recycling constraints. This provides a constrained model framework to evaluate the effect of individual model assumptions without having to run a full set of sensitivity analyses, thereby providing *a priori* understanding of the underlying response mechanisms through which the effect is realized. We suggest that before implementing a new function into the full structure of a plant-soil model, one could use the quasi-equilibrium framework as a testbed to examine the effect of the new assumption.

The quasi-equilibrium framework requires that additional model assumptions be analytically solvable, which is increasingly not the case for complex modelling structures. However, as we demonstrate here, studying the behaviour of a reduced-complexity model can nonetheless provide real insight into model behaviour. In some cases, the quasi-equilibrium framework can highlight where additional complexity is not valuable. For example, here we showed that adding complexity in the representation of plant N uptake did not result in significantly different predictions of plant response to eCO<sub>2</sub>. Where the quasi-equilibrium framework indicates little effect of more complex assumptions, there is a strong case for keeping simpler assumptions in the model. However, we do acknowledge that the quasi-equilibrium framework operates

on time-scales of  $> 5$  years; where fine-scale temporal responses are important, the additional complexity may be warranted.

The multiple element limitation framework developed by Rastetter and Shaver (1992) analytically evaluates the relationship between short-term and long-term plant responses to  $e\text{CO}_2$  and nutrient availability under different model assumptions. It was shown that there could be markedly difference in the short-term and long-term ecosystem responses to  $e\text{CO}_2$  (Rastetter et al., 1997; Rastetter and Shaver, 1992). More specifically, Rastetter et al. (1997) showed that the ecosystem NPP response to  $e\text{CO}_2$  appeared on several characteristic timescales: 1) there was an instantaneous increase in NPP, which results in an increased vegetation C:N ratio, 2) on a timescale of a few years, the vegetation responded to  $e\text{CO}_2$  by increasing uptake effort for available N through increased allocation to fine roots, 3) on a timescale of decades, there was a net movement of N from soil organic matter to vegetation, which enables vegetation biomass to accumulate, and 4) on the timescale of centuries, ecosystem responses were dominated by increases in total ecosystem N, which enable organic matter to accumulate in both vegetation and soils. Both the multiple element limitation framework and the quasi-equilibrium framework provides information about the equilibrium responses. These approaches also provide information about the degree to which the ecosystem relies on internally recycled N vs. exchanges of with external sources and sinks. The multiple element limitation framework also offers insight into the C-N interaction that influences transient dynamics. These analytical frameworks are both useful tools for making quantitative assessments of model assumptions.

A related model assumption evaluation tool is the traceability framework, which decomposes complex models to various simplified component variables such as ecosystem C storage capacity or residence time, and hence helps to identify structures and parameters that are uncertain among models (Shi et al., 2015b; Xia et al., 2013; Xia et al., 2012). Both the traceability and quasi-equilibrium frameworks provide analytical solutions to describe how and why model predictions diverge. The traceability framework decomposes complex simulations into a common set of component variables, explaining differences due to these variables. In contrast, the quasi-equilibrium analysis investigates the impacts and behaviour of a

specific model assumption, which is more indicative of mechanisms and processes. Subsequently, one can relate the effect of a model assumption more mechanistically to the processes that govern the relationship between plant N:C ratio and NPP, as depicted in Figure 1, thereby facilitating the efforts to reduce model uncertainties.

5 Models diverge in future projections of plant responses to increases in CO<sub>2</sub> because of the different assumptions that they make. Applying model evaluation frameworks, such as the quasi-equilibrium framework, to attribute these differences will not necessarily reduce multi-model prediction spread in the short-term (Lovenduski and Bonan, 2017). Many model assumptions are still empirically derived, and there is a lack of mechanistic and observational constraints on the effect size, meaning that it is important  
10 to apply models incorporating diverse process representations. However, use of the quasi-equilibrium framework can provide crucial insights into why model predictions differ, and thus help identify the critical measurements that would allow to discriminate among alternative models. As such, it is an invaluable tool for model inter-comparison and benchmarking analysis. We recommend use of this framework to analyze likely outcomes of new model assumptions before introducing them to complex  
15 model structures.

## Appendix A. Baseline quasi-equilibrium model derivation

Here we show how baseline quasi-equilibrium framework is derived. Specifically, there are two analytical constraints that form the foundation of the quasi-equilibrium framework, namely the photosynthetic  
5 constraint, and the nitrogen cycling constraint. The derivation follows Comins and McMurtrie (1993), which is further elaborated in work by (McMurtrie et al., 2000; Medlyn and Dewar, 1996), and evaluated (Comins, 1994).

### A1. Photosynthetic constraint

10 Firstly, gross primary production (GPP) in the simulation mode is calculated using a light-use efficiency approach named MATE (Model Any Terrestrial Ecosystem) (McMurtrie et al., 2008; Medlyn et al., 2011; Sands, 1995), in which absorbed photosynthetically active radiation is estimated from leaf area index ( $L$ ) using Beer's Law, and is then multiplied by a light-use efficiency (LUE) which depends on the foliar N:C ratio ( $n_f$ ) and atmospheric CO<sub>2</sub> concentration ( $C_a$ ).

$$GPP = LUE(n_f, C_a) \cdot I_0 \cdot (1 - e^{-kL}) \quad (\text{Eq. A1})$$

15 where  $I_0$  is the incident radiation,  $k$  is the canopy light extinction coefficient, and  $L$  is leaf area index. The derivation of LUE for the MATE model is described in full by McMurtrie et al. (2008); our version differs only in that the key parameters determining the photosynthetic rate follow the empirical relationship with foliar N:C ratio given by Walker et al. (2014a) and the expression for stomatal conductance follows Medlyn et al. (2011).

