16 **Abstract**

17 Improving global-scale model representations of near-surface soil moisture and  
18 groundwater hydrology is important for accurately simulating terrestrial processes  
19 and predicting climate change effects on water resources. Most existing land surface  
20 models, including the default E3SM Land Model (ELMv0), which we modify here,  
21 routinely employ different formulations for water transport in the vadose and  
22 phreatic zones. Clark et al. (2015) identified a variably saturated Richards equation  
23 flow model as an important capability for improving simulation of coupled soil  
24 moisture and shallow groundwater dynamics. In this work, we developed the  
25 Variably Saturated Flow Model (VSFM) in ELMv1 to unify the treatment of soil  
26 hydrologic processes in the unsaturated and saturated zones. VSFM was tested on  
27 three benchmark problems and results were evaluated against observations and an  
28 existing benchmark model (PFLOTRAN). The ELMv1-VSFM's subsurface drainage  
29 parameter,  $f_d$ , was calibrated to match an observationally-constrained and spatially-  
30 explicit global water table depth (WTD) product. Optimal spatially-explicit  $f_d$  values  
31 were obtained for 79% of global  $1.9^0 \times 2.5^0$  gridcells, while the remaining 21% of  
32 global gridcells had predicted WTD deeper than the observationally-constrained  
33 estimate. Comparison with predictions using the default  $f_d$  value demonstrated that  
34 calibration significantly improved predictions, primarily by allowing much deeper  
35 WTDs. Model evaluation using the International Land Model Benchmarking package  
36 (ILAMB) showed that improvements in WTD predictions did not degrade model skill  
37 for any other metrics. We evaluated the computational performance of the VSFM  
38 model and found that the model is about 30% more expensive than the default ELMv0  
39 with an optimal processor layout. The modular software design of VSFM not only  
40 provides flexibility to configure the model for a range of problem setups, but also  
41 allows building the model independently of the ELM code, thus enabling  
42 straightforward testing of model's physics against other models.

## 43 **1 Introduction**

44 Groundwater, which accounts for 30% of freshwater reserves globally, is a vital  
45 human water resource. It is estimated that groundwater provides 20-30% of global  
46 freshwater withdrawals (Petra, 2009; Zektser and Evertt, 2004), and that irrigation  
47 accounts for ~70% of these withdrawals (Siebert et al., 2010). Climate change is  
48 expected to impact the quality and quantity of groundwater in the future (Alley,  
49 2001). As temporal variability of precipitation and surface water increases in the  
50 future due to climate change, reliance on groundwater as a source of fresh water for  
51 domestic, agriculture, and industrial use is expected to increase (Taylor et al., 2013).

52 Local environmental conditions modulate the impact of rainfall changes on  
53 groundwater resources. For example, high intensity precipitation in humid areas may  
54 lead to a decrease in groundwater recharge (due to higher surface runoff), while arid  
55 regions are expected to see gains in groundwater storage (as infiltrating water  
56 quickly travels deep into the ground before it can be lost to the atmosphere)  
57 (Kundzewicz and Doli, 2009). Although global climate models predict changes in  
58 precipitation over the next century (Marvel et al., 2017), few global models that  
59 participated in the recent Coupled Model Inter-comparison Project (CMIP5; Taylor et  
60 al. (2012)) were able to represent global groundwater dynamics accurately (e.g.  
61 Swenson and Lawrence (2014))

62 Modeling studies have also investigated impacts, at watershed to global scales,  
63 on future groundwater resources associated with land-use (LU) and land-cover (LC)  
64 change (Dams et al., 2008) and ground water pumping (Ferguson and Maxwell, 2012;  
65 Leng et al., 2015). Dams et al. (2008) predicted that LU changes would result in a small  
66 mean decrease in subsurface recharge and large spatial and temporal variability in  
67 groundwater depth for the Kleine Nete basin in Belgium. Ferguson and Maxwell  
68 (2012) concluded that groundwater-fed irrigation impacts on water exchanges with  
69 the atmosphere and groundwater resources can be comparable to those from a 2.5 °C  
70 increase in air temperature for the Little Washita basin in Oklahoma, USA. By  
71 performing global simulations of climate change scenarios using CLM4, Leng et al.  
72 (2015) concluded that the water source (i.e., surface or groundwater) used for

73 irrigation depletes the corresponding water source while increasing the storage of  
74 the other water source. Recently, Leng et al. (2017) showed that irrigation method  
75 (drip, sprinkler, or flood) has impacts on water balances and water use efficiency in  
76 global simulations.

77 Groundwater models are critical for developing understanding of  
78 groundwater systems and predicting impacts of climate (Green et al., 2011). Kollet  
79 and Maxwell (2008) identified critical zones, i.e., regions within the watershed with  
80 water table depths between 1 – 5 m, where the influence of groundwater dynamics  
81 was largest on surface energy budgets. Numerical studies have demonstrated impacts  
82 of groundwater dynamics on several key Earth system processes, including soil  
83 moisture (Chen and Hu, 2004; Liang et al., 2003; Salvucci and Entekhabi, 1995; Yeh  
84 and Eltahir, 2005), runoff generation (Levine and Salvucci, 1999; Maxwell and Miller,  
85 2005; Salvucci and Entekhabi, 1995; Shen et al., 2013), surface energy budgets  
86 (Alkhaier et al., 2012; Niu et al., 2017; Rihani et al., 2010; Soylu et al., 2011), land-  
87 atmosphere interactions (Anyah et al., 2008; Jiang et al., 2009; Leung et al., 2011;  
88 Yuan et al., 2008), vegetation dynamics (Banks et al., 2011; Chen et al., 2010), and soil  
89 biogeochemistry (Lohse et al., 2009; Pacific et al., 2011).

90 Recognizing the importance of groundwater systems on terrestrial processes,  
91 groundwater models of varying complexity have been implemented in land surface  
92 models (LSMs) in recent years. Groundwater models in current LSMs can be classified  
93 into four categories based on their governing equations. Type-1 models assume a  
94 quasi-steady state equilibrium of the soil moisture profile above the water table  
95 (Hilberts et al., 2005; Koster et al., 2000; Walko et al., 2000). Type-2 models use a  $\theta$ -  
96 based (where  $\theta$  is the water volume content) Richards equation in the unsaturated  
97 zone coupled with a lumped unconfined aquifer model in the saturated zone.  
98 Examples of one-dimensional Type-2 models include Liang et al. (2003), Yeh and  
99 Eltahir (2005), Niu et al. (2007), and Zeng and Decker (2009). Examples of quasi  
100 three-dimensional Type-2 models are York et al. (2002); Fan et al. (2007); Miguez-  
101 Macho et al. (2007); and Shen et al. (2013). Type-3 models include a three-  
102 dimensional representation of subsurface flow based on the variably saturated

103 Richards equation (Maxwell and Miller, 2005; Tian et al., 2012). Type-3 models  
104 employ a unified treatment of hydrologic processes in the vadose and phreatic zones  
105 but lump changes associated with water density and unconfined aquifer porosity into  
106 a specific storage term. The fourth class (Type-4) of subsurface flow and reactive  
107 transport models (e.g., PFLOTRAN (Hammond and Lichtner, 2010), TOUGH2 (Pruess  
108 et al., 1999), and STOMP (White and STOMP, 2000)) combine a water equation of  
109 state (EoS) and soil compressibility with the variably saturated Richards equation.  
110 Type-4 models have not been routinely coupled with LSMs to address climate change  
111 relevant research questions. Clark et al. (2015) summarized that most LSMs use  
112 different physics formulations for representing hydrologic processes in saturated and  
113 unsaturated zones. Additionally, Clark et al. (2015) identified incorporation of  
114 variably saturated hydrologic flow models (i.e., Type-3 and Type-4 models) in LSMs  
115 as a key opportunity for future model development that is expected to improve  
116 simulation of coupled soil moisture and shallow groundwater dynamics.

