10 **Abstract.**

11

12 Soil erosion by rainfall and runoff is an important process behind the redistribution of soil organic carbon (SOC) over land,
13 hereby impacting the exchange of carbon (C) between land, atmosphere and rivers. However, the net role of soil erosion in
14 the global C cycle is still unclear as it involves small-scale SOC removal, transport and re-deposition processes that can
15 only be addressed over selected small regions with measurements and models. This leads to uncertainties in future
16 projections of SOC stocks and complicates the evaluation of strategies to mitigate climate change through increased SOC
17 sequestration.

18

19 In this study we present the parsimonious process-based Carbon Erosion DYNAMics model (CE-DYNAM) that links
20 sediment dynamics resulting from water erosion with the C cycle along a cascade of hillslopes, floodplains and rivers. The
21 model simulates horizontal soil and C transfers triggered by erosion across landscapes and the resulting changes in land-
22 atmosphere CO₂ fluxes at a resolution of about 8 km at the catchment scale. CE-DYNAM is the result of the coupling of a
23 previously developed coarse-resolution sediment budget model and the ecosystem C cycle and erosion removal model
24 derived from the ORCHIDEE land surface model. CE-DYNAM is driven by spatially explicit historical land use change,
25 climate forcing, and global atmospheric CO₂ concentrations affecting ecosystem productivity, erosion rates and residence
26 times of sediment and C in deposition sites. The main features of CE-DYNAM are (1) the spatially explicit simulation of
27 sediment and C fluxes linking hillslopes and floodplains, (2) the low number of parameters that allow running the model at
28 large spatial scales and over long-time scales, and (3) its compatibility with any global land surface model, hereby,
29 providing opportunities to study the effect of soil erosion under global changes.

30

31 We present the model structure, concepts, and evaluation at the scale of the Rhine catchment for the period 1850-2005 AD.
32 Model results are validated against independent estimates of gross and net soil and C erosion rates, and the spatial
33 variability of SOC stocks from high-resolution modeling studies and observational datasets. We show that despite local
34 differences, the resulting soil and C erosion rates, and SOC stocks from our rather coarse-resolution modelling approach
35 are comparable to high-resolution estimates and observations at sub-basin level. The model also shows that SOC storage
36 increases exponentially with basin area for floodplains in contrast to hillslopes as is seen in observations. We find that soil

37 erosion mobilized 159 Tg (10^{12} g) of C under changing climate and land use, assuming that the erosion loop of the C cycle
38 was in near steady-state by 1850. This caused a net C sink equal to 1% of the Net Primary Productivity of the Rhine
39 catchment over 1850-2005 AD. This sink is a result of the dynamic replacement of C on eroding sites that increases in this
40 period due to rising atmospheric CO₂ concentrations enhancing the litter C input to the soil from primary production.

43

44 1 Introduction

45

46 Soils contain more carbon (C) than the atmosphere and living biomass together. Relatively small disturbances
47 (anthropogenic or natural) to soil C pools over large areas could add up to substantial C emissions (Ciais et al., 2013). With
48 the removal of natural vegetation and the introduction of mechanized agriculture, humans have accelerated soil erosion
49 rates. Over the last two to three decades, studies have shown that water erosion (soil erosion by rainfall and runoff)
50 amplified by human activities has substantially impacted the terrestrial C budget (Doetterl et al., 2012; Lal, 2003; Lugato et
51 al., 2018; Van Oost et al., 2007, 2012; Stallard, 1998; Wang et al., 2017). However, the net effect of water erosion on the C
52 cycle at regional to global scale is still under debate. This leads to uncertainties in the future projections of the soil organic
53 C (SOC) reservoir, and complicates the evaluation of strategies to mitigate climate change by increased SOC sequestration.
54 The study of Stallard (1998) was one of the first to show that water erosion does not only lead to additional C emissions
55 but can also sequester C due to the photosynthetic replacement of SOC at eroding sites and the stabilization of SOC in
56 deeper layers at burial sites. The study of van Oost et al. (2007) was the first to confirm the importance of the sequestration
57 of SOC by agricultural erosion at global scale using isotope tracers. Wang et al. (2017) gathered data on SOC profiles from
58 erosion and deposition sites and confirmed that water erosion on agricultural land that started from the early/middle
59 Holocene has caused a large net global land C sink. Other studies, however, argue that soil erosion is a net C source to the
60 atmosphere due to increased SOC decomposition following soil aggregate breakdown during transport and at deposition
61 sites (Lal et al, 2003; Lugato et al., 2018). Most studies modeling soil erosion and its net effect on SOC dynamics at global
62 scale, however, did not account for the full range of complex effects of climate change, CO₂ fertilization increasing
63 productivity and potentially soil C inputs, harvest of biomass, land use change, and changes in cropland management. In
64 addition, models used at large spatial scales mainly focus on hillslopes and removal processes and neglect floodplain
65 sediment and SOC dynamics. This can lead to substantial biases in the assessment of net effects of SOC erosion at
66 catchment scale because floodplains can store substantial amounts of sediment and C (Berhe et al., 2007; Hoffmann et al.,
67 2013a).

68

69 Furthermore, soil erosion is one of the main contributors to particulate organic carbon (POC) fluxes in rivers and C export
70 to the coastal ocean. The riverine POC fluxes are usually much smaller than the SOC erosion fluxes, because only a small
71 fraction of eroded material is entering the river network and POC losses in the river network occur due to decomposition
72 and burial on floodplains and in benthic sediments. Therefore, uncertainties in large-scale SOC erosion rates will lead to

73 even larger uncertainties in lateral C fluxes between land and ocean for past and future scenarios estimated by global
74 empirical models on riverine C export (Ludwig and Probst, 1998; Mayorga et al., 2010).

75

76 To address these knowledge gaps, we present a parsimonious process-based modelling approach that integrates sediment
77 dynamics resulting from water erosion with SOC dynamics and the horizontal transport of sediment and C in the
78 continuum from hillslopes, to floodplains and rivers. With this approach we are not only able to simulate lateral soil and C
79 transfers triggered by erosion across landscapes but also the resulting changes in the land-atmosphere CO₂ fluxes. The
80 modelling approach uses a simple sediment budget model which is coupled to SOC erosion removal, C input from litter
81 fall, and SOC decomposition processes diagnosed from the ORCHIDEE global land surface model (LSM) in an offline
82 setting (Naipal et al., 2018). We parameterized and applied the resulting model, known as CE-DYNAM for the Rhine
83 catchment, although it is intended to be made applicable to other large catchments globally. CE-DYNAM combines soil
84 erosion processes, for which small scale differences in topography are of utter importance, with a state-of-the-art
85 representation of large-scale SOC dynamics driven by land use and environmental factors (climate, atmospheric CO₂) as
86 simulated by the ORCHIDEE LSM. The flexible structure of CE-DYNAM makes the model adaptable to the SOC
87 dynamics of any other LSM. In this way it is possible to study the main processes behind the linkages between soil erosion
88 and the global C cycle.

89

90 In the next sections we give a detailed overview of CE-DYNAM model structure, the coupling of erosion, deposition and
91 transport with the coarse-resolution SOC dynamics of ORCHIDEE. We then discuss its application for the Rhine
92 catchment, model limitations, uncertainties and its potentials.