20 In the quasi-equilibrium framework, the photosynthetic constraint is derived by assuming that the foliage C pool ( $C_f$ ) has equilibrated. That is, the new foliage C production equals turnover, which is assumed to be a constant fraction ( $s_f$ ) of the pool:

$$a_f NPP = s_f C_f \quad (\text{Eq. A2})$$

where  $a_f$  is the allocation coefficient for foliage. From Eq. A1, net primary production is a function of the foliar N:C ratio and the foliage C pool:

$$NPP = LUE(n_f, C_a) \cdot I_0 \cdot (1 - e^{-k\sigma C_f}) \cdot CUE \quad (\text{Eq. A3})$$

Where  $\sigma$  is the specific leaf area. Combining two equations above leads to an implicit relationship between  $NPP$  and  $n_f$ :

$$NPP = LUE(n_f, C_a) \cdot I_0 \cdot (1 - e^{-k\sigma a_f NPP/s_f}) \cdot CUE \quad (\text{Eq. A4})$$

5 which is the photosynthetic constraint.

## A2. Nutrient recycling constraint

The nitrogen cycling constraint is derived by assuming that nitrogen inputs to, and outputs from, the equilibrated pools, are equal. Based on the assumed residence times of the passive SOM (~400 years),  
 10 slow SOM (15 years) and woody biomass (50 years) pools, we can calculate the nutrient recycling constraint at three different timescales: very long (VL, > 500 years, all pools equilibrated), long (L, 100 – 500 years, all pools equilibrated except the passive pool), or medium (M, 5-50 years, all pools equilibrated except slow, passive and wood pools).

15 At the VL-term, we have:

$$N_{in} = N_{loss} \quad (\text{Eq. A5})$$

where  $N_{in}$  is the total N input into the system, and  $N_{loss}$  is the total N lost from the system via leaching and volatilisation. Following Comins and McMurtrie (1993), the flux  $N_{in}$  is assumed to be a constant. The total N loss term is proportional to the rate of N mineralization ( $N_m$ ), following:

$$N_{loss} = l_n \cdot N_m \quad (\text{Eq. A6})$$

where  $l_n$  is the fraction of N mineralization that is lost. It is assumed that mineralised N that is not lost is  
5 taken up by plants ( $N_U$ ):

$$N_U = N_m - N_{loss} \quad (\text{Eq. A7})$$

Combining with Eq. A6, we have:

$$N_{loss} = \frac{l_n}{(1 - l_n)} N_U \quad (\text{Eq. A8})$$

The plant N uptake rate depends on production (NPP) and plant N:C ratios, according to:

$$N_U = NPP \cdot (a_f n_{fl} + a_w n_w + a_r n_r) \quad (\text{Eq. A9})$$

Where  $a_f$ ,  $a_w$  and  $a_r$  are the allocation coefficients for foliage, wood and roots, respectively, and  $n_{fl}$ ,  $n_w$   
10 and  $n_r$  are the N:C ratios for foliage litter, wood and roots, respectively. Foliage litter N:C ratio ( $n_{fl}$ ) is  
proportional to  $n_f$ , according to Table 2. Combining Eq. A9 with Eq. A5 and Eq. A8, we obtain a function  
of NPP that can be related to total N input, which is the nutrient recycling constraint at the VL-term,  
expressed as:

$$NPP = \frac{N_{in}(1 - l_n)}{l_n(a_f n_{fl} + a_w n_w + a_r n_r)} \quad (\text{Eq. A10})$$

Since  $n_w$  and  $n_r$  are assumed proportional to  $n_f$ , the nutrient recycling constraint also links NPP and  $n_f$ .  
The intersection with the photosynthetic constraint yields the very-long term equilibria of both NPP and  
15  $n_f$ .

At the L-term, we now have to consider N flows leaving and entering the passive SOM pool, which is no  
longer equilibrated:

$$N_{in} + N_{Rp} = N_{loss} + N_{Sp} \quad (\text{Eq. A11})$$

where  $N_{Rp}$  and  $N_{Sp}$  are the release and sequestration of the passive SOM N pool, respectively. The release flux,  $N_{Rp}$ , can be assumed to be constant on the L-term timescale. The sequestration flux,  $N_{Sp}$ , can be calculated as a function of NPP. In G'DAY, as with most carbon-nitrogen coupled ecosystem models, carbon flows out of the soil pools are directly related to the pool size. As demonstrated by Comins and  
 5 McMurtrie (1993), such soil models have the mathematical property of linearity, meaning that carbon flows out of the soil pools are proportional to the production input to the soil pool, or NPP. Furthermore, the litter input into the soil pools is assumed proportional to foliar N:C ratio, with the consequence that N sequestered in the passive SOM is also related to foliar N:C ratio. The sequestration flux into the passive soil pool ( $N_{Sp}$ ) can thus be written as:

$$N_{Sp} = NPP n_p (\Omega_{pf} \cdot a_f + \Omega_{pw} \cdot a_w + \Omega_{pr} \cdot a_r) \quad (\text{Eq. A12})$$

10 Where  $n_p$  is the N:C ratio of the passive SOM pool,  $\Omega_{pf}$ ,  $\Omega_{pw}$  and  $\Omega_{pr}$  are the burial coefficients for foliage, wood and roots (the proportion of plant carbon production that is ultimately buried in the passive pool), respectively. The burial coefficients  $\Omega_{pf}$ ,  $\Omega_{pw}$  and  $\Omega_{pr}$  depend on the N:C ratios of foliage, wood and root litter (detailed derivation in Comins and McMurtrie, 1993). Combining and re-arranging, we obtain nutrient recycling constraint at the L-term as:

$$NPP = \frac{N_{in} + N_{Rp}}{n_p (\Omega_{pr} a_r + \Omega_{pf} a_f + \Omega_{pw} a_w) + \frac{l_n}{1 - l_n} (a_f n_{fl} + a_w n_w + a_r n_r)} \quad (\text{Eq. A13})$$

15 Similarly, at the M-term, we have:

$$N_{in} + N_{Rp} + N_{Rs} + N_{Rw} = N_{loss} + N_{Sp} + N_{Ss} + N_{Sw} \quad (\text{Eq. A14})$$

Where  $N_{R_s}$  and  $N_{R_w}$  are the N released from slow SOM and wood pool, respectively, and  $N_{S_s}$  and  $N_{S_w}$  are the N stored in slow SOM and wood pool, respectively (Medlyn et al., 2000). The nutrient recycling constraint at the M-term can thus be derived as:

$$NPP = \frac{N_{in} + N_{R_p} + N_{R_s} + N_{R_w}}{a_f (\Omega_{s_f} n_s + \Omega_{p_f} n_p) + a_r (\Omega_{s_r} n_s + \Omega_{p_r} n_p) + \frac{l_n}{1 - l_n} (a_f n_{fl} + a_w n_w + a_r n_r) + a_w n_w} \quad (\text{Eq. A15})$$

Where  $n_s$  is the slow SOM pool N:C ratio,  $\Omega_{s_f}$  and  $\Omega_{s_r}$  are foliage and root C sequestration rate into slow SOM pool, respectively (Medlyn et al., 2000). The intersection between the nitrogen recycling constraint and the photosynthetic constraint provides analytical solution to both NPP and  $n_f$  at different timescales, we can then interpret how changing model assumptions affect the predicted plant responses to elevated CO<sub>2</sub>.