117 The Energy, Exascale, Earth System Model (E3SM) is a new Earth System  
118 Modeling project sponsored by the U.S. Department of Energy (DOE) (E3SM Project,  
119 2018). The E3SM model started from the Community Earth System Model (CESM)  
120 version 1\_3\_beta10 (Oleson, 2013). Specifically, the initial version (v0) of the E3SM  
121 Land Model (ELM) was based off the Community Land Model's (CLM's) tag 4\_5\_71.  
122 ELMv0 uses a Type-2 subsurface hydrology model based on Zeng and Decker (2009).  
123 In this work, we developed in ELMv1 a Type-4 Variably Saturated Flow model (VSFM)  
124 to provide a unified treatment of soil hydrologic processes within the unsaturated  
125 and saturated zones. The VSFM formulation is based on the isothermal, single phase,  
126 variably-saturated (RICHARDS) flow model within PFLOTRAN (Hammond and  
127 Lichtner, 2010). While PFLOTRAN is a massively parallel, three-dimensional  
128 subsurface model, the VSFM is a serial, one-dimensional model that is appropriate for  
129 climate scale applications.

130 This paper is organized into several sections: (1) brief review of the ELMv0  
131 subsurface hydrology model; (2) overview of the VSFM formulation integrated in  
132 ELMv1; (3) application of the new model formulation to three benchmark problems;  
133 (4) development of a subsurface drainage parameterization necessary to predict

134 global water table depths (WTDs) comparable to recently released observationally-  
 135 constrained estimates; (5) comparison of ELMv1 global simulations with the default  
 136 subsurface hydrology model and VSFM against multiple observations using the  
 137 International Land Model Benchmarking package (ILAMB; Hoffman et al. (2017));  
 138 and (6) a summary of major findings.

## 139 **2 Methods**

### 140 **2.1 Current Model Formulation**

141 Water flow in the unsaturated zone is often described by the  $\theta$ -based Richards  
 142 equation:

$$\frac{\partial \theta}{\partial t} = -\nabla \cdot \mathbf{q} - Q \quad (1)$$

143 where  $\theta$  [ $\text{m}^3$  of water  $\text{m}^{-3}$  of soil] is the volumetric soil water content,  $t$  [s] is time,  $\mathbf{q}$   
 144 [ $\text{m s}^{-1}$ ] is the Darcy water flux, and  $Q$  [ $\text{m}^3$  of water  $\text{m}^{-3}$  of soil  $\text{s}^{-1}$ ] is a soil moisture  
 145 sink term. The Darcy flux,  $\vec{q}$ , is given by

$$\mathbf{q} = -K\nabla(\psi + z) \quad (2)$$

147 where  $K$  [ $\text{ms}^{-1}$ ] is the hydraulic conductivity,  $z$  [m] is height above some datum in the  
 148 soil column and  $\psi$  [m] is the soil matric potential. The hydraulic conductivity and soil  
 149 matric potential are modeled as non-linear function of volumetric soil moisture  
 150 following Clapp and Hornberger (1978):

$$K = \Theta_{ice} K_{sat} \left( \frac{\theta}{\theta_{sat}} \right)^{2B+3} \quad (3)$$

$$\psi = \psi_{sat} \left( \frac{\theta}{\theta_{sat}} \right)^{-B} \quad (4)$$

151 where  $K_{sat}$  [ $\text{m s}^{-1}$ ] is saturated hydraulic conductivity,  $\psi_{sat}$  [m] is saturated soil  
 152 matric potential,  $B$  is a linear function of percentage clay and organic content (Oleson,  
 153 2013), and  $\Theta_{ice}$  is the ice impedance factor (Swenson et al., 2012). ELMv0 uses the

155 modified form of Richards equation of Zeng and Decker (2009) that computes Darcy  
156 flux as

$$\mathbf{q} = -K\nabla(\psi + z - C) \quad (5)$$

157 where C is a constant hydraulic potential above the water table,  $z_{\nabla}$ , given as

$$C = \psi_E + z = \psi_{sat} \left( \frac{\theta_E(z)}{\theta_{sat}} \right)^{-B} + z = \psi_{sat} + z_{\nabla} \quad (6)$$

158 where  $\psi_E$  [m] is the equilibrium soil matric potential,  $z$  [m] is height above a  
159 reference datum,  $\theta_E$  [ $\text{m}^3 \text{m}^{-3}$ ] is volumetric soil water content at equilibrium soil  
160 matric potential, and  $z_{\nabla}$  [m] is height of water table above a reference datum. ELMv0  
161 uses a cell-centered finite volume spatial discretization and backward Euler implicit  
162 time integration. By default, ELMv0's vertical discretization of a soil column yields 15  
163 soil layers of exponentially varying soil thicknesses that reach a depth of 42.1 m Only  
164 the first 10 soils layers (or top 3.8 m of each soil column), are hydrologically active,  
165 while thermal processes are resolved for all 15 soils layers. The nonlinear Darcy flux  
166 is linearized using Taylor series expansion and the resulting tridiagonal system of  
167 equations is solved by LU factorization.

168 Flow in the saturated zone is modeled as an unconfined aquifer below the soil  
169 column based on the work of Niu et al. (2007). Exchange of water between the soil  
170 column and unconfined aquifer depends on the location of the water table. When the  
171 water table is below the last hydrologically active soil layer in the column, a recharge  
172 flux from the last soil layer replenishes the unconfined aquifer. A zero-flux boundary  
173 condition is applied to the last hydrologically active soil layer when the water table is  
174 within the soil column. The unconfined aquifer is drained by a flux computed based  
175 on the SIMTOP scheme of Niu et al. (2007) with modifications to account for frozen  
176 soils (Oleson, 2013).

## 177 **2.2 New VSFM Model Formulation**

178 In the VSFM formulation integrated in ELMv1, we use the mass conservative form of  
179 the variably saturated subsurface flow equation (Farthing et al., 2003; Hammond and  
180 Lichtner, 2010; Kees and Miller, 2002):

$$\frac{\partial(\phi s_w \rho)}{\partial t} = -\nabla \cdot (\rho \mathbf{q}) - Q \quad (7)$$

181 where  $\phi$  [m<sup>3</sup> m<sup>-3</sup>] is the soil porosity,  $s_w$  [-] is saturation,  $\rho$  [kg m<sup>-3</sup>] is water density,  
 182  $\mathbf{q}$  [m s<sup>-1</sup>] is the Darcy velocity, and  $Q$  [kg m<sup>-3</sup> s<sup>-1</sup>] is a water sink. We restrict our model  
 183 formulation to a one-dimensional system and the flow velocity is defined by Darcy's  
 184 law:

$$\mathbf{q} = -\frac{k k_r}{\mu} \nabla(P + \rho g z) \quad (8)$$

185 where  $k$  [m<sup>2</sup>] is intrinsic permeability,  $k_r$  [-] is relative permeability,  $\mu$  [Pa s] is  
 186 viscosity of water,  $P$  [Pa] is pressure,  $g$  [m s<sup>-2</sup>] is the acceleration due to gravity, and  
 187  $z$  [m] is elevation above some datum in the soil column.