93

94 **2 Methods**

95

96 **2.1 General model description**

97

98 CE-DYNAM version 1 (v1) is the result of coupling a large-scale erosion and sediment budget model (Naipal et al., 2016)
99 with the SOC scheme of the land surface model ORCHIDEE (Krinner et al., 2005). The most important features of the
100 model are (1) the spatially explicit simulation of lateral sediment and C transport fluxes linking hillslopes and floodplains,
101 (2) consistent simulation of vertical C fluxes coupled with horizontal transport, (3) the low number of parameters that
102 allows running the model at large spatial scales and over long time-scales up to several thousands of years, (4) generic
103 input fields for application to any region or catchment, and (5) compatibility with land surface models (LSMs).

104

105 In the ORCHIDEE LSM, terrestrial C is represented by 8 biomass pools, 4 litter pools and 3 SOC pools. Each of the pools
106 varies in space, time and over the 12 Plant Functional Types (PFTs). An extra PFT is used to represent bare soil. Natural
107 and anthropogenic disturbances to the C pools include fire, crop harvest, changes to GPP, litterfall, autotrophic and
108 heterotrophic respiration as a result of climatic changes (Krinner et al., 2005; Guimberteau et al., 2018). The C-cycle
109 processes are represented by a C emulator that reproduces for each PFT all C pools and fluxes between the pools exactly as

110 in ORCHIDEE in absence of erosion. A net land use change scheme is included in the emulator with mass-conservative
111 bookkeeping of SOC and C input when a PFT is changed into another from anthropogenic land use change (Naipal et al.,
112 2018). The sediment budget model has been added in the emulator to simulate large-scale long-term soil and SOC
113 redistribution by water erosion using coarse-resolution precipitation, land-cover and LAI data from Earth System Models
114 (Naipal et al. 2015, 2016). The C emulator including erosion removal was developed by Naipal et al. (2018) to reproduce
115 SOC vertical profile, removal of soil and SOC starting from the topsoil, and compensatory SOC storage from litter input.
116 As soil erosion is assumed not to change soil and hydraulic parameters but only the SOC dynamics, the emulator allows
117 substituting for the ORCHIDEE model and performing simulations on time scales of millennia with a daily time step,
118 which would be a very computationally expensive or nearly impossible with the full LSM. The concept and all equations of
119 the emulator are described in Naipal et al. (2018). The following subsections describe the different components of the CE-
120 DYNAM that couples the C and soil removal scheme (Naipal et al., 2018) with the horizontal transport and burial of
121 eroded soil and C (Naipal et al., 2016).

122

123 **2.2 The soil erosion scheme**

124

125 The potential gross soil erosion rates are calculated by the Adjusted Revised Universal Soil Loss Equation (Adj. RUSLE)
126 model (Naipal et al., 2015), which is part of the sediment budget model (Fig 1). In the Adj. RUSLE the yearly average soil
127 erosion rate is a product of rainfall erosivity (R), slope steepness (S), land cover and management (Cm) and soil erodibility
128 (K):

129

$$130 \quad E = S * R * K * Cm \quad (1)$$

131

132 The slope-length (L) and support practice (P) factors, which are part of the original Revised Universal Soil Loss Equation
133 (RUSLE) model (Renard et al., 1997), have been excluded here because their quantification still includes many
134 uncertainties and is not practical for applications at regional to global scales. These factors are a function of local manmade
135 structures and management practices which are difficult to assess for present day and whose changes over the past are even
136 more uncertain. In addition, we focus in this study on potential soil erosion and do not consider erosion-control practices.

137 Naipal et al. (2015) have developed a methodology to derive the slope factor S and the erosivity factor R from 5 arcmin
138 resolution data on elevation and precipitation, hereby preserving the high-resolution spatial variability in slope and
139 temporal variability in erosivity. Despite the comparatively coarse resolution of the erosion model, the so derived R factor
140 was shown to compare well with the corresponding high-resolution product published by Panagos et al. (2017).

141

142 **2.3 The sediment deposition and transport scheme**

143

144 The sediment deposition and transport scheme have been adapted from the sediment budget model described by Naipal et
145 al. (2016), which has been calibrated and validated for the Rhine catchment (Fig 1). In the sediment budget model each
146 grid cell contains a floodplain fraction, which is needed to ensure sediment transport between the grid cells (transport from

147 one grid cell to another can only follow the connectivity of floodplains). We followed a 2-step methodology to derive
148 floodplains in the Rhine catchment, as soil databases usually do not identify floodplain soil as a separate soil class. First,
149 grid cells were identified that consisted entirely out of floodplains. For this we used the gridded global data set of soil at 5
150 arcminute resolution, with intact regolith, and sedimentary deposit thicknesses of Pelletier et al. (2016) (Table 1), and
151 identified lowlands and hillslopes based on soil thickness and depth to bedrock. The lowlands were classified as grid cells
152 that contain only floodplains and no hillslopes. Second, we calculated the floodplain fraction of a grid cell (A_{fl}) that has
153 both hillslopes and floodplains as a function of stream length and width based on the methodology developed by Hoffmann
154 et al. (2007):

155

$$156 \quad A_{fl} = L_{stream} * W_{stream} \quad (2)$$

157

158 where L_{stream} is the stream length derived from the HydroSHEDS database (Lehner and Grill, 2013) (Table 1).

159

$$160 \quad W_{stream} = a * A_{upstream}^b \quad (3)$$

161

162 Where, $A_{upstream}$ is the upstream catchment area, and a is equal to 60.8, and b is equal to 0.3.

163

164 The parameters a and b have been derived from the scaling behavior of floodplain width as estimated from measurements
165 on the Rhine (Hoffmann et al., 2007). The sediment deposition on hillslopes (D_{hs}) and floodplains (D_{fl}) is calculated as a
166 function of the gross soil removal rates (E) with the following equations:

167

$$168 \quad D_{fl} = f * E \quad (4a)$$

$$169 \quad D_{hs} = (1 - f) * E \quad (4b)$$

$$170 \quad f = a_f * e^{\left(\frac{b_f * \theta}{\theta_{max}}\right)} \quad (5)$$

171

172 Where, f is the floodplain deposition factor at 8 km resolution that determines the fraction of gross eroded material
173 transported and deposited in the floodplain fraction of a grid cell. a_f and b_f are constant parameters that relate f to the
174 average topographical slope (θ) of a grid cell depending on the type of land cover. θ_{max} is the maximum topographical
175 slope of the entire Rhine catchment.

176

177 The parameters a_f and b_f are chosen in such a way that f varies between 0.2 and 0.5 for cropland, reflecting the decreased
178 sediment connectivity between hillslopes and floodplains created by manmade structures such as ditches and hedges. For
179 natural vegetation such as forest and natural grassland, a_f and b_f are chosen in a way that f varies between 0.5 and 0.8
180 assuming that in these landscapes hillslopes and floodplains are well-connected. In each case and within the defined
181 boundaries, the slope gradient determines the final value of f . Eroded material that has not been deposited in the floodplains
182 stays on the hillslopes and is assumed to be deposited at the foot of the hillslopes as colluvial sediment.