Table 1: A brief summary of the processes and model assumptions evaluated based on the quasi-equilibrium analyses

Processes	Assumptions	Findings	Key reference
Stoichiometry	Wood N:C flexibility	Flexible wood N:C ratio induced a strong NPP response to eCO <sub>2</sub> .	Comins and McMurtrie, 1993; Comins, 1994; Kirschbaum et al., 1994; McMurtrie and Comins, 1996; Kirschbaum et al., 1998
	Soil N:C flexibility	Soil N:C ratio flexibility fundamentally underpin NPP response to eCO <sub>2</sub> .	McMurtrie and Comins, 1996; Medlyn et al., 2000; McMurtrie et al., 2001
	Litter N:C flexibility	Decreased new litter N:C ratio did not significantly alter NPP response to eCO <sub>2</sub> , but a substantial decrease in old litter N:C ratio led to a significant CO <sub>2</sub> effect at the medium-term.	McMurtrie et al., 2000
Allocation	Dynamic allocation as a response to changes in leaf N:C ratio	Changes in C allocation between different parts do not significantly alter NPP response to eCO <sub>2</sub> .	Kirschbaum et al., 1994
	Linear stem and leaf allocation coupling	With stem allocation proportional to leaf allocation, NPP response to eCO <sub>2</sub> is significant, even when N deposition is unchanged.	Medlyn and Dewar, 1996
Nutrient supply and loss	N fixation	N deficit induced by CO <sub>2</sub> fertilization can be eliminated by stimulation of N fixation.	Comins, 1994
	N fixation	Enhanced N fixation via root exudation leads to a small effect on production in the short term but a very large effect in the long term.	McMurtrie et al., 2000
	Leaf N retranslocation	Changes in leaf N retranslocation fraction do not significantly affect NPP response to eCO <sub>2</sub> .	Kirschbaum et al., 1994
	Litter supply	Increased litter quantity only leads to a minimal CO <sub>2</sub> effect on production.	McMurtrie et al., 2000
	Nutrient supply and loss	Systems that are more open with respect to nutrient gains and losses are likely to be more responsive to eCO <sub>2</sub> .	Kirschbaum et al., 1998
	N mineralization	Increased temperature induced a long-term increase in NPP response to eCO <sub>2</sub> because of increased N mineralization and plant N uptake rates	Medlyn et al., 2000
	N immobilization	When both T and CO <sub>2</sub> increase, C sink is insensitive to variability in soil N:C ratio, however, with fixed soil N:C, C sink is primarily a temperature response, whereas with variable soil N:C, it is a combined temperature-CO <sub>2</sub> response.	McMurtrie et a., 2001
Photosynthesis	LUE coefficient	Effect of leaf N:C ratio on LUE coefficient induces a small effect on CO <sub>2</sub> sensitivity of plant.	Kirschbaum et al., 1994
	SLA	Introducing leaf N:C dependency of SLA induces no significantly different NPP response to eCO <sub>2</sub> .	Kirschbaum et al., 1994

Table 2: Definitions of key variables for the baseline equations

Symbol	Definition	Value	Unit
$a_{CO_2}, e_{CO_2}$	Ambient and elevated $CO_2$ concentration, respectively	400, 800	ppm
$N_{in}$	Total nitrogen into the system (atmospheric deposition and fixation)	0.004	$t\ ha^{-1}\ yr^{-1}$
$T_{air}, T_{soil}, T_{leaf}$	Temperature of air, soil, and leaf, respectively	20, 15, 25	$^{\circ}C$
CUE	Plant carbon use efficiency	0.5	unitless
NUE	Plant nitrogen use efficiency = $NPP / N_u$	Calculated	$kg\ C\ kg\ N^{-1}$
$\sigma$	Specific leaf area	5	$m^2\ kg^{-1}$
$\omega$	Carbon content of biomass	0.45	unitless
$a_f, a_r, a_w$	Carbon allocation fraction to leaf, root and wood, respectively	0.2, 0.2, 0.6	unitless
$n_f, n_r, n_w, n_l$	N:C ratio of leaf, root, wood, and leaf litter, respectively		unitless
$t_f$	Leaf retranslocation rate	0.5	$yr^{-1}$
$r_w, r_r$	Proportion of wood and root N:C ratio to leaf N:C ratio, respectively	0.005, 0.7	unitless
$s_f, s_r, s_w$	Turnover rates of leaf, root and wood, respectively	0.5, 1.5, 0.01	$yr^{-1}$
$n_a, n_s, n_p$	C:N ratio for active, slow, passive SOM pool, respectively	15, 20, 10	unitless
$I_n$	Fraction of N mineralization lost from the system	0.05	unitless
$I_{n, rate}$	Mineral N pool lost rate	0.05	$yr^{-1}$
$O_{acq}, O_{resorb}, O_{active}$	Total, resorption, and active C cost of N acquisition, respectively	Calculated	$kg\ C\ kg\ N^{-1}$
$\Omega_{sl}, \Omega_{pl}$	Proportion of leaf litter enters into slow and passive SOM pool, respectively	Calculated	unitless
$\Omega_{sr}, \Omega_{pr}$	Proportion of root litter enters into slow and passive SOM pool, respectively	Calculated	unitless
$\Omega_{sw}, \Omega_{pw}$	Proportion of wood litter enters into slow and passive SOM pool, respectively	Calculated	unitless
$N_{Ss}, N_{Sp}, N_{Sw}$	N stored in slow, passive SOM, and wood pool, respectively	Calculated	$t\ ha^{-1}\ yr^{-1}$
$N_{Rs}, N_{Rp}, N_{Rw}$	N released from slow, passive SOM, and wood pool, respectively	Calculated	$t\ ha^{-1}\ yr^{-1}$
$N_U$	N uptake rate	Calculated	$t\ ha^{-1}\ yr^{-1}$
$N_{min}$	Mineral N pool	Calculated	$t\ ha^{-1}$