188 In order to close the system, a constitutive relationship is used to express  
 189 saturation and relative permeability as a function of soil matric pressure. Analytic  
 190 Water Retention Curves (WRCs) are used to model effective saturation ( $s_e$ )

$$s_e = \left( \frac{s_w - s_r}{1 - s_r} \right) \quad (9)$$

191 where  $s_w$  is saturation and  $s_r$  is residual saturation. We have implemented Brooks  
 192 and Corey (1964) (equation 10) and van Genuchten (1980) (equation 11) WRCs:

$$s_e = \begin{cases} \left( \frac{-P_c}{P_c^0} \right)^{-\lambda} & \text{if } P_c < P_c^0 \\ 1 & \text{if } P_c \geq 0 \end{cases} \quad (10)$$

$$s_e = \begin{cases} [1 + (\alpha |P_c|)^n]^{-m} & \text{if } P_c < 0 \\ 1 & \text{if } P_c \geq 0 \end{cases} \quad (11)$$

193 where  $P_c$  [Pa] is the capillary pressure,  $P_c^0$  [Pa] is the air entry pressure, and  $\alpha$  [Pa<sup>-1</sup>]  
 194 is inverse of the air entry pressure,  $\lambda$  [-] is the exponent in the Brooks and Corey  
 195 parameterization, and  $n$  [-] and  $m$  [-] are van Genuchten parameters. The capillary  
 196 pressure is computed as  $P_c = P - P_{ref}$  where  $P_{ref}$  is  $P_c^0$  for Brooks and Corey WRC  
 197 and typically the atmospheric pressure (=101,325 [Pa]) is used for van Genuchten  
 198 WRC. In addition, a smooth approximation of equation (10) and (11) was developed  
 199 to facilitate convergence of the nonlinear solver (Appendix A). Relative soil  
 200 permeability was modeled using the Mualem (1976) formulation:

$$\kappa_r(s_e) = \begin{cases} s_e^{0.5} \left[ 1 - \left( 1 - s_e^{1/m} \right)^m \right] & \text{if } P < P_{ref} \\ 1 & \text{if } P \geq P_{ref} \end{cases} \quad (12)$$

201 where  $m = 1 - 1/n$ . Lastly, we used an EoS for water density,  $\rho$ , that is a nonlinear  
 202 function of liquid pressure,  $P$ , and liquid temperature,  $T$ , given by Tanaka et al.  
 203 (2001):

$$\rho(P, T) = \left[ 1 + (k_0 + k_1 T + k_2 T^2)(P - P_{ref}) \right] a_5 \left[ 1 - \frac{(T + a_1)^2 (T + a_2)}{a_3 (T + a_4)} \right] \quad (13)$$

204 where

$$k_0 = 50.74 \times 10^{-11} [\text{Pa}^{-1}]$$

$$k_1 = -0.326 \times 10^{-11} [\text{Pa}^{-1}\text{C}^{-1}]$$

$$k_2 = 0.00416 \times 10^{-11} [\text{Pa}^{-1}\text{C}^2]$$

$$a_1 = -3.983035 [\text{C}]$$

$$a_2 = 301.797 [\text{C}]$$

$$a_3 = 522558.9 [\text{C}^{-2}]$$

$$a_4 = 69.34881 [\text{C}]$$

$$a_5 = 999.974950 [\text{kg m}^{-3}]$$

205 The sink of water due to transpiration from a given plant functional type (PFT)  
 206 is vertically distributed over the soil column based on area and root fractions of the  
 207 PFT. The top soil layer has an additional flux associated with balance of infiltration  
 208 and soil evaporation. The subsurface drainage flux is applied proportionally to all soil  
 209 layers below the water table. Details on the computation of water sinks are given in  
 210 Oleson (2013) Unlike the default subsurface hydrology model, the VFSM is applied  
 211 over the full soil depth (in the default model, 15 soil layers). The VFSM model replaces  
 212 both the  $\theta$ -based Richards equation and the unconfined aquifer of the default model  
 213 and uses a zero-flux lower boundary condition. In the VFSM model, water table depth  
 214 is diagnosed based on the vertical soil liquid pressure profile. Like the default model,  
 215 drainage flux is computed based on the modified SIMTOP approach and is vertically  
 216 distributed over the soil layers below the water table.

217 **2.2.1 Discrete Equations**

218 We use a cell-centered finite volume discretization to decompose the spatial  
 219 domain,  $\Omega$ , into  $N$  non-overlapping control volumes,  $\Omega_n$ , such that  $\Omega = \cup_{n=1}^N \Omega_i$  and  $\Gamma_n$   
 220 represents the boundary of the  $n$ -th control volume. Applying a finite volume integral  
 221 to equation (7) and the divergence theorem yields

$$\frac{\partial}{\partial t} \int_{\Omega_n} (\phi s_w \rho) dV = - \int_{\Gamma_n} (\rho \mathbf{q}) \cdot d\mathbf{A} - \int_{\Omega_n} Q dV \quad (14)$$

222 The discretized form of the left hand side term and first term on the right hand side  
 223 of equation (14) are approximated as:  
 224

$$\frac{\partial}{\partial t} \int_{\Omega_n} (\phi s_w \rho) dV \approx \left( \frac{d}{dt} (\phi s_w \rho) \right) V_n \quad (15)$$

$$\int_{\Gamma_n} (\rho \mathbf{q}) \cdot d\mathbf{A} \approx \sum_{n'} (\rho \mathbf{q})_{nn'} \cdot \mathbf{A}_{nn'} \quad (16)$$

225 where  $\mathbf{A}_{nn'}$  [m<sup>2</sup>] is the common face area between the  $n$ -th and  $n'$ -th control volumes.  
 226 After substituting equations (15) and (16) in equation (14), the resulting ordinary  
 227 differential equation for the variably saturated flow model is

$$\left( \frac{d}{dt} (\phi s_w \rho) \right) V_n = - \sum_{n'} (\rho \mathbf{q})_{nn'} \cdot \mathbf{A}_{nn'} - Q_n V_n \quad (17)$$

228 We perform temporal integration of equation (17) using the backward-Euler scheme:

$$\left( \frac{(\phi s_w \rho)_n^{t+1} - (\phi s_w \rho)_n^t}{\Delta t} \right) V_n = - \sum_{n'} (\rho \mathbf{q})_{nn'}^{t+1} \cdot \mathbf{A}_{nn'} - Q_n^{t+1} V_n \quad (18)$$

229 Rearranging terms of equation (18) results in a nonlinear equation for the unknown  
 230 pressure at timestep  $t + 1$  as

$$\left( \frac{(\phi s_w \rho)_n^{t+1} - (\phi s_w \rho)_n^t}{\Delta t} \right) V_n + \sum_{n'} (\rho \mathbf{q})_{nn'}^{t+1} \cdot \mathbf{A}_{nn'} + Q_n^{t+1} V_n = 0 \quad (19)$$

231 In this work, we find the solution to the nonlinear system of equations given by  
 232 equation (19) using Newton's method via the Scalable Nonlinear Equations Solver  
 233 (SNES) within the Portable, Extensible Toolkit for Scientific Computing (PETSc)

234 library (Balay et al., 2016). PETSc provides a suite of data structures and routines for  
235 the scalable solution of partial differential equations. VSFM uses the composable data  
236 management (DMComposite) provided by PETSc (Brown et al., 2012), which enables  
237 the potential future application of the model to solve tightly coupled multi-  
238 component, multi-physics processes as discussed in section 3.4. A Smooth  
239 approximation of the Brooks and Corey (1964) (SBC) water retention curve was  
240 developed to facilitate faster convergence of the nonlinear solver (Appendix A).  
241 ELMv0 code for subsurface hydrologic processes only supports two vertical mesh  
242 configurations and a single set of boundary and source-sink conditions. The  
243 monolithic ELMv0 code does not allow for building of code for individual process  
244 representations independent of ELMv0 code, thus precluding easy testing of the  
245 model against analytical solutions or simulation results from other models. The  
246 modular software design of VSFM overcomes ELMv0's software limitation by  
247 allowing VSFM code to be built independently of the ELM code. This flexibility of  
248 VSFM's build system allows for testing of the VSFM physics in isolation without any  
249 influence from the rest of ELM's physics formulations. Additionally, VSFM can be  
250 easily configured for a wide range of benchmark problems with different spatial grid  
251 resolutions, material properties, boundary conditions, and source-sink forcings.