183

184 The floodplain fractions of the grid cells are connected through a 8 km resolution flow routing network (Naipal et al.,
185 2016), where the rivers and streams are indirectly included in the floodplain area but not explicitly simulated. By routing
186 the sediment and C through the floodplain fractions of grid cells we lump together the slow process of riverbank erosion by
187 river dynamics (time scale \approx a few years to thousands of years), and the rather fast process of transport of eroded material
188 by the rivers (time scale \approx days). The rate by which sediment and SOC leave the floodplain of a grid cell to go to the
189 floodplain of an adjacent grid cell is determined by the sediment residence time. The sediment residence time (τ) is a
190 function of the upstream contributing area ($Flowacc$):

191

$$192 \tau = e^{\frac{Flowacc - a_{\tau}}{b_{\tau}}} \quad (6)$$

193

194 The study of Hoffmann et al. (2008) shows that the majority of floodplain sediments have a residence time that ranges
195 between 0 and 2000 years, with a median of 50 years. The constants a_{τ} and b_{τ} are chosen in such way that basin τ varies
196 between the 5th and 95th percentile of those observations, with a median for the whole catchment of 50 years. These
197 constants are uniform for the whole basin. Floodplain C storage follows the same residence time as sediment on top of the
198 actual decomposition rate of C in a grid cell of ORCHIDEE. The routing of sediment and C between the grid cells follows
199 a multiple-flow routing scheme. In this scheme the flow coming from a certain grid cell is distributed across all lower-lying
200 neighbors based on a weight (W , dimensionless) that is calculated as a function of the contour length (c):

201

$$202 W_{(i+k,j+l)} = \frac{\theta_{(i+k,j+l)} * c_{(i+k,j+l)}}{\sum_{k,l=-1}^1 [\theta_{(i+k,j+l)} * c_{(i+k,j+l)}]} \quad (7)$$

203

204 Where c is $0.5 * \text{grid size (m)}$ in the cardinal direction and $0.354 * \text{grid size (m)}$ in the diagonal direction. (i, j) is the grid cell
205 in consideration where i counts grid cells in the latitude direction and j in the longitude direction. $i+k$ and $j+l$ specify the
206 neighboring grid cell where k and l can be either $-1, 0$ or 1 . θ is calculated as the division between the difference in
207 elevation (h) give in meters difference and the grid cell size (d), also in meters:

208

$$209 \theta_{(i+k,j+l)} = \frac{h_{(i,j)} - h_{(i+k,j+l)}}{d} \quad (8)$$

210

211 The sediment and C routing is done continuously at a daily time-step to preserve numerical stability of the model. More
212 detailed explanation of the methods presented in this section can be found in the study of Naipal et al. (2016).

213

214 **2.4 Litter dynamics**

215

216 The four litter pools in the emulator are an below- and an above- ground litter pool, each split into a metabolic and a
217 structural pool with different turnover rates as implemented in ORCHIDEE (Krinner et al., 2005). The belowground litter
218 pools consist mostly out of root residues. Both the biomass and litter pools have a loss flux due to fire as incorporated in
219 ORCHIDEE by the Spitfire model of Thonicke et al. (2010). The litter that is not respired or burnt is transferred to the SOC

220 pools based on the Century model (Parton et al., 1987) and the vertical discretization scheme SOC scheme presented by
221 Naipal et al., (2018).

222

223 The vertical discretization scheme was introduced in the emulator to account for a declining C input and SOC respiration
224 with depth, and consists of 20 layers with each 10 cm thickness. The litter to soil fluxes from above-ground litter pools are
225 all attributed to the top 10 cm of the soil profile. The litter to soil fluxes from belowground litter pools are distributed
226 exponentially over the whole soil profile according to:

227

$$228 \quad I_{be}(z) = I_{obe} * e^{-r*z} \quad (9)$$

229

230 Where I_{obe} is the below-ground litter input to the surface soil layer and r is the PFT-specific vertical root-density
231 attenuation coefficient as used in ORCHIDEE. The sum of all layer-dependent litter to soil fractions is equal to the total
232 litter to soil flux as calculated by ORCHIDEE. The vertical SOC profile is modified by erosion and the resulting deposition
233 fluxes, which is discussed in detail the following sections.

234

235 **2.5 Crop harvest and yield**

236

237 We adjusted the representation of crop harvest from ORCHIDEE by assuming a variable harvest index for C3 plants that
238 increases during the historical period as shown in the study of Hay (1995) for Wheat and Barley, which are also the main
239 C3 crops in the Rhine catchment. The harvest index is defined by the ratio of harvested grain biomass to above-ground dry
240 matter production (Krinner et al., 2005). In this study the harvest index increases linearly between 0.26 and 0.46 (Naipal et
241 al. 2018) consistent with the average values of Hay (1995). We also found that in certain cases the cropland NPP was too
242 high during the entire period of 1850-2005, especially in the early part of the 20th Century. This is because the cropland
243 photosynthetic rates were adjusted in ORCHIDEE to give a cropland NPP representative of present day values that are
244 higher than for the low input agriculture of the early 20th Century. To derive a more realistic NPP for crop and barley in the
245 Rhine catchment we used the long-term crop yield data obtained from a dataset on 120000 yield observations over the 20th
246 century in Northeast French Départements (NUTS3 administrative division) (Schauberger et al., 2018). According to the
247 yield data assembled by Schauburger et al. (2018), yields in Northeast France for these crops increased fourfold during the
248 last century. Note that crop residues like straw constituted a larger fraction of the total biomass in 1850 than in 2005, but
249 those residues were likely collected and used for animal feed, housing fuel. We did not account for this harvest of residue
250 in the simulation of SOC.

251

252 **2.6 SOC dynamics without erosion**

253

254 The change in the carbon content of the PFT-specific SOC pools in the emulator without soil erosion as described by
255 Naipal et al. (2018) (Fig 1):

256

$$257 \quad \frac{dSOC_a(t)}{dt} = lit_a(t) + k_{pa} * SOC_p(t) + k_{sa} * SOC_s(t) - (k_{ap} + k_{as} + k_{0a}) * SOC_a(t) \quad (10)$$

$$258 \quad \frac{dSOC_s(t)}{dt} = lit_s(t) + k_{as} * SOC_a(t) - (k_{sa} + k_{sp} + k_{0s}) * SOC_s(t) \quad (11)$$

$$259 \quad \frac{dSOC_p(t)}{dt} = k_{ap} * SOC_a(t) + k_{sp} * SOC_s(t) - (k_{pa} + k_{0p}) * SOC_p(t) \quad (12)$$

260

261 Where, SOC_a , SOC_s , and SOC_p (g C m^{-2}) are the active, slow and passive SOC, respectively. The distinction of these SOC
 262 pools, defined by their residence times, are based on the study of Parton *et al.* (1987). The active SOC pool has the lowest
 263 residence time (1 - 5 years) and the passive the highest (200-1500 years). lit_a and lit_s ($\text{g C m}^{-2} \text{ day}^{-1}$) are the daily litter
 264 input rates to the active and slow SOC pools, respectively; k_{0a} , k_{0s} and k_{0p} (day^{-1}) are the respiration rates of the active,
 265 slow and passive pools, respectively; k_{as} , k_{ap} , k_{pa} , k_{sa} , k_{sp} are the coefficients determining the flux from the active to the
 266 slow pool, from the active to the passive pool, from the passive to the active pool, from the slow to the active pool and
 267 from the slow to the passive pool, respectively.