5 Table 3: Magnitudes of the CO<sub>2</sub> fertilization effect on net primary production (NPP) at various time steps for different model assumptions. NPP<sub>a</sub> and NPP<sub>e</sub> represent very long-term equilibrium point of NPP at ambient and elevated CO<sub>2</sub> conditions, respectively. I, M, L, and VL represent percent change in NPP as a result of elevated CO<sub>2</sub> at instantaneous, medium, long, and very-long term time points, respectively. All experiments except “baseline, fixed wood NC” assume variable wood N:C ratio.

Experiment	NPP <sub>a</sub>	NPP <sub>e</sub>	I	M	L	VL
<b>Baseline model, variable wood NC</b>	1.67	1.90	15.1	3.2	12.3	13.3
<b>Baseline model, fixed wood NC</b>	1.49	1.66	15.9	0.8	7.9	10.9
<b>Explicit N uptake, fixed coefficient, variable wood NC</b>	1.68	1.91	15.1	3.2	12.4	13.3
<b>Explicit N uptake, fixed coefficient, fixed wood NC</b>	1.52	1.68	15.8	0.8	8.2	11.1
<b>Explicit N uptake, saturating function of root, variable wood NC</b>	1.68	1.91	15.1	3.2	12.4	13.3
<b>Explicit N uptake, saturating function of Nmin, variable wood NC</b>	1.71	1.96	15.0	3.2	13.7	15.0
<b>Priming, variable wood NC</b>	1.67	1.90	15.1	12.2	12.0	13.3
<b>Priming, fixed wood NC</b>	1.49	1.66	15.9	1.8	8.3	10.9
<b>Relative demand, variable wood NC</b>	1.35	1.42	16.6	0.3	2.9	4.9
<b>Relative demand, fixed wood NC</b>	1.13	1.15	17.9	0.2	1.1	1.7

Table 4. Relationship between nitrogen uptake coefficient ( $u$ ) and quasi-equilibrium points of leaf N:C ratio ( $n_f$ ) and net primary production (NPP) at the very-long (VL), long (L), medium (M) and instantaneous time points.

$u$ ( $\text{yr}^{-1}$ )	$\text{CO}_2$ (ppm)	$n_f$			NPP ( $\text{kg C m}^{-2} \text{ yr}^{-1}$ )			
		VL	L	M	VL	L	M	I
0.2	400	0.0049	0.0049	0.0049	1.35	1.35	1.35	-
0.2	800	0.0043	0.0039	0.0026	1.53	1.51	1.39	1.57
0.5	400	0.01	0.01	0.0107	1.54	1.54	1.54	-
0.5	800	0.01	0.008	0.005	1.75	1.72	1.59	1.78
1	400	0.02	0.02	0.0196	1.68	1.68	1.68	-

5 Table 5. Effect of priming on key soil process coefficients. Coefficient  $k_{\text{slow}}$  is the decomposition coefficient for the slow SOM pool ( $\text{yr}^{-1}$ );  $a_{\text{pass}}$  is the reburial fraction of the passive SOM (i.e. the fraction of passive SOM re-enters passive SOM);  $a_{\text{slow}}$  is the reburial fraction of the slow SOM;  $\Omega_{\text{p}}$  is the burial coefficient for plant materials entering the passive SOM pool;  $\Omega_{\text{s}}$  is the burial coefficient for plant materials entering the slow SOM pool; and  $C_{\text{slow}}$  is the total carbon stock of the slow SOM pool ( $\text{g C m}^{-2}$ ). Both models assume variable wood N:C ratio.

<b>Model</b>	<b><math>k_{\text{slow}}</math></b>	<b><math>a_{\text{pass}}</math></b>	<b><math>a_{\text{slow}}</math></b>	<b><math>\Omega_{\text{p}}</math></b>	<b><math>\Omega_{\text{s}}</math></b>	<b><math>C_{\text{slow}}</math></b>
baseline	0.067	0.011	0.211	0.002	0.155	4726
priming	0.185	0.011	0.211	0.001	0.163	1624