### 252 **2.3 VSFM single-column evaluation**

253 We tested the VSFM with three idealized 1-dimensional test problems. First, the  
254 widely studied problem for 1D Richards equation of infiltration in dry soil by Celia et  
255 al. (1990) was used. The problem setup consists of a 1.0 m long soil column with a  
256 uniform initial pressure of  $-10.0$  m ( $= 3535.5$  Pa). Time invariant boundary  
257 conditions applied at the top and bottom of soil column are  $-0.75$  m ( $= 93989.1$  Pa)  
258 and  $-10.0$  m ( $= 3535.5$  Pa), respectively. The soil properties for this test are given in  
259 Table 1. A vertical discretization of 0.01 m is used in this simulation.

260 Second, we simulated transient one-dimensional vertical infiltration in a two-  
261 layered soil system as described in Srivastava and Yeh (1991). The domain consisted  
262 of a 2 m tall soil column divided equally in two soil types. Except for soil intrinsic  
263 permeability, all other soil properties of the two soil types are the same. The bottom

264 soil is 10 times less permeable than the top (Table1). Unlike Srivastava and Yeh  
265 (1991), who used exponential functions of soil liquid pressure to compute hydraulic  
266 conductivity and soil saturation, we used Mualem (1976) and van Genuchten (1980)  
267 constitutive relationships. Since our choice of constitutive relationships for this setup  
268 resulted in absence of an analytical solution, we compared VSFM simulations against  
269 PFLOTRAN results. The domain was discretized in 200 control volumes of equal soil  
270 thickness. Two scenarios, wetting and drying, were modeled to test the robustness of  
271 the VSFM solver robustness. Initial conditions for each scenario included a time  
272 invariant boundary condition of 0 m (=  $1.01325 \times 10^5$  Pa) for the lowest control  
273 volume and a constant flux of  $0.9 \text{ cm hr}^{-1}$  and  $0.1 \text{ cm hr}^{-1}$  at the soil surface for wetting  
274 and drying scenarios, respectively.

275 Third, we compare VSFM and PFLOTRAN predictions for soil under variably  
276 saturated conditions. The 1-dimensional 1 m deep soil column was discretized in 100  
277 equal thickness control volumes. A hydrostatic initial condition was applied such that  
278 water table is 0.5 m below the soil surface. A time invariant flux of  $2.5 \times 10^{-5} \text{ m s}^{-1}$  is  
279 applied at the surface, while the lowest control volume has a boundary condition  
280 corresponding to the initial pressure value at the lowest soil layer. The soil properties  
281 used in this test are the same as those used in the first evaluation.

## 282 **2.4 Global Simulations and groundwater depth analysis**

283 We performed global simulations with ELMv1-VSFM at a spatial resolution of  
284  $1.9^{\circ}$  (latitude)  $\times$   $2.5^{\circ}$  (longitude) with a 30 [min] time-step for 200 years, including a  
285 180 year spinup and the last 20 years for analysis. The simulations were driven by  
286 CRUNCEP meteorological forcing from 1991-2010 (Piao et al., 2012) and configured  
287 to use prescribed satellite phenology.

288 For evaluation and calibration, we used the Fan et al. (2013) global  $\sim 1$  km  
289 horizontal resolution WTD dataset (hereafter F2013 dataset), which is based on a  
290 combination of observations and hydrologic modeling. We aggregated the dataset to  
291 the ELMv1-VSFM spatial resolution. ELM-VSFM's default vertical soil discretization  
292 uses 15 soil layers to a depth of  $\sim 42$  m, with an exponentially varying soil thickness.  
293 However,  $\sim 13\%$  of F2013 land gridcells have a water table deeper than 42 m. We

294 therefore modified ELMv1-VSFM to extend the soil column to a depth of 150 m with  
295 59 soil layers; the first nine soil layer thicknesses were the same as described in  
296 Oleson (2013) and the remaining layers (10-59) were set to a thickness of 3 m.

## 297 **2.5 Estimation of the subsurface drainage parameterization**

298 In the VSFM formulation, the dominant control on long-term GW depth is the  
299 subsurface drainage flux,  $q_d$  [ $\text{kg m}^{-2} \text{s}^{-1}$ ], which is calculated based on water table  
300 depth,  $z_v$ [m], (Niu et al. (2005)):

$$q_d = q_{d,max} \exp(-f_d z_v) \quad (20)$$

301 where  $q_{d,max}$  [ $\text{kg m}^{-2} \text{s}^{-1}$ ] is the maximum drainage flux that depends on gridcell slope  
302 and  $f_d$  [ $\text{m}^{-1}$ ] is an empirically-derived parameter. The subsurface drainage flux  
303 formulation of Niu et al. (2005) is similar to the TOPMODEL formulation (Beven and  
304 Kirkby, 1979) and assumes the water table is parallel to the soil surface. While  
305 Sivapalan et al. (1987) derived  $q_{d,max}$  as a function of lateral hydraulic anisotropy,  
306 hydraulic conductivity, topographic index, and decay factor controlling vertical  
307 saturated hydraulic conductivity, Niu et al. (2005) defined  $q_{d,max}$  as a single  
308 calibration parameter. ELMv0 uses  $f_d = 2.5 \text{ m}^{-1}$  as a global constant and estimates  
309 maximum drainage flux when WTD is at the surface as  $q_{d,max} = 10 \sin(\beta) \text{ kg m}^{-2} \text{ s}^{-1}$ ,  
310 where  $\beta$  [radians] is mean grid cell topographic slope. Of the two parameters,  $f_d$  and  
311  $q_{d,max}$ , available for model calibration, we choose to calibrate  $f_d$  because the  
312 uncertainty analysis by Hou et al. (2012) identified it as the most significant  
313 hydrologic parameter in CLM4. To improve on the  $f_d$  parameter values, we  
314 performed an ensemble of global simulations with  $f_d$  values of 0.1, 0.2, 0.5, 1.0, 2.5,  
315 5.0, 10.0, and 20  $\text{m}^{-1}$ . Each ensemble simulation was run for 200 years to ensure an  
316 equilibrium solution, and the last 20 years were used for analysis. A non-linear  
317 functional relationship between  $f_d$  and  $WTD$  was developed for each gridcell and  
318 then the F2013 dataset was used to estimate an optimal  $f_d$  for each gridcell.

## 319 **2.6 Global ELM-VSFM evaluation**

320 With the optimal  $f_d$  values, we ran a ELM-VSFM simulation using the protocol  
321 described above. We then used the International Land Model Benchmarking package

322 (ILAMB) to evaluate the ELMv1-VSFM predictions of surface energy budget, total  
323 water storage anomalies (TWSA), and river discharge (Collier et al., 2018; Hoffman et  
324 al., 2017). ILAMB evaluates model prediction bias, RMSE, and seasonal and diurnal  
325 phasing against multiple observations of energy, water, and carbon cycles at in-situ,  
326 regional, and global scales. Since ELM-VSFM simulations in this study did not include  
327 an active carbon cycle, we used the following ILAMB benchmarks for water and  
328 energy cycles: (i) latent and surface energy fluxes using site-level measurements from  
329 FLUXNET (Lasslop et al., 2010) and globally from FLUXNET-MTE (Jung et al., 2009));  
330 (ii) terrestrial water storage anomaly (TWSA) from the Gravity Recovery And Climate  
331 Experiment (GRACE) observations (Kim et al., 2009); and (iii) stream flow for the 50  
332 largest global river basins (Dai and Trenberth, 2002). We applied ILAMB benchmarks  
333 for ELMv1-VSFM simulations with default and calibrated  $f_d$  to ensure improvements  
334 in WTD predictions did not degrade model skill for other processes.