268 The vertical C discretization scheme in the emulator assumes that the SOC respiration rates decrease exponentially with
 269 depth:

270

$$271 \quad k_i(z) = k_{0i}(z) * e^{-re * z} \quad (13)$$

272

273 Where k_i is the respiration rate at a soil depth z and re (m^{-1}) is a coefficient representing the impact of external factors, such
 274 as oxygen availability that decreases with depth. k_{0i} is the respiration rate of the surface soil layer for a certain SOC pool i .
 275 The variable re is determined in such a way that the total soil respiration of a certain pool over the entire soil profile
 276 without erosion is similar to the output of the full ORCHIDEE model. Detailed description of how this is done can be
 277 found in the study of Naipal *et al.* (2018).

278

279 **2.7 C erosion on hillslopes**

280

281 In the model we assume that soil erosion takes place on hillslopes, and not in the floodplains due to the usually low
 282 topographical slope of floodplains. The factor ($I-f$) determines the fraction of the eroded soil that is deposited in the
 283 colluvial reservoirs (Fig 1). Soil erosion always removes a fraction of the SOC stock in the upper soil layer depending on
 284 the erosion rate and bulk density of the soil. The next soil layer contains less C and therefore at the following time-step less
 285 C will be eroded under the same erosion rate. To account for this effect, the SOC profile evolution is dynamically tracked
 286 in the model and updated at a daily time step, conform with the method of Wang *et al.* (2015). First, a fraction of the C
 287 from each soil pool in proportion to the erosion height is removed from the surface layer. Then, at the same erosion rate,
 288 SOC from the subsoil layer becomes the surface layer, maintaining the soil layer thickness in the vertical discretization
 289 scheme. Similarly, the SOC from the subsoil later also moves upward one layer. The change in C content due to erosion of
 290 the PFT-specific pools for hillslopes can be represented by the following equations:

291

$$292 \quad \frac{dSOC_{Hsi}(z,t)}{dt} = k_E * SOC_{Hsi}(z + 1, t) - k_E * SOC_{Hsi}(z, t) \quad (14)$$

293

294 Where $dSOC_{HSi}(z,t)$ is the change in hillslope SOC of a component pool i at a depth z and at time step t . The daily erosion
 295 fraction k_E (dimensionless) is calculated as following:

296

$$297 \quad k_E = \frac{f * \left(\frac{E}{365}\right)}{BD * dz} \quad (15)$$

298

299 Where, E is the erosion rate ($t \text{ ha}^2 \text{ year}^{-1}$), f is the floodplain deposition factor, BD is the average bulk density of the soil
 300 profile (g cm^{-3}) and dz is the soil thickness ($=0.1 \text{ m}$).

301

302 This part of the model has been already applied at the global scale as the C removal model presented by Naipal et al.
 303 (2018) and is here extended with the deposition term detailed above.

304

305 **2.8 C deposition and transport in floodplains**

306

307 The SOC profile dynamics of floodplains are controlled by: (1) C input from the hillslopes, (2) C import by lateral
 308 transport from the floodplain fractions of upstream neighboring grid cells, and (3) C export to the floodplain fractions of
 309 downstream neighboring grid cells (Fig 1). First, the net eroded flux from the surface layer of the hillslope fraction of the
 310 grid cell ($k_E * SOC_{HS}(0)$) is incorporated in the surface layer of the floodplain. At the same deposition rate, the SOC of the
 311 surface layer of the floodplain is incorporated in the subsoil layer. Similarly, a fraction of the SOC of the subsoil layer is
 312 moved downward one layer. It should be noted that C selectivity is not taken into account here, meaning that the C pools
 313 of the deposited material are the same as the eroded material from the topsoil of eroding areas. At the same time a fraction
 314 of the C of the surface layer proportional to the sediment residence time (τ) is exported out of the catchment following the
 315 sediment routing scheme. This process represents the river bank erosion and resulting POC export by rivers. It should be
 316 noted that rivers and streams are not explicitly represented in the model. As we do not have information on the sub-grid
 317 spatial distribution of land cover fractions we first sum the exported C flux over all PFTs before assigning the flux
 318 proportionally to the land cover fractions of the receiving downstream-lying grid cells. The C that is imported from the
 319 neighboring grid cells follows the same procedure as the deposition of eroded material. The change in C content due to
 320 deposition and river export/import of the PFT-specific pools for floodplains can be represented by the following equations:

321

$$322 \quad \frac{dSOC_{FLi}(z,t)}{dt} = \left((k_D + k_{i_{out}}) * SOC_{FLi}(z-1, t) \right) + \left(\frac{1}{(\tau * 365)} * SOC_{FLi}(z+1, t) \right) - \left(\left(k_D + \frac{1}{(\tau * 365)} + k_{i_{out}} \right) * SOC_{FLi}(z, t) \right),$$

$$323 \quad \text{for } z > 0 \quad (16)$$

324

$$325 \quad \frac{dSOC_{FLi}(0,t)}{dt} = \sum_{n=1}^{n=9} \left(k_{i_{out}}(n) * SOC_{FLi}(0, t)(n) \right) + \left(k_E * SOC_{HSi}(0, t) \right) + \left(\frac{1}{(\tau * 365)} * SOC_{FLi}(1, t) \right) - \left(\left(k_D + \frac{1}{(\tau * 365)} + \right.$$

$$326 \quad \left. k_{i_{out}} \right) * SOC_{FLi}(0, t) \right), \text{ for } z=0 \quad (17)$$

327

328 Where n is the neighboring grid cell that flows into the current grid cell, $dSOC_{FLi}(z,t)$ is the change in floodplain SOC of a
329 component pool i at a depth z and at time step t , and SOC_{HS} is the hillslope SOC stock. k_D is the deposition rate and equal
330 to:

331

$$332 \quad k_D = \frac{k_E * AREA_{HS}}{AREA_{FL}} \quad (18)$$

333

334 Where $AREA_{HS}$ is the hillslope area and $AREA_{FL}$ is the floodplain area (m^2). $k_{i_{out}}$ is the import rate per C pool i from
335 neighboring grid cells (dimensionless) and can be calculated as:

336

$$337 \quad k_{i_{out}} = \frac{\sum_{n=1}^{n=9} (W * \frac{1}{T * 365} * AREA_{FL})(n)}{AREA_{FL}} \quad (19)$$

338

339 Where, W is the weight index of equation 7.

340

341 **2.9 The land use change bookkeeping model**

342

343 The land use change bookkeeping scheme includes the yearly changes in forest, grassland and cropland areas in each grid
344 cell as reconstructed by Peng et al. (2017) (Table 1). Peng et al. (2017) derived historical changes in PFT fractions based
345 on LUHv2 land use dataset (Hurt et al., 2011), historical forest area data from Houghton, and present day forest area from
346 ESA CCI satellite land cover (European Space Agency, ESA, 2014). By using different transition rules and independent
347 forest data to constrain the changes in crop and urban PFTs he derived the most suitable historical PFT maps.

348

349 When land use change takes place, the litter and SOC pools of all shrinking PFTs are summed and allocated proportionally
350 to the expanding PFTs, maintaining the mass-balance. In this way the litter pools and SOC stocks get impacted by different
351 input and respiration rates for each soil layer. When forest is reduced, three wood products with decay rates of 1, 10 and
352 100 years are formed and harvested. The biomass pools of other shrinking land cover types are transformed to litter and
353 allocated to the expanding PFTs. For more details on the land use scheme see the study of Naipal et al. (2018).