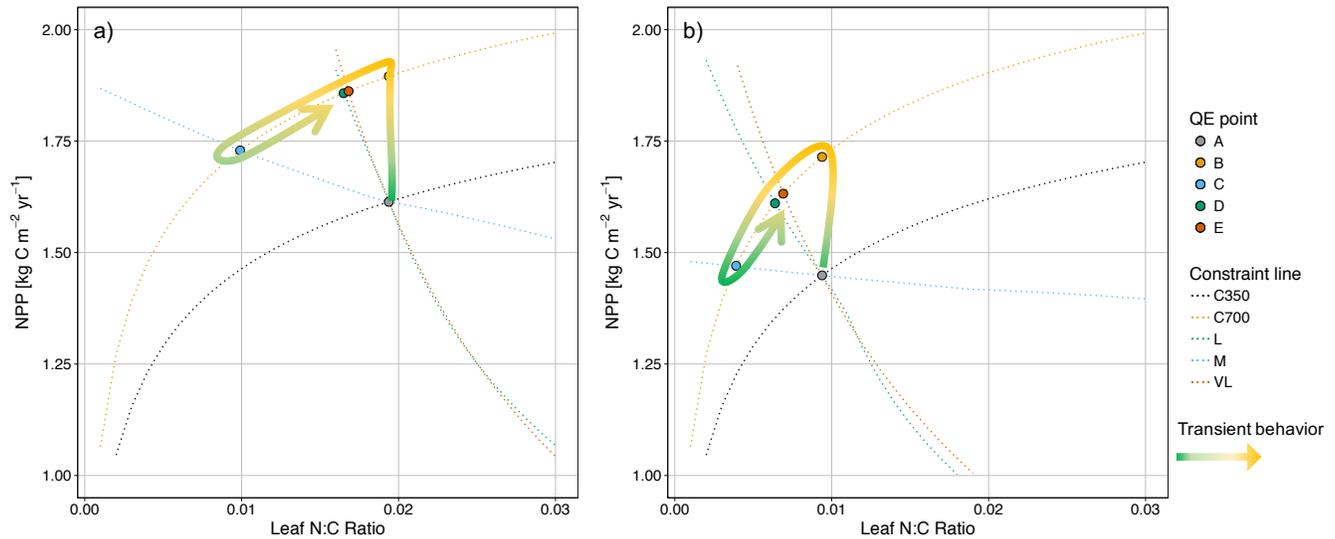

Figure 1: Graphic expression of the baseline quasi-equilibrium framework in understanding plant production response to elevated  $\text{CO}_2$ , based on photosynthetic (C400, C800 refer to  $\text{CO}_2 = 400$  ppm and 800 ppm, respectively) and nitrogen cycling constraints at the medium (M), long (L) and very long (VL) terms, under the assumption of a) variable wood N:C ratio, and b) fixed wood N:C ratio. The photosynthetic constraint is an analytical expression of the Farquhar leaf photosynthesis model that relates leaf chemistry (i.e. NC ratio) with production, simplifying leaf to canopy scaling. The nutrient recycling constraint is an analytical expression of the soil nutrient down-regulation effect on production, assuming soil organic matter structures as in Figure 2. The quasi-equilibrium points at various timescales (A, C, D and E) were calculated by solving for the intersection of the photosynthetic and nutrient cycling constraints through the two-timing approximation. Initially the system is in equilibrium between photosynthetic N demand and soil N supply at  $\text{CO}_2 = 400$  ppm (A). The instantaneous response to doubling of  $\text{CO}_2$  is a sharp increase in production at a constant leaf N concentration (B). Under nutrient limited condition, soil N supply cannot sustain this increase in production over time. A negative feedback moves the quasi-equilibrium point towards point C, where the M-term pools equilibrate with  $\text{eCO}_2$ . The system gradually moves toward point D and E as the L and VL pools equilibrate. The downward slopes of the N recycling constraint curves with increasing leaf N:C ratio is due to the increased proportional loss of mineralized N through leaching as the rate of N cycling increases with leaf N concentration.