### 335 **3 Results and discussion**

#### 336 **3.1 VSFM single-column evaluation**

337 For the 1D Richards equation infiltration in dry soil comparison, we evaluated  
338 the solutions at 24-hr against those published by Celia et al. (1990) (Figure 1). The  
339 VSFM solver accurately represented the sharp wetting front over time, where soil  
340 hydraulic properties change dramatically due to non-linearity in the soil water  
341 retention curve.

342 For the model evaluation of infiltration and drying in layered soil, the results of  
343 the VSFM and PFLOTRAN are essentially identical. In both models and scenarios, the  
344 higher permeability top soil responds rapidly to changes in the top boundary  
345 condition and the wetting and drying fronts progressively travel through the less  
346 permeable soil layer until soil liquid pressure in the entire column reaches a new  
347 steady state by about 100 h (Figure 2).

348 We also evaluated the VSFM predicted water table dynamics against PFLOTRAN  
349 predictions from an initial condition of saturated soil below 0.5 m depth. The  
350 simulated water table rises to 0.3 m depth by 1 day and reaches the surface by 2 days,

351 and the VSFM and PFLOTRAN predictions are essentially identical Figure 3. Soil  
352 properties, spatial discretization, and timestep used for the three single-column  
353 problems are summarized in Table 1 These three evaluation simulations demonstrate  
354 the VSFM accurately represents soil moisture dynamics under conditions relevant to  
355 ESM-scale prediction.

### 356 **3.2 Subsurface drainage parameterization estimation**

357 The simulated nonlinear WTD- $f_d$  relationship is a result of the subsurface  
358 drainage parameterization flux given by equation (20) (Figure 4(a) and (b)). For  
359  $0.1 \leq f_d \leq 1$ , the slope of the WTD- $f_d$  relationship for all gridcells is log-log linear  
360 with a slope of  $-1.0 \pm 0.1$ . The log-log linear relationship breaks down for  $f_d > 1$ ,  
361 where the drainage flux becomes much smaller than infiltration and  
362 evapotranspiration (Figure 4(c) and (d)). Thus, at larger  $f_d$ , the steady state  $z_v$   
363 becomes independent of  $f_d$  and is determined by the balance of infiltration and  
364 evapotranspiration.

365 For 79% of the global gridcells, the ensemble range of simulated WTD spanned  
366 the F2013 dataset. The optimal value of  $f_d$  for each of these gridcells was obtained by  
367 linear interpolation in the log-log space (e.g., Figure 4 (a)). For the remaining 21% of  
368 gridcells where the shallowest simulated WTD across the range of  $f_d$  was deeper than  
369 that in the F2013 dataset, the optimal  $f_d$  value was chosen as the one that resulted in  
370 the lowest absolute WTD error (e.g., Figure 4 (b)). At large  $f_d$  values, the drainage flux  
371 has negligible effects on WTD, yet simulated WTD is not sufficiently shallow to match  
372 the F2013 observations, which indicates that either evapotranspiration is too large  
373 or infiltration is too small. There was no difference in the mean percentage of sand  
374 and clay content between grids cells with and without an optimal  $f_d$  value. The  
375 optimal  $f_d$  has a global average of  $1.60 \text{ m}^{-1} \pm 2.68 \text{ m}^{-1}$  and 72% of global gridcells have  
376 an optimal  $f_d$  value lower than the global average (Figure 5).

### 377 **3.3 Global simulation evaluation**

378 The ELMv1-VSFM predictions are much closer to the F2013 dataset (Figure 6a)  
379 using optimal globally-distributed  $f_d$  values (Figure 6c) compared to the default  $f_d$

380 value (Figure 6b). The significant reduction in WTD bias (model – observation) is  
381 mostly due to improvement in the model’s ability to accurately predict deep WTD  
382 using optimal  $f_d$  values. In the simulation using optimal globally-distributed  $f_d$   
383 values, all gridcells with WTD bias > 3.7 m were those for which an optimal  $f_d$  was  
384 not found. The mean global bias, RMSE, and  $R^2$  values improved in the new ELMv1-  
385 VSFM compared to the default model (Table 2). The 79% of global grid cells for which  
386 an optimal  $f_d$  value was estimated had significantly better water table prediction  
387 with a bias, RMSE, and  $R^2$  of -0.04 m, 0.67 m, and 0.99, respectively, as compared to  
388 the remaining 21% of global gridcells that had a bias, RMSE, and  $R^2$  of -9.82 m, 18.08  
389 m, and 0.31, respectively. The simulated annual WTD range, which we define to be  
390 the difference between maximum and minimum WTD in a year, has a spatial mean  
391 and standard deviation of 0.32 m and 0.58 m, respectively, using optimal  $f_d$  values  
392 (Figure 7 (a)). The annual WTD range decreased by 0.24 m for the 79% of the grid  
393 cells for which an optimal  $f_d$  value was estimated (Figure 7 (b)).

394 Globally-averaged WTD in ELMv1-VSFM simulations with default  $f_d$  and  
395 optimal  $f_d$  values were 10.5 m and 20.1 m, respectively. Accurate prediction of deep  
396 WTD in the simulation with optimal  $f_d$  caused very small differences in near-surface  
397 soil moisture (Figure 8). The 79% of grid cells with an optimal  $f_d$  value had deeper  
398 globally-averaged WTDs than when using the default  $f_d$  value (24.3 m vs. 8.6 m). For  
399 these 79% of grid cells, the WTD was originally deep enough to not impact near-  
400 surface conditions (Kollet and Maxwell, 2008); therefore, further lowering of WTD  
401 led to negligible changes in near-surface hydrological conditions.

402 The International Land Model Benchmarking (ILAMB) package (Hoffman et al.,  
403 2017) provides a comprehensive evaluation of predictions of carbon cycle states and  
404 fluxes, hydrology, surface energy budgets, and functional relationships by  
405 comparison to a wide range of observations. We used ILAMB to evaluate the  
406 hydrologic and surface energy budget predictions from the new ELMv1-VSFM model  
407 (Table 3). Optimal  $f_d$  values had inconsequential impacts on simulated surface  
408 energy fluxes at site-level and global scales. Optimal  $f_d$  values led to improvement in  
409 prediction of deep WTD (with a mean value of 24.3 m) for grid cells that had an  
410 average WTD of 8.7 m in the simulation using default  $f_d$  values. Thus, negligible

411 differences in surface energy fluxes between the two simulations are consistent with  
412 the findings of Kollet and Maxwell (2008), who identified decoupling of groundwater  
413 dynamics and surface processes at a WTD of  $\sim 10$  m. There were slight changes in bias  
414 and RMSE for predicted TWSA, but the ILAMB score remained unchanged. The TWSA  
415 amplitude is lower for the simulation with optimal  $f_d$  values, consistent with the  
416 associated decrease in annual WTD range. ELM's skill in simulating runoff for the 50  
417 largest global watersheds remained unchanged. Two additional 10-years long  
418 simulations were performed to investigate the sensitivity of VSFM simulated WTD to  
419 spatial and temporal discretization. Results show that simulated WTD is insensitive  
420 to temporal discretization, and has small sensitivity to vertical spatial resolution. See  
421 supplementary material for details regarding setup and analysis of results from the  
422 two additional simulations.