354

355 **2.10 Study-Area**

356

357 The model is tested for the Rhine catchment (Fig 2), which has a total basin area of 185,000 km^2 covering five different
358 countries in Central Europe. Its large size is beneficial for the application of a coarse-resolution model such as CE-
359 DYNAM to study large-scale regional dynamics in the C cycle due to soil erosion. The Rhine catchment has a very
360 interesting topography, with steep slopes larger than 20% upstream in the Alps, and large, wide and flat floodplains at the
361 foot of the Alps, the upper Rhine and the lower Rhine. The floodplains store large amounts of sediment and C that
362 originally was eroded from the steep hillslopes upstream. This makes it possible to study the long-term effect of erosion on

363 hillslope and floodplain dynamics. Furthermore, the Rhine catchment has been experiencing different stages of land use
364 change over the Holocene, with land degradation dating back to more than 5500 years ago (Dotterweich, 2013). In contrast,
365 during the last two decades there has been a general afforestation and soil erosion has been decreasing. These land use
366 changes and changes in erosion make an interesting and important case to study the effect of anthropogenic activities on
367 the C cycle in Europe.

368

369 In addition, the Rhine catchment has been the focus of many erosion studies providing observations on erosion and
370 sediment dynamics that can be used for model validation (Asselman, 1999; Asselman et al., 2003; Erkens, 2009; Hoffmann
371 et al., 2007, 2008, 2013a, 2013b; Naipal et al., 2016). The global sediment budget model that forms the basis for the
372 sediment dynamics of CE-DYNAM has been validated and calibrated for the Rhine catchment with observations on
373 sediment storage from Hoffmann et al. (2013b) and derived scaling relationships between sediment storage and basin area
374 (Naipal et al., 2016). These scaling relationships are also applicable for SOC storage and basin area. He found that for
375 floodplains the sediment and C storage increase in a non-linear way with basin area, while hillslopes show linear increase.
376 We will use these relationships to validate the spatial variability in SOC storage of floodplains and hillslopes simulated by
377 CE-DYNAM. The scaling relationships have the form of a simple power law:

378

$$379 \quad M = a * \left(\frac{A}{A_{ref}}\right)^b \quad (20)$$

380

381 Where M is the sediment storage or the SOC storage, a is the storage (Mt) related to an arbitrary chosen area A_{ref} , while b is
382 the scaling exponent.

383

384 **2.11 Input data and model simulations**

385 To create the C emulator that forms the underlying C cycle part of CE-DYNAM, we first ran the full ORCHIDEE model
386 for the period 1850-2005 at a coarse resolution of 2.5°degrees latitude and 3.75° degrees longitude, and output all C pools
387 and fluxes. The pools and fluxes were then archived together and used to derive the turnover rates to build the emulator.
388 The SOC scheme of the emulator that has been modified to account for soil erosion processes has been made to run at a
389 spatial resolution of 5arcmin, similar to the original global sediment budget model. Then, we performed three main
390 simulations with CE-DYNAM for the Rhine catchment. Simulation S0: The baseline simulation or no-erosion simulation,
391 where SOC dynamics are similar to the full ORCHIDEE model. Simulation S1: The erosion -only simulation, where the
392 hillslopes erode and all eroded C is respired to the atmosphere without reaching the colluvial and alluvial deposition sites.
393 Simulation S2: The simulation with full sediment dynamics where hillslopes and floodplains are connected and can bury or
394 loose C. We ran the emulator for 2000 years at a daily time step with the initial climate and land cover of the period 1850-
395 1860. Afterwards, we performed the transient simulations for the period 1851-2005 at a daily time step with changing
396 climate and land cover conditions. However, after 2000 years the model the passive SOC pool was still not in complete
397 equilibrium with a change between 0.8 and 1 g C m⁻² year⁻¹. Therefore, we subtracted the additional increase in SOC stocks
398 resulting from the disequilibrium state from the SOC stocks of the transient simulations before analyzing the transient
399 results.

400 Finally, to ensure a faster performance of CE-DYNAM we delineated the Rhine catchment in 7 large sub-basins based on
401 the flow direction and ran in parallel for each of the sub-basins at the daily timestep. After each year the sub-catchments
402 exchanged the C between each other.

403

404 **3 Results**

405

406 **3.1 Model validation**

407

408 We performed a detailed model validation of the sediment and the C part of the model based on the following steps: (1)
409 Validation of soil erosion rates using high-resolution model estimates and observations from other studies, (2) validation of
410 C erosion rates using high-resolution estimates for Europe from the study of Lugato et al. (2018), (3) validation of the
411 spatial variability of sediment storage, (4) validation of SOC stocks using data from a global soil database and a European
412 land use survey.

413

414 For the validation of gross soil erosion rates we used the high-resolution model estimates from the study of Panagos et al.
415 (2015), who applied the RUSLE2015 model at a 100 m resolution at European scale for the year 2010. The RUSLE2015 is
416 derived from the original RUSLE model with some modifications to the model parameters, especially the L, C and P
417 factors. We also used independent high-resolution erosion estimates from the study of Cerdan et al. (2010), which were
418 based on an extensive database of measured erosion rates under natural rainfall in Europe.

419

420 We show that the quantile distribution of our gross soil erosion rates fall in between the estimates of these two studies (Fig
421 3A&B). It should be noticed that our study and the study of Cerdan et al. (2010) simulated potential soil erosion rates, not
422 accounting for erosion control practices that are captured by the P-factor. We also compared the quantile distribution of our
423 net soil erosion rates from hillslopes with those of the study of Lugato et al. (2018), and show that they are similar (Fig
424 3C). Lugato et al. (2018) extended the RUSLE2015 model with a hillslope sediment deposition and transport scheme based
425 on the sediment delivery ratio concept.

426

427 For the comparison of the spatial variability of gross soil erosion rates we used the relationship of erosion to the
428 topographical slope and rainfall erosivity. These two parameters are argued to explain about 70% of the total potential soil
429 erosion rates at regional scales (Doetterl et al., 2012). We show that in our study and the study of Lugato et al. (2018)
430 erosion rates increase with increasing slope and erosivity, and that erosion can be high for very steep slopes with a low
431 erosivity (Fig 4). However, the difference between small and large erosion rates in our study is high, indicating an
432 underestimation of local variability in erosivity and slope. Overall, our results show that our coarse-resolution erosion
433 model is capable of producing reliable estimates of potential soil erosion rates and their spatial variability for the Rhine
434 catchment.

435

436 For the validation of gross C erosion rates, we used the results from Lugato et al. (2018), where they coupled the
437 RUSLE2015 erosion model to the Century bio-geochemistry model. They provided an enhanced and a reduced erosion-
438 induced C sink uncertainty scenario, based on different assumptions for C burial and C mineralization during transport. We
439 find that the quantile distribution of our simulated erosion and deposition rates is close to that of Lugato et al. (2018) (Fig
440 5A-D). We also find that the relation between soil erosion and C erosion rates of our study is similar to the relation of
441 Lugato et al. (2018) and falls within the uncertainty range (Fig 6). The coarse resolution of our model may explain the
442 decreased variability between the estimates.