20

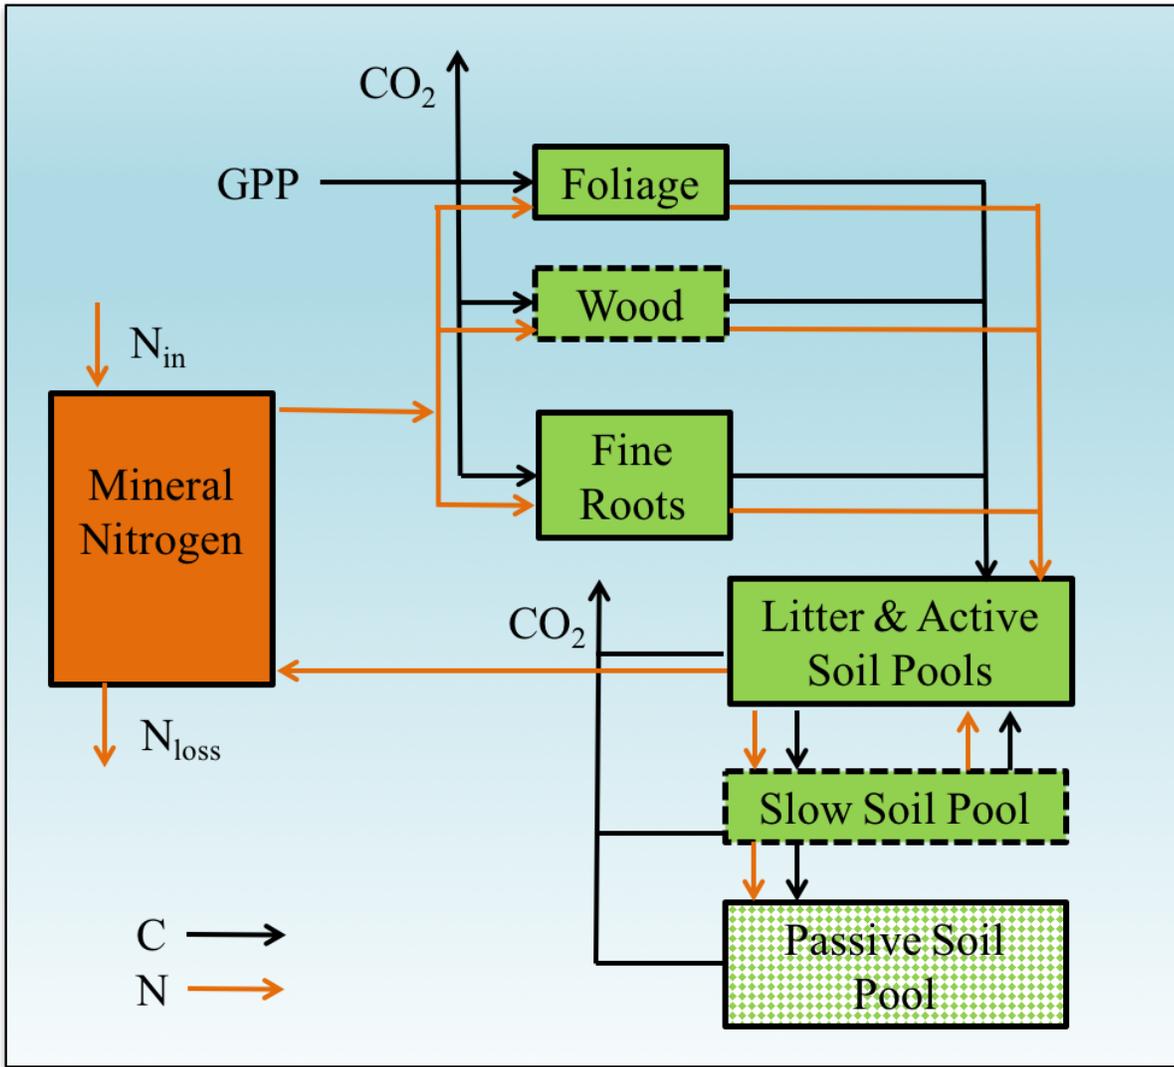

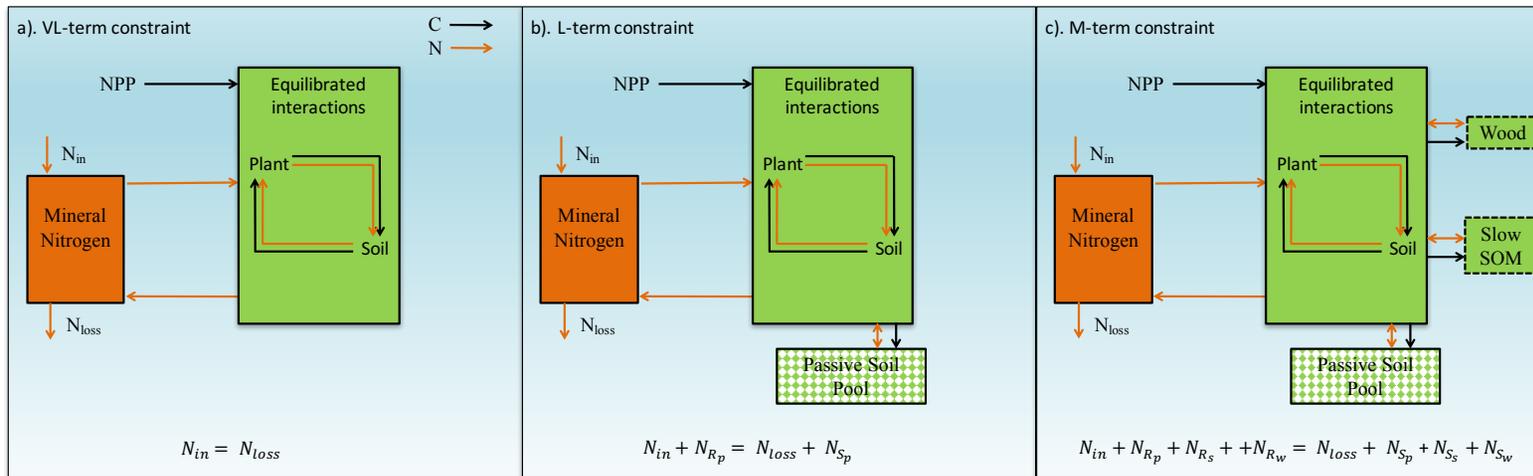

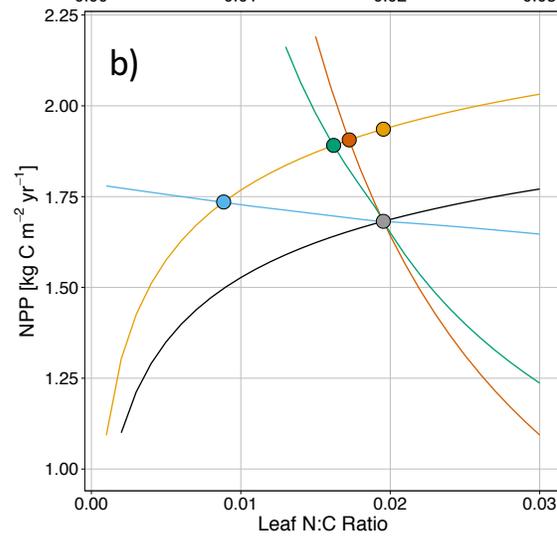

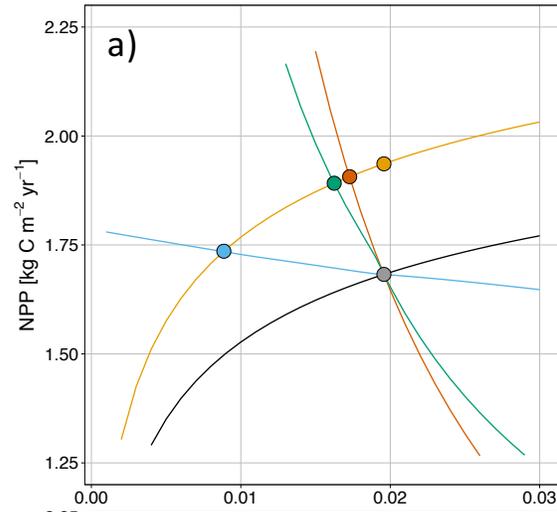

Figure 2: Framework of the Generic Decomposition And Yield (G'DAY) model. Boxes represent pools; arrowed line represent fluxes. Boxes with dotted boundaries are M term recycling pools (wood and slow soil). Box filled with diamonds is the L term recycling pool (passive soil).

5

5 Figure 3: Graphic and mathematical illustrations of the a) very-long (VL) term, b) long (L) term, and c) medium (M) term nutrient recycling constraints. VL-constraint considers all plant-soil processes are in equilibrium, L-constraint considers all but passive SOM are in equilibrium, and M-constraint considers all but woody biomass, slow and passive SOM pools are in equilibrium.

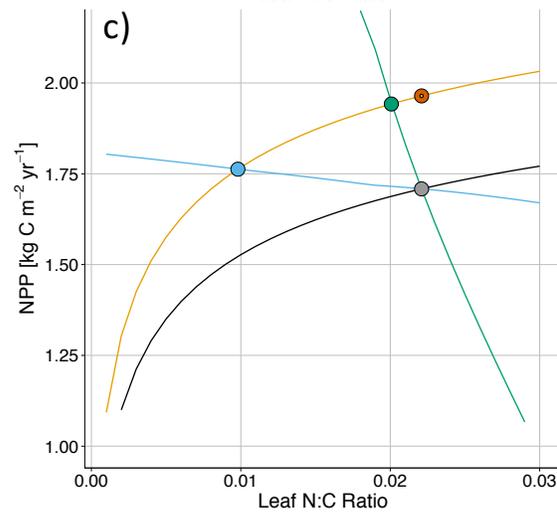

Figure 4: Graphic interpretation of the effect of different nutrient uptake assumptions on plant response to CO<sub>2</sub> fertilization. Functions are: a) plant N uptake as a function of a constant coefficient, with a variable wood N:C ratio assumption, b) plant N uptake as a saturating function of root biomass and also linearly depends upon mineral N pool, and c) plant N uptake as a saturating function of mineral N pool and also linearly depends upon root biomass. Constraint lines C400, C800, M, L and VL refer to photosynthetic constraints at CO<sub>2</sub> = 400 ppm, CO<sub>2</sub> = 800 ppm, medium term, long term, and very-long term nutrient recycling constraints, respectively. Point A is the quasi-equilibrium point at CO<sub>2</sub> = 400 ppm, point B is the instantaneous response point at elevated CO<sub>2</sub>, points C, D, and E are the M, L and VL term equilibrium points at elevated CO<sub>2</sub>. The N uptake coefficient is set to 1 yr<sup>-1</sup>.