423 Finally, we evaluated the computational costs of implementing VSFM in ELM  
424 and compared them to the default model. We performed 5-year long simulations for  
425 default and VSFM using 96, 192, 384, 768, and 1536 cores on the Edison  
426 supercomputer at the National Energy Research Scientific Computing Center. Using  
427 an optimal processor layout, we found that ELMv1-VSFM is  $\sim 30\%$  more expensive  
428 than the default ELMv1 model (Supplementary material Fig S 1). We note that the  
429 relative computational cost of the land model in a fully coupled global model  
430 simulation is generally very low. Dennis et al. (2012) reported computational cost of  
431 the land model to be less than 1% in ultra-high-resolution CESM simulations. We  
432 therefore believe that the additional benefits associated with the VSFM formulation  
433 are well justified by this modest increase in computational cost. In particular, VSFM  
434 allows a greater variety of mesh configurations and boundary conditions, and can  
435 accurately simulate WTD for the  $\sim 13\%$  of global grid cells that have a water table  
436 deeper than 42 [m] (Fan et al. (2013).

### 437 **3.4 Caveats and Future Work**

438 The significant improvement in WTD prediction using optimal  $f_d$  values  
439 demonstrates VSFM's capabilities to model hydrologic processes using a unified  
440 physics formulation for unsaturated-saturated zones. However, several caveats

441 remain due to uncertainties in model structure, model parameterizations, and climate  
442 forcing data.

443 In this study, we assumed a spatially homogeneous depth to bedrock (DTB) of  
444 150 m. Recently, Brunke et al. (2016) incorporated a global ~1 km dataset of soil  
445 thickness and sedimentary deposits (Pelletier et al., 2016) in CLM4.5 to study the  
446 impacts of soil thickness spatial heterogeneity on simulated hydrological and thermal  
447 processes. While inclusion of heterogeneous DTB in CLM4.5 added more realism to  
448 the simulation setup, no significant changes in simulated hydrologic and energy  
449 fluxes were reported by Brunke et al. (2016). Presently, work is ongoing in the E3SM  
450 project to include variable DTB within ELM and future simulations will examine the  
451 impact of those changes on VSFM's prediction of WTD. Our use of the 'satellite  
452 phenology' mode, which prescribes transient LAI profiles for each plant functional  
453 type in the gridcell, ignored the likely influence of water cycle dynamics and nutrient  
454 constraints on the C cycle (Ghimire et al., 2016; Zhu et al., 2016). Estimation of soil  
455 hydraulic properties based on soil texture data is critical for accurate LSM predictions  
456 (Gutmann and Small, 2005) and this study does not account for uncertainty in soil  
457 hydraulic properties.

458 Lateral water redistribution impacts soil moisture dynamics (Bernhardt et al.,  
459 2012), biogeochemical processes in the root zone (Grant et al., 2015), distribution of  
460 vegetation structure (Hwang et al., 2012), and land-atmosphere interactions (Chen  
461 and Kumar, 2001; Rihani et al., 2010). The ELMv1-VSFM developed in this study does  
462 not include lateral water redistribution between soil columns and only simulates  
463 vertical water transport. Lateral subsurface processes can be included in LSMs via a  
464 range of numerical discretization approaches of varying complexity, e.g., adding  
465 lateral water as source/sink terms in the 1D model, implementing an operator split  
466 approach to solve vertical and lateral processes in a non-iterative approach (Ji et al.,  
467 2017), or solving a fully coupled 3D model (Bisht et al., 2017; Bisht et al., 2018; Kollet  
468 and Maxwell, 2008). Additionally, lateral transport of water can be implemented in  
469 LSMs at a subgrid level (Milly et al., 2014) or grid cell level (Miguez-Macho et al.,  
470 2007). The current implementation of VSFM is such that each processor solves the  
471 variably saturated Richards equation for all independent soil columns as one single

472 problem. Thus, extension of VSFM to solve the tightly coupled 3D Richards equation  
473 on each processor locally while accounting for lateral transport of water within grid  
474 cells and among grid cells is straightforward. The current VSFM implementation can  
475 also be easily extended to account for subsurface transport of water among grid cells  
476 that are distributed across multiple processors by modeling lateral flow as  
477 source/sink terms in the 1D model. Tradeoffs between approaches to represent  
478 lateral processes and computational costs need to be carefully studied before  
479 developing quasi or fully three-dimensional land surface models (Clark et al., 2015).

480 Transport of water across multiple components of the Soil Plant Atmosphere  
481 Continuum (SPAC) has been identified as a critical process in understanding the  
482 impact of climate warming on the global carbon cycle (McDowell and Allen, 2015).  
483 Several SPAC models have been developed by the ecohydrology community and  
484 applied to study site-level processes (Amenu and Kumar, 2008; Bohrer et al., 2005;  
485 Manoli et al., 2014; Sperry et al., 1998), yet implementation of SPAC models in global  
486 LSMs is limited (Clark et al., 2015). Similarly, current generation LSMs routinely  
487 ignore advective heat transport within the subsurface, which has been shown to be  
488 important in high-latitude environments by multiple field and modeling studies  
489 (Bense et al., 2012; Frampton et al., 2011; Grant et al., 2017; Kane et al., 2001). The  
490 use of PETSc's DMComposite in VSFM provides flexibility for solving a tightly coupled  
491 multi-component problem (e.g., transport of water through the soil-plant continuum)  
492 and multi-physics problem (e.g., fully coupled conservation of mass and energy  
493 equations in the subsurface). DMComposite allows for an easy assembly of a tightly  
494 coupled multi-physics problem from individual physics formulations (Brown et al.,  
495 2012).

#### 496 **4 Summary and Conclusion**

497 Starting from the climate-scale land model ELMv0, we incorporated a unified  
498 physics formulation to represent soil moisture and groundwater dynamics that are  
499 solved using PETSc. Application of VSFM to three benchmark problems  
500 demonstrated its robustness to simulated subsurface hydrologic processes in

501 coupled unsaturated and saturated zones. Ensemble global simulations at  $1.9^0 \times 2.5^0$   
 502 were performed for 200 years to obtain spatially heterogeneous estimates of the  
 503 subsurface drainage parameter,  $f_d$ , that minimized mismatches between predicted  
 504 and observed WTDs. In order to simulate the deepest water table reported in the Fan  
 505 et al. (2013) dataset, we used 59 vertical soil layers that reached a depth of 150 m.