443

444 For the validation of SOC stocks we used the Global Dataset for Earth System Modeling (GSDE) (Shangguan et al., 2014)
445 available at a spatial resolution of 1km and the Land Use/Land Cover Area Frame Survey (LUCAS) (Palmieri et al., 2011).
446 The LUCAS topsoil SOC stocks, available at a high spatial resolution of 500 m, were calculated using the LUCAS SOC
447 content for Europe (de Brogniez et al., 2015) and soil bulk density derived from soil texture datasets (Ballabio et al., 2016).
448 We find that the simulated top 20 cm SOC stocks per land cover type generally fall within the quantile range of the
449 LUCAS SOC stocks (Fig 7). We also find that the simulation with erosion does not substantially change this result but
450 leads to slightly lower SOC stocks due to the impact of erosion and POC export out of the catchment. Furthermore, we find
451 that in both the erosion and no-erosion simulation the SOC stocks for grassland are higher than for forest. This is also
452 observed in the study of Wiesmeier et al. (2012) in South-Germany where they found considerable higher SOC stocks for
453 grassland with a median of 11.8 kg C m⁻² compared to forest based on the analysis of 1460 soil profiles.

454

455 To validate the spatial variability of SOC stocks we delineated 13 sub-basins in the non-Alpine region. We found a realistic
456 spatial variability in topsoil SOC stocks after comparing our simulated SOC stocks from the erosion simulation with the
457 SOC stocks of GSDE and LUCAS at sub-basin level (Table 2).

458

459 For the validation of sediment storage in hillslopes and on floodplains we used the same approach as in Naipal et al.
460 (2016), where we based our validation on measured Holocene SOC deposits from the study of Hoffmann et al. (2013).
461 Hoffmann et al. (2013) did an inventory of 41 hillslope and 36 floodplain sediment and SOC deposits related to soil
462 erosion over the last 7500 years. They found that the sediment and SOC deposits were related to the basin size according to
463 certain scaling functions, where floodplain deposits increased in a non-linear way with basin size while the hillslope
464 deposits showed a linear increase with basin size. We selected the grid cells that contained the points of observation of the
465 study of Hoffmann et al. (2013) and found a significantly larger exponent of the scaling relationship between floodplain
466 SOC storage and basin area compared to hillslope SOC storage, which corresponds to the findings of Hoffmann et al.
467 (2013). However, this is not the case when deriving the scaling relationships at sub-basins level (Table 3).

468

469 **3.2 Model application**

470

471 We find an average annual soil erosion rate of 4.66 t ha⁻¹ year⁻¹ over the period 1850-2005, which is 1.7 times larger than
472 the average erosion rate simulated for the last millennium (Naipal et al., 2016) and 3.8 times larger than the average

473 erosion rate of the Holocene (Hoffmann et al., 2013). This soil erosion flux mobilized around 159 Tg of C over the period
474 1850-2005, of which 37% is deposited in colluvial reservoirs, 63% is deposited in alluvial reservoirs and 0.2% is exported
475 out of the catchment.

476

477 Over the period 1850-2005 there is a general afforestation in the Rhine catchment that started around 1920 AD (Fig 8B).
478 This afforestation takes place in the non-Alpine part of the Rhine and leads to a long-term decreasing trend in gross soil
479 and SOC erosion rates on hillslopes in the non-Alpine region (Fig 8D). In the Alpine part of the Rhine there was a
480 conversion of cropland and forest to grassland. Cropland decreases by 75% over the period 1920 and 1960, while forest
481 decreases by 16% over the period 1910-1950. The conversion of forest to grassland has a stronger impact on the soil
482 erosion rates than the conversion of cropland to forest, resulting in an increase of soil erosion rates over the period 1910-
483 1950 (Fig 8C). This increase is amplified by increased yearly precipitation in this region. Because the soil erosion rates in
484 the Alps are generally much larger than the soil erosion rates in the non-Alpine region due to the steep landscape, the
485 Alpine region dominates the trend in gross soil erosion and C erosion of the entire in the period 1910-1950 (Fig 8C). As a
486 result, the summed gross soil and C erosion rates over the whole Rhine catchment do not show a specific trend (Fig 8C).
487 The temporal variability in the soil and C erosion rates is a result of changes in precipitation (Fig 8A), however, land use
488 change dominates the overall long-term trend. Although precipitation is temporarily very variable, spatially it does not vary
489 significantly over the Rhine.

490

491 Furthermore, we find that the temporal variability in C erosion rates follow the soil erosion rates closely, indicating that
492 soil erosion dominates the variations in C erosion over this time-period, while increased SOC stocks due to CO₂
493 fertilization and afforestation play a secondary role as a slowly, varying trend.

494

495 We find that the cumulative C erosion removal flux of 159 Tg leads to a cumulative net C sink of 90 Tg C for the whole
496 Rhine region (Fig 8E). This is about 1% of the cumulative NPP and about one fourth of the cumulative land C sink of the
497 Rhine without erosion. For the non-Alpine part of the Rhine, erosion leads to a net C sink of 55 Tg C, which equals to one
498 fifth of the total land C sink without erosion. It should be noted that these are potential fluxes, assuming that the
499 photosynthetic replacement of C is not affected by the degradation of soil due to the removal of nutrients, declining water-
500 holding capacity and other negative changes to the soil structure and texture (processes not covered by our model). The
501 breaking point in the graphs of figure 8E and F around 1910AD is a result of the climate data used as input.

502

503 To better understand the erosion-induced net C flux (Fig 8E, F), we analyzed the erosion-induced C exchange with the
504 atmosphere by creating C budgets for the entire Rhine catchment for the period 1850-1860 and for the period 1950-2005
505 (Fig 9A&B). These C budgets also shed light on changes in the linkage between lateral and vertical C fluxes over time. As
506 we do not explicitly track the movement of eroded C through all reservoirs (for example between eroding hillslopes and
507 colluvial reservoirs), we make use of the changes in SOC stocks and NEP of the three main simulations (S0, S1, S2) to
508 derive the erosion-induced vertical C fluxes.

509

510 By subtracting the Net Ecosystem Productivity of hillslopes (NEP_{HS}), which is the difference between NPP and
511 heterotrophic respiration, of the no-erosion simulation (S0) from the erosion-only simulation (S1), we derive the additional
512 photosynthetic replacement of SOC on eroding sites (eq 21):

513

$$514 \quad E_{rep} = NEP_{HS}(S1) - NEP_{HS}(S0) \quad (21)$$

515

516 Where, E_{rep} is the potential dynamic Photosynthetic replacement of C on eroding sites (assuming no feedback of erosion on
517 NPP). Part of the eroded C that is transported to and deposited in colluvial reservoirs can be respired or buried (Eq. 22).
518 The difference between NEP of simulation S2 and S1 is the NEP caused by the deposition of eroded C in colluvial areas
519 and equal to the difference between the burial and respiration of C in colluvial sites. As we do not explicitly track the
520 respiration of deposited material in the model, we can only derive the net respiration or net burial of the colluvial deposits
521 ($R_{c_{net}}$) with the following equation:

522

$$523 \quad R_{c_{net}} = NEP_{HS}(S2) - NEP_{HS}(S1) \quad (22)$$

524

525 The same concept can be applied for the net respiration of floodplains:

526

$$527 \quad R_{a_{net}} = NEP_{FL}(S2) - NEP_{FL}(S0) \quad (23)$$

528

529 Where, NEP_{FL} is the floodplain Net Ecosystem Productivity, and $R_{a_{net}}$ is the net respiration or net burial of alluvial
530 deposits. Positive values for $R_{a_{net}}$ or $R_{c_{net}}$ indicate a net burial (respiration S2 < respiration S0/S1) of the deposited
531 material. We find that dynamic replacement of C on eroding sites increased by 39% at the end of the period despite
532 decreasing soil erosion rates (Fig 9A&B). This increase in the photosynthetic replacement of C is due to the globally
533 increasing CO₂ concentrations known as the CO₂ fertilization effect, amplified by the afforestation trend in the Rhine over
534 this period. Without this fertilization effect, soil erosion and deposition would be likely a weaker C sink or even a C source
535 over the period 1850-2005. Furthermore, we find that the yearly average gross C erosion flux from eroding sites decreased
536 slightly by 2%, while the yearly deposition fluxes in colluvial and alluvial sites decreased by 3.5 % and 0.6%, respectively.
537 The decrease in the deposition flux to floodplains is compensated by better sediment connectivity between hillslopes and
538 floodplains due to afforestation. Forests have less man-made structures that can prevent the erosion fluxes from reaching
539 the floodplains, which is represented by a higher floodplain deposition ' f ' factor in the model.

540

541 We also find that colluvial reservoirs show a net respiration flux throughout the time period (Fig 9A&B). This is consistent
542 with previous studies who found that colluvial sites can be areas of increased CO₂ emissions (Billings et al., 2019; Van
543 Oost et al., 2012). However, the difference between the start and end of the transient period is triggered by the net
544 respiration/burial flux of deposited C in floodplains. While at the start of the period, deposition in alluvial reservoirs leads
545 to a substantial net burial flux (~0.8 times the floodplain deposition), at the end of the period respiration of deposited SOC
546 in floodplains is larger than this burial flux (Fig 9B). This is a result of an increased respiration of deposited material over

547 the entire catchment, most likely due to increasing temperatures over 1850-2005. The constant removal of C-rich topsoil
548 and its deposition in alluvial and colluvial reservoirs makes the deposited sediments generally richer in C than soils on
549 erosion-neutral sites, providing more substrate for respiration. The largest increase in total respiration of alluvial and
550 colluvial deposits takes place in the Alps due to the initial increase in erosion rates resulting in large deposits of C.

551

552 We also observe declining erosion rates over the non-Alpine region leading to decreasing or less strong increasing dynamic
553 replacement of C. Both processes, the decrease in burial dynamic C replacement, contribute to a reduced increase in the
554 erosion-induced net C sink over time (Fig 8E, F).

555

556 **4 Discussion**

557

558 **4.1 Initial conditions and past global changes**

559

560 Initial climate and land cover/use conditions needed to perform the equilibrium simulation together with the length of the
561 transient period are essential parameters that determine the resulting spatial distribution of soil and C. Landscapes are in a
562 constant transient state due to global changes, such as climate change, land use change, accelerated soil erosion. However,
563 we assumed an equilibrium state so that we can quantify the changes during the transient period. The more one goes back
564 in time to select the initial conditions and the longer the transient period that covers the essential historical environmental
565 changes, the more accurate are the present-day distribution of SOC stocks, sediment storages, and related fluxes. This is
566 especially true when analyzing the redistribution of soil and C as a result of erosion, deposition and transport, as these soil
567 processes can be very slow. For example, the study of Naipal et al. (2016) shows that by simulating the soil erosion
568 processes for the last millennium a spatial distribution of sediment storages that is similar to observations can be found. In
569 this study we modeled steady state initial conditions of the period 1850-1860 due to constraints in data availability on
570 precipitation and temperature, and because the aim of this study is to present the potential and limitations of CE-DYNAM
571 rather than provide precise values for soil and C stocks and fluxes. By focusing only on the period 1850-2005 we miss the
572 effects of significant land use changes in the past that coincided with times of strong precipitation such as in the 14th and
573 18th century. These major anthropogenic changes in the last Holocene substantially affected the present-day spatial
574 distribution and size of SOC stocks. As a result, we find that floodplains store less SOC than hillslopes at the end of the
575 transient period (Fig 10A), which is different from the findings of Hoffmann et al. (2013) and what can be derived from
576 global soil databases. Hoffmann et al. (2013) showed that the large amount of C stored in the deeper layers of the
577 floodplains can be several thousands of years old. In addition, the high C stocks in floodplains also result from higher local
578 plant productivity due to favorable soil nutrient and hydrological conditions. In our study we do not capture this effect and
579 we do not look at a timescale long enough to capture this distinction between SOC storage in floodplains and in hillslopes.
580 However, we did not find that the vertical distribution of C in floodplain sediment is more homogenous or shows a less
581 strong decrease in C with depth (Fig 10B). This is in line with the findings of previous studies (Hoffmann et al., 2013;
582 Billings et al., 2019).

583

584 **4.2 Model limitations**

585

586 Although CE-DYNAM explicitly account for hillslope and floodplains re-deposition, it neglects important processes
587 affecting the C dynamics in floodplains. The model does not account for a slower respiration rate due to low-oxygen
588 conditions, physical and chemical stabilization (Berhe et al., 2008; Martínez-mena et al., 2019) or a higher NPP for
589 nutrient-rich floodplains (Van Oost et al., 2012; Hoffmann et al., 2013). The oxidation and preservation of C in deposition
590 environments, especially in alluvial reservoirs remain highly uncertain (Billings et al., 2019). Furthermore, the model does
591 not take into account the selectivity of erosion, often expressed as the enrichment ratio, where the C content of eroding soil
592 can be higher than that of the original soil. The enrichment ratio can be very variable across landscapes, while the
593 importance of erosion selectivity for C is still under debate (Nadeu et al., 2015; Wang et al., 2010).

594

595 CE-DYNAM does not account for different ratios between the SOC pools (active, slow, passive) with depth due to the
596 limitation in information to constrain these fractions for floodplains and hillslopes. However, this can be potentially
597 important for respiration of C in depositional sites and during transport. Studies show that the labile C is decomposed first
598 during sediment transport and directly after deposition, leaving behind the more recalcitrant C in deposition sites (Berhe
599 et al., 2007; Billings et al., 2019). Due to the simplistic nature of our coarse-resolution model and the lack of data on
600 oxidation of eroded C during transport we did not include C respiration during transport in the model. We also do not take
601 into account the transformation of POC to DOC and their fate in rivers and streams. The model also lacks dams in and
602 fixed river banks of the Rhine river. In this way, CE-DYNAM provides only a potential state of soil and SOC redistribution
603 as would be under more natural conditions. Furthermore, there is no feedback between soil erosion and plant productivity
604 in the model. To account for such process soil erosion processes would need to be explicitly included in a land surface
605 model such as ORCHIDEE. The lack of this feedback results in an unlimited dynamic replacement of C on eroding sites.