10

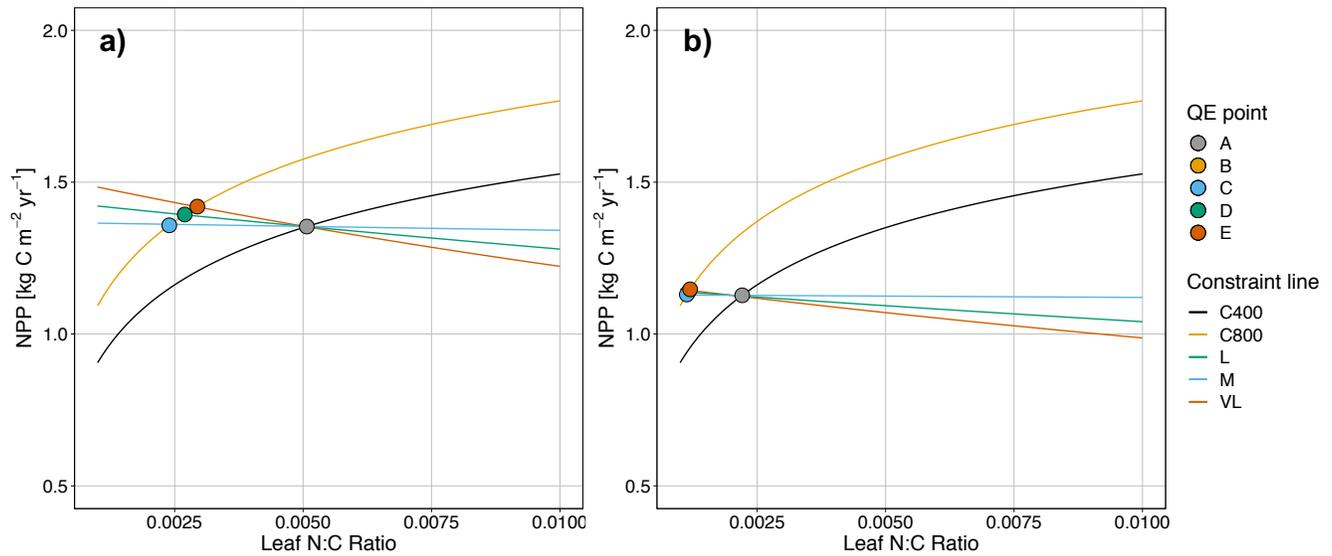

Figure 5: Graphic interpretation of the effect on  $\text{CO}_2$  responses with models incorporating relative demand assumption, based on variable (a) and fixed (b) wood N:C ratio assumptions. Constraint lines C400, C800, M, L and VL refer to photosynthetic constraints at  $\text{CO}_2 = 400$  ppm,  $\text{CO}_2 = 800$  ppm, medium term, long term, and very-long term nutrient recycling constraints, respectively. Point A is the quasi-equilibrium point at  $\text{CO}_2 = 400$  ppm, point B is the instantaneous response point at elevated  $\text{CO}_2$ , points C, D, and E are the M, L and VL term equilibrium points at elevated  $\text{CO}_2$ .