506 An optimal  $f_d$  was obtained for 79% of the grids cells in the domain. For the  
 507 remaining 21% of grid cells, simulated WTD always remained deeper than observed.  
 508 Calibration of  $f_d$  significantly improved global WTD prediction by reducing bias and  
 509 RMSE and increasing  $R^2$ . Grids without an optimal  $f_d$  were the largest contributor of  
 510 error in WTD predication. ILAMB benchmarks on simulations with default and  
 511 optimal  $f_d$  showed negligible changes to surface energy fluxes, TWSA, and runoff.  
 512 ILAMB metrics ensured that model skill was not adversely impacted for all other  
 513 processes when optimal  $f_d$  values were used to improve WTD prediction.  
 514

## 515 **5 Appendix**

### 516 **5.1 Smooth approximation of Brooks-Corey water retention curve**

517 The Brooks and Corey (1964) water retention curve of equation (10) has a  
 518 discontinuous derivative at  $P = P_c^0$ . Figure A 1 illustrates an example. To improve  
 519 convergence of the nonlinear solver at small capillary pressures, the smoothed  
 520 Brooks-Corey function introduces a cubic polynomial,  $B(P_c)$ , in the neighborhood of  
 521  $P_c^0$ .

$$s_e = \begin{cases} (-\alpha P_c)^{-\lambda} & \text{if } P_c \leq P_u \\ B(P_c) & \text{if } P_u < P_c < P_s \\ 1 & \text{if } P_s \leq P_c \end{cases} \quad (21)$$

522 where the breakpoints  $P_u$  and  $P_s$  satisfy  $P_u < P_c^0 < P_s \leq 0$ . The smoothing  
 523 polynomial

$$B(P_c) = b_0 + b_1(P_c - P_s) + b_2(P_c - P_s)^2 + b_3(P_c - P_s)^3 \quad (22)$$

524 introduces four more parameters, whose values follow from continuity. In particular  
 525 matching the saturated region requires  $B(P_s) = b_0 = 1$ , and a continuous derivative

526 at  $P_c = P_s$  requires  $B'(P_s) = b_1 = 0$ . Similarly, matching the value and derivative at  
 527  $P_c = P_u$  requires

$$b_2 = \frac{-1}{\Delta^2} \left[ 3 - (\alpha P_u)^{-\lambda} \left( 3 + \frac{\lambda \Delta}{P_u} \right) \right] \quad (23)$$

$$b_3 = \frac{-1}{\Delta^3} \left[ 2 - (\alpha P_u)^{-\lambda} \left( 2 + \frac{\lambda \Delta}{P_u} \right) \right] \quad (24)$$

528 where  $\Delta = P_u - P_s$ . Note  $P_u \leq \Delta < 0$ .

529 In practice, setting  $P_u$  too close to  $P_c^0$  can produce an unwanted local maximum  
 530 in the cubic smoothing regime, resulting in  $s_e > 1$ . Avoiding this condition requires  
 531 that  $B(P_c)$  increase monotonically from  $P_c = P_u$ , where  $B'(P_c) > 0$ , to  $P_c = P_s$ , where  
 532  $B'(P_c) = 0$ . Thus a satisfactory pair of breakpoints ensures

$$B'(P_c) = [P_c - P_s][2b_2 + 3b_3(P_c - P_s)] > 0 \quad (25)$$

533 throughout  $P_u \leq P_c < P_s$ .

534 Let  $P_c^*$  denote a local extremum of  $B$ , so that  $B'(P_c^*) = 0$ . If  $P_c^* \neq P_s$ , it follows  
 535  $P_c^* - P_s = -2b_2/(3b_3)$ . Rewriting equation 22,  $B'(P_c) = (P_c - P_s)3b_3(P_c - P_c^*)$  shows  
 536 that  $B'(P_c^*) > 0$  requires either: (1)  $b_3 < 0$  and  $P_c^* < P_u$ ; or (2)  $b_3 > 0$  and  $P_c^* > P_u$ .  
 537 The first possibility places  $P_c^*$  outside the cubic smoothing regime, and so does not  
 538 constrain the choice of  $P_u$  or  $P_s$ . The second possibility allows an unwanted local  
 539 extremum at  $P_u < P_c^* < P_s$ . In this case,  $b_3 > 0$  implies  $b_2 < 0$  (since  $P_c^* < P_s \leq 0$ ).  
 540 Then since  $B''(P_c^*) = -2b_2$ , the local extremum is a maximum, resulting in  $s_e(P_c^*) >$   
 541 1.

542 Given a breakpoint  $P_s$ , one strategy for choosing  $P_u$  is to guess a value, then  
 543 check whether the resulting  $b_2$  and  $b_3$  produces  $P_u < P_c^* < P_s$ . If so,  $P_u$  should be  
 544 made more negative. An alternative strategy is to choose  $P_u$  in order the guarantee  
 545 acceptable values for  $b_2$  and  $b_3$ . One convenient choice forces  $b_2 = 0$ . Another picks  
 546  $P_u$  in order to force  $b_3 = 0$ . Both of these reductions: (1) ensure  $B(P_c)$  has a positive  
 547 slope throughout the smoothing interval; (2) slightly reduce the computation cost of  
 548 finding  $s_e(P_c)$  for  $P_c$  on the smoothing interval; and (3) significantly reduce the  
 549 computational cost of inverting the model, in order to find  $P_c$  as a function of  $s_e$ .

550 As shown in Figure A 1, the two reductions differ mainly in that setting  $b_2 = 0$   
 551 seems to produce narrower smoothing regions (probably due to the fact that this

552 choice gives zero curvature at  $P_c = P_s$ , while  $b_3 = 0$  yields a negative second  
 553 derivative there). However, we have not verified this observation analytically.

554 Both reductions require solving a nonlinear expression either equation (23) or  
 555 (24), for  $P_u$ . While details are beyond the scope of this paper, we note that we have  
 556 used a bracketed Newton-Raphson's method. The search switches to bisection when  
 557 Newton-Raphson would jump outside the bounds established by previous iterations,  
 558 and by the requirement  $P_u < P_c^0$ . In any event, since the result of this calculation may  
 559 be cached for use throughout the simulation, it need not be particularly efficient.

## 560 5.2 Residual equation of VSFM formulation

561 The residual equation for the VSFM formulation at  $t + 1$  time level for  $n$ -th control  
 562 volume is given by

$$R_n^{t+1} \equiv \left( \frac{(\phi s_w \rho)_n^{t+1} - (\phi s_w \rho)_n^t}{\Delta t} \right) V_n + \sum_{n'} (\rho \mathbf{q})_{nn'}^{t+1} \cdot \mathbf{A}_{nn'} + Q_n^{t+1} V_n = 0 \quad (26)$$

563 where  $\phi$  [mm<sup>3</sup> mm<sup>-3</sup>] is the soil porosity,  $s_w$  [-] is saturation,  $\rho$  [kg m<sup>-3</sup>] is water  
 564 density,  $\vec{q}_{nn'}$  [m s<sup>-1</sup>] is the Darcy flow velocity between  $n$ -th and  $n'$ -th control  
 565 volumes,  $A_{nn'}$  [m s<sup>-1</sup>] is the interface face area between  $n$ -th and  $n'$ -th control  
 566 volumes  $Q$  [kg m<sup>-3</sup> s<sup>-1</sup>] is a sink of water. The Darcy velocity is computed as

$$\mathbf{q}_{nn'} = - \left( \frac{\kappa \kappa_r}{\mu} \right)_{nn'} \left[ \frac{P_{n'} - P_n - \rho_{nn'} (\mathbf{g} \cdot \mathbf{d}_{nn'})}{d_n + d_{n'}} \right] \mathbf{n}_{nn'} \quad (27)$$

567 where  $\kappa$  [m<sup>-2</sup>] is intrinsic permeability,  $\kappa_r$  [-] is relative permeability,  $\mu$  [Pa s] is  
 568 viscosity of water,  $P$  [Pa] is pressure,  $\mathbf{g}$  [m s<sup>-2</sup>] is the acceleration due to gravity,  
 569  $d_n$  [m] and  $d_{n'}$  [m] is distance between centroid of  $n$ -th and  $n'$ -th control volume to  
 570 the common interface between the two control volumes,  $\mathbf{d}_{nn'}$  is a distance vector  
 571 joining centroid of  $n$ -th and  $n'$ -th control volume, and  $\mathbf{n}_{nn'}$  is a unit normal vector  
 572 joining centroid of  $n$ -th and  $n'$ -th control volume.