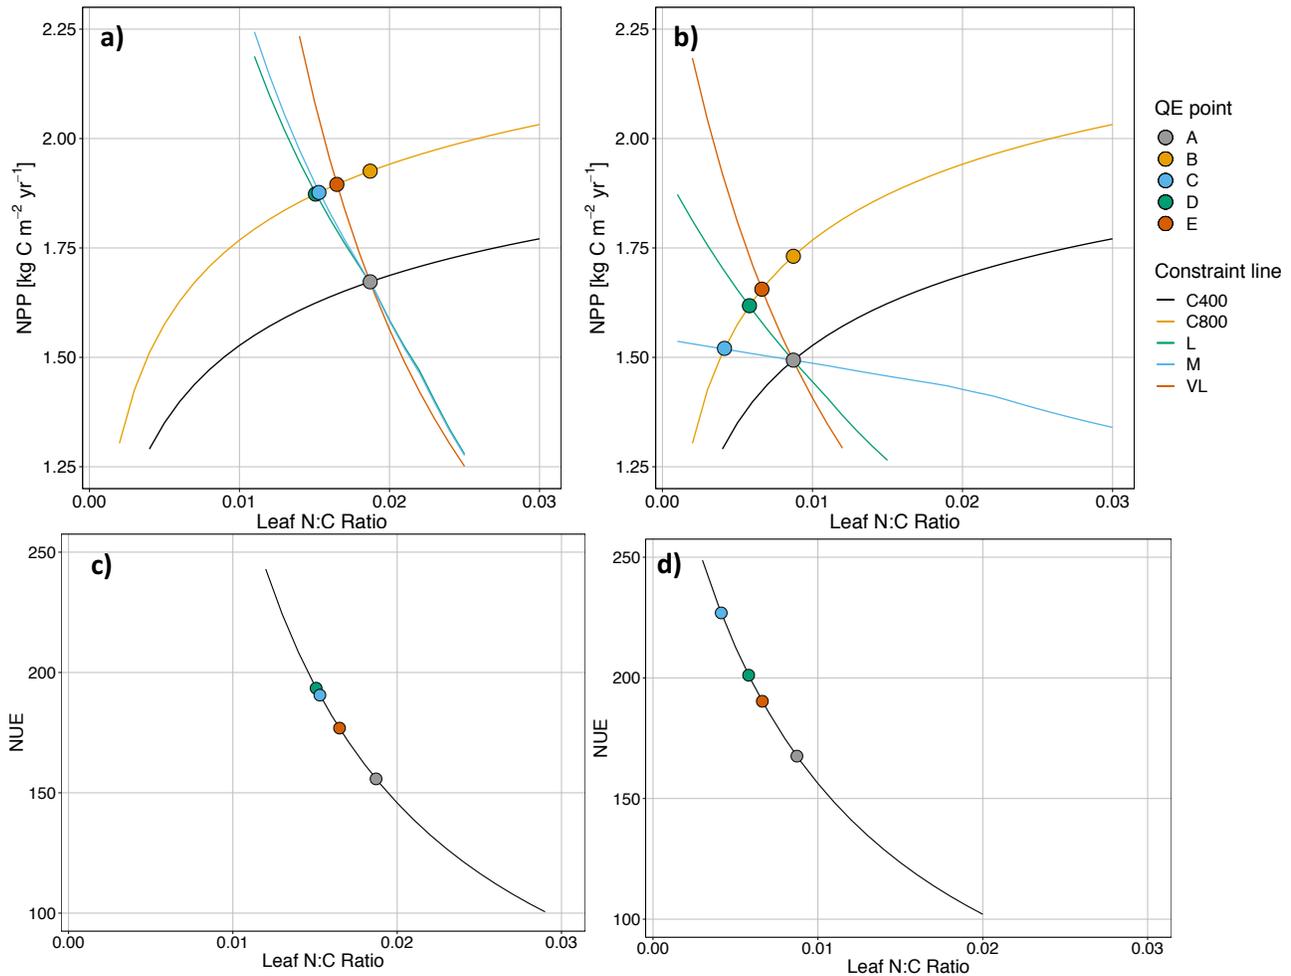

Figure 6: Graphic interpretation of the priming effect on plant net primary production (a and b) and nitrogen use efficiency (c and d) response to CO<sub>2</sub> fertilization, under variable wood N:C ratio (a and c) and fixed wood N:C ratio assumptions (b and d). Constraint lines C400, C800, M, L and VL refer to photosynthetic constraints at CO<sub>2</sub> = 400 ppm, CO<sub>2</sub> = 800 ppm, medium term, long term, and very-long term nutrient recycling constraints, respectively. Point A is the quasi-equilibrium point at CO<sub>2</sub> = 400 ppm, point B is the instantaneous response point at elevated CO<sub>2</sub>, points C, D, and E are the M, L and VL term equilibrium points at elevated CO<sub>2</sub>.

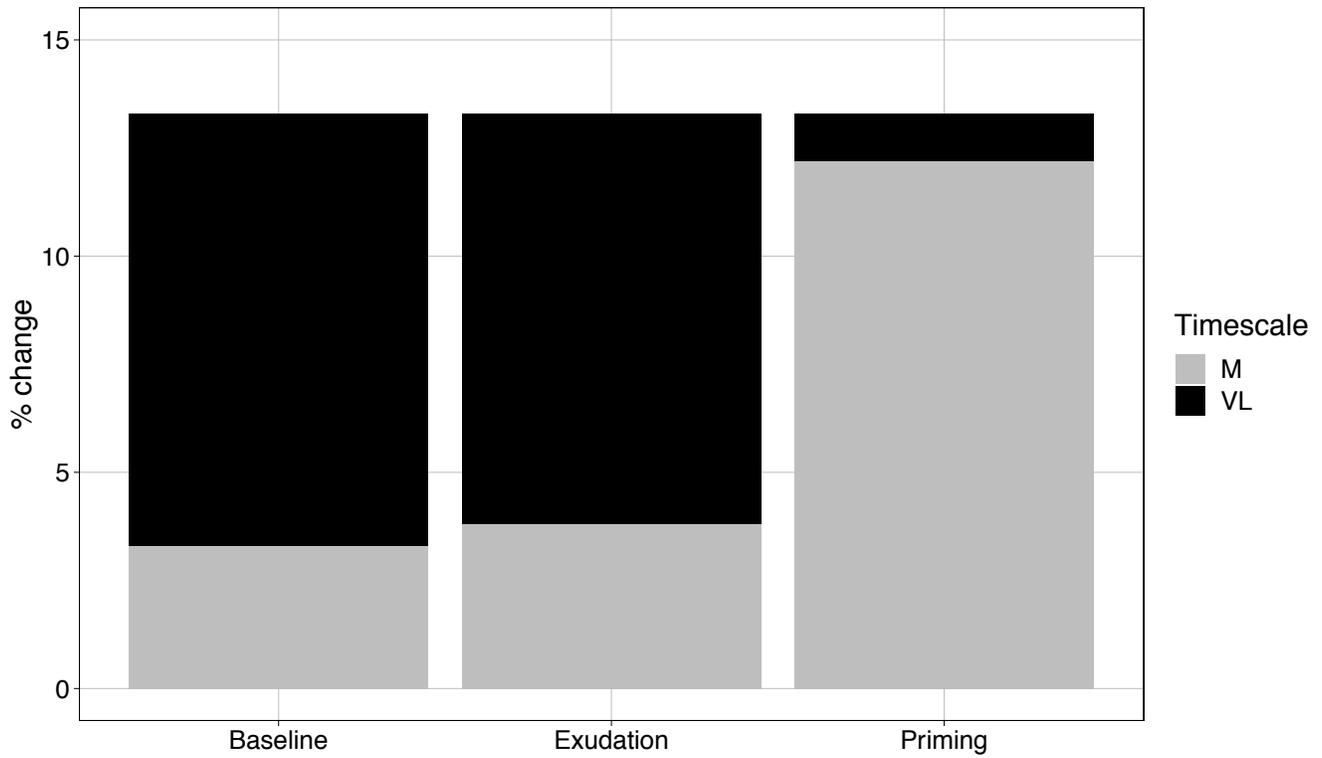

Figure 7: Comparison of medium term (M) and very long term (VL) net primary production response to elevated CO<sub>2</sub> (% change), with models incorporating no priming and exudation effect (baseline), only exudation effect (exudation), and both exudation and priming effect (priming).