573 The density at the interface of control volume,  $\rho_{nn'}$ , is computed as inverse  
 574 distance weighted average by

$$\rho_{nn'} = \omega_n \rho_n + \omega_{n'} \rho_{n'} \quad (28)$$

575 where  $\omega_n$  and  $\omega_{n'}$  are given by

$$\omega_n = \frac{d_n}{d_n + d_{n'}} = (1 - \omega_{n'}) \quad (29)$$

576 The first term on the RHS of equation 27 is computed as the product of distance  
 577 weighted harmonic average of intrinsic permeability,  $k_{nn'}$ , and upwinding of  
 578  $k_r/\mu (= \lambda)$  as

$$\left(\frac{k k_r}{\mu}\right)_{nn'} = k_{nn'} \left(\frac{k_r}{\mu}\right)_{nn'} = \left[\frac{k_n k_{n'} (d_n + d_{n'})}{k_n d_{n'} + k_{n'} d_n}\right] \lambda_{nn'} \quad (30)$$

579 where

$$\lambda_{nn'} = \begin{cases} (k_r/\mu)_n & \text{if } \vec{q}_{nn'} > 0 \\ (k_r/\mu)_{n'} & \text{otherwise} \end{cases} \quad (31)$$

580 By substituting equation 28, 29 and 30 in equation 27, we obtain

$$\mathbf{q}_{nn'} = - \left[ \frac{k_n k_{n'}}{k_n d_{n'} + k_{n'} d_n} \right] \lambda_{nn'} [P_{n'} - P_n - \rho_{nn'} (\mathbf{g} \cdot \mathbf{d}_{nn'})] \mathbf{n}_{nn'} \quad (32)$$

581

### 582 5.3 Jacobian equation of VSFM formulation

583 The discretized equations of VSFM leads to a system of nonlinear equations given by  
 584  $\mathbf{R}^{t+1}(\mathbf{P}^{t+1}) = \mathbf{0}$ , which are solved using Newton's method using the Portable,  
 585 Extensible Toolkit for Scientific Computing (PETSc) library. The algorithm of  
 586 Newton's method requires solution of the following linear problem

$$\mathbf{J}^{t+1,k}(\mathbf{P}^{t+1,k}) \Delta \mathbf{P}^{t+1,k} = -\mathbf{R}^{t+1,k}(\mathbf{P}^{t+1,k}) \quad (33)$$

587 where  $\mathbf{J}^{t+1,k}(\mathbf{P}^{t+1,k})$  is the Jacobian matrix. In VSFM, the Jacobian matrix is  
 588 computed analytically. The contribution to the diagonal and off-diagonal entry of the  
 589 Jacobian matrix from  $n$ -th residual equations are given by

$$J_{nn} = \frac{\partial R_n}{\partial P_n} = \left(\frac{V_n}{\Delta t}\right) \frac{\partial(\rho \phi s_w)}{\partial P_n} + \sum_{n'} \frac{\partial(\rho \mathbf{q})_{nn'}}{\partial P_n} A_{nn'} + \frac{\partial Q_n^{t+1}}{\partial P_n} V_n \quad (34)$$

$$J_{nn'} = \frac{\partial R_n}{\partial P_{n'}} = \sum_{n'} \frac{\partial(\rho \mathbf{q})_{nn'}}{\partial P_{n'}} A_{nn'} + \frac{\partial Q_n^{t+1}}{\partial P_{n'}} V_n \quad (35)$$

590 The derivative of the accumulation term in  $J_{nn}$  is computed as

$$\frac{\partial(\rho \phi s_w)}{\partial P_n} = \phi s_w \frac{\partial \rho}{\partial P_n} + \rho s_w \frac{\partial \phi}{\partial P_n} + \rho \phi \frac{\partial s_w}{\partial P_n} \quad (36)$$

591 The derivative of flux between  $n$ -th and  $n'$ -th control volume with respect to  
 592 pressure of each control volume is given as

$$\frac{\partial(\rho\mathbf{q})_{nn'}}{\partial P_n} = \rho_{nn'} \frac{\partial\mathbf{q}_{nn'}}{\partial P_n} + \mathbf{q}_{nn'}\omega_n \frac{\partial\rho_n}{\partial P_n} \quad (37)$$

593

$$\frac{\partial(\rho\mathbf{q})_{nn'}}{\partial P_{n'}} = \rho_{nn'} \frac{\partial\mathbf{q}_{nn'}}{\partial P_{n'}} + \mathbf{q}_{nn'}\omega_{n'} \frac{\partial\rho_{n'}}{\partial P_{n'}} \quad (38)$$

594 Lastly, the derivative of Darcy velocity between  $n$ -th and  $n'$ -th control volume with  
 595 respect to pressure of each control volume is given as

$$\frac{\partial\mathbf{q}_{nn'}}{\partial P_n} = \left[ \frac{k_n k_{n'}}{k_n d_{n'} + k_{n'} d_n} \right] \lambda_{nn'} \left[ 1 + \omega_n (\mathbf{g} \cdot \mathbf{d}_{nn'}) \frac{\partial\rho_n}{\partial P_n} \right] \mathbf{n}_{nn'} + \mathbf{q}_{nn'} \frac{\partial(\ln(\lambda_{nn'}))}{\partial P_n} \quad (39)$$

$$\begin{aligned} \frac{\partial\mathbf{q}_{nn'}}{\partial P_{n'}} &= \left[ \frac{k_n k_{n'}}{k_n d_{n'} + k_{n'} d_n} \right] \lambda_{nn'} \left[ -1 + \omega_n (\mathbf{g} \cdot \mathbf{d}_{nn'}) \frac{\partial\rho_{n'}}{\partial P_{n'}} \right] \mathbf{n}_{nn'} \quad (40) \\ &+ \mathbf{q}_{nn'} \frac{\partial(\ln(\lambda_{nn'}))}{\partial P_{n'}} \end{aligned}$$

#### 596 **5.4 Numerical checks in VSFM**

597 VSFM uses a two-stage check to determine an acceptable numerical  
 598 solution:

599 Stage-1: At any temporal integration stage, the model attempts to solve  
 600 the set of nonlinear equations given by Equation (19) with a given  
 601 timestep. If the model fails to find a solution to the nonlinear equations  
 602 with a given error tolerance settings, the timestep is reduced by half and  
 603 the model again attempts to solve the nonlinear problem. If the model  
 604 fails to find a solution after a maximum number of time step cuts  
 605 (currently 20), the model reports an error and stops execution. None of  
 606 the simulations reported in this paper failed this check.

607 Stage-2: After a numerical solution for the nonlinear problem is obtained,  
 608 a mass balance error is calculated as the difference between input and

609 output fluxes and change in mass over the integration timestep. If the  
610 mass balance error exceeds  $10^{-5}$  kg m<sup>-2</sup>, the error tolerances for the  
611 nonlinear problem are tightened by a factor of 10 and the model re-enters  
612 Stage-1. If the model fails to find a solution with an acceptable mass  
613 balance error after 10 attempts of tightening error tolerances, the model  
614 reports an error and stops execution. None of the simulations reported in  
615 this paper failed this check.

## 616 **6 Code availability**

617 The standalone VSFM code is available at <https://github.com/MPP-LSM/MPP> and the  
618 DOI for the code is <https://doi.org/10.5281/zenodo.1412949>. Notes on how to run  
619 the VSFM for all benchmark problems and compare results against PFLOTRAN at  
620 <https://bitbucket.org/gbisht/notes-for-gmd-2018-44>.

621 The research was performed using E3SM v1.0 and the code is available at  
622 <https://github.com/E3SM-Project/E3SM>.

## 623 **7 Competing interests**

624 The authors declare that they have no conflict of interest.