606

607 **5 Conclusions**

608

609 We presented a novel spatially-explicit and process-based C erosion dynamics model, CE-DYNAM, which simulates the
610 redistribution of soil and C over land as a result of water erosion and calculates the role of this redistribution for C budgets
611 at catchment scale. We demonstrate that CE-DYNAM captures the spatial variability in soil erosion, carbon erosion and
612 SOC stocks of the Rhine catchment when compared to high-resolution estimates and observations. We also show that the
613 quantile ranges of erosion and deposition rates and C stocks fall within the uncertainty ranges of previous estimates at
614 basin or sub-basin level. Furthermore, we demonstrate the model ability to disentangle vertical C fluxes resulting from the
615 redistribution of C over land and develop C budgets that can shed light on the role of erosion in the C cycle. The simple
616 structure of CE-DYNAM and the relative low amount of parameters makes it possible to run several simulations to
617 investigate the role of individual processes on the C cycle such as removal by erosion only, or the role of deposition and
618 transport. Its compatibility with land surface models makes it possible to investigate the long-term and large-scale effect of
619 erosion processes under various global changes such as increasing atmospheric CO₂ concentrations, changes to
620 precipitation and temperature, and land use change.

621

622 The application of CE-DYNAM for the Rhine catchment for the period 1850-2005 AD reveals three key findings:

- 623 • Soil erosion leads to a cumulative net C sink of 90 Tg by the end of the period, which is equal to one fourth of the
624 cumulative land C sink of the Rhine without erosion. This C sink is a result of an increasing dynamic replacement
625 of C on eroding sites due to the CO₂ fertilization effect, despite decreasing soil and C erosion rates over the largest
626 part of the catchment. We conclude that it is important to take global changes such as climate change into account
627 to better quantify the net effect of erosion on the C cycle.
- 628 • The erosion-induced C sink decreases over time due to decreasing erosion rates and increasing respiration of
629 deposited C in alluvial and colluvial reservoirs. In contrast to colluvial reservoirs, alluvial reservoirs experience a
630 net C burial. However, this net C burial can become net C respiration due to changes in the climate such as global
631 warming. We conclude that burial of eroded C in floodplains plays an essential role in the strength of the erosion-
632 induced C sink.
- 633 • Initial climate and land cover conditions and the transient period over which erosion under global changes takes
634 place are essential for the determination if soil erosion is a net C sink or source and to what extent.

635

636 Altogether, these results indicate that despite model uncertainties related to the relative coarse spatial resolution, missing or
637 simplified processes, CE-DYNAM represents an important step forwards into integrating soil erosion processes and
638 sediment dynamics in Earth system models.

639

640 **Code and data availability**

641

642 The source code of CE-DYNAM is included as a supplement to this paper. Model data can be accessed from the Zenodo
643 repository under the doi:10.5281/zenodo.2642452 (not published yet). For the other data sets that are listed in Table 1, it is
644 encouraged to contact the first authors of the original references.

645

646 **Author contributions**

647

648 VN built and implemented the mode. YW provided the basic structure for the model. All authors contributed in the
649 interpretation of the results and wrote the paper.

650

651 **Competing interests**

652

653 *The authors declare that they have no conflict of interest.*

842 **Table 1:** Model input datasets

Dataset	Spatial resolution	Temporal resolution	Period	Source
Historical land cover and land use change	0.25 degrees	annual	1850-2005	Peng et al. (2017)
Climate data (precipitation & temperature) for ORCHIDEE	0.5 degrees	6 hourly	1900-2012	CRU-NCEP version 5.3.2; https://crudata.uea.ac.uk/cru/data/ncep/ ; last access: 5 April 2019
precipitation for the Adj. RUSLE	0.5 degrees	monthly	1850-2005	ISIMIP2b (Frieler et al., 2017)
Soil	1 km	-	-	Global Soil Dataset for Earth System Modeling, GSDE (Shangguan H.W., Dai Y., Duan Q., Liu B., 2014)
Topography	30 arcseconds	-	-	GTOPO30; U.S. Geological Survey, EROS Data Center Distributed Active Archive Center 2004; https://www.ngdc.noaa.gov/mgg/topo/gltiles.html ; last access: 5 April 2019
Flow accumulation	30 arcseconds	-	-	HydroSHEDS (Lehner et al., 2013); https://www.hydrosheds.org/ ; last access: 5 April 2019
Hillslopes/Floodplain area	5 arcminutes	-	-	Pelletier et al. (2016)
River network & stream length	30 arcseconds	-	-	Hydrosheds (Lehner et al., 2008)

843
 844

845 **Table 2:** This table shows the results of the linear regression between the simulated total SOC stocks (Tg of C per year)
 846 and those of the Global Soil dataset for Earth System Modeling (GSDE) and from the LUCAS database. The regression is
 847 done after aggregating the data at sub-basin level for the 13 sub-basins that were delineated in the Rhine catchment.
 848 RMSE is the root mean square error given in Tg of C per year, while the r-value is the spatial correlation coefficient.

Regression	r-value	p-value	RMSE
This study versus LUCAS	0.96	<0.01	28.69
This study versus GSDE	0.95	<0.01	29.32

849
 850

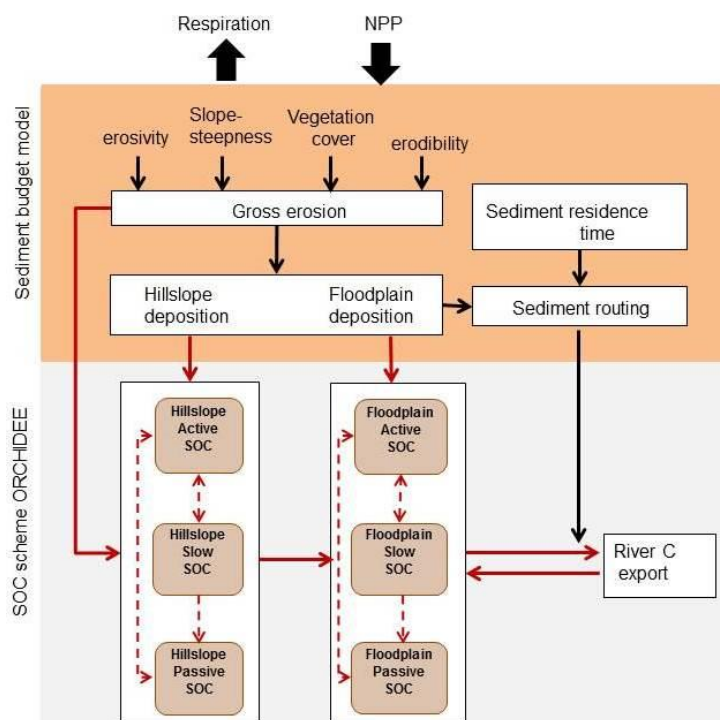

851 **Table 3:** This table presents the scaling exponent (b) of equation 20 for floodplains and hillslopes. The scaling exponent
 852 was derived for selected points in the Rhine catchment for which measurements on the SOC storage were taken by
 853 Hoffmann et al. (2013), and at sub-basin level after the data on area and SOC stocks was aggregated for each of the 13 sub-
 854 basins of the Rhine.

	Scaling exponent floodplains	Scaling exponent hillslopes
Hoffmann et al. (2013)	1.23±0.06	1.08±0.07

This study (selected points where measurements were taken)	1.14	0.83
This study (based on the 13 sub-basins)	1.06	1.00

870 study and (B) RUSLE2015

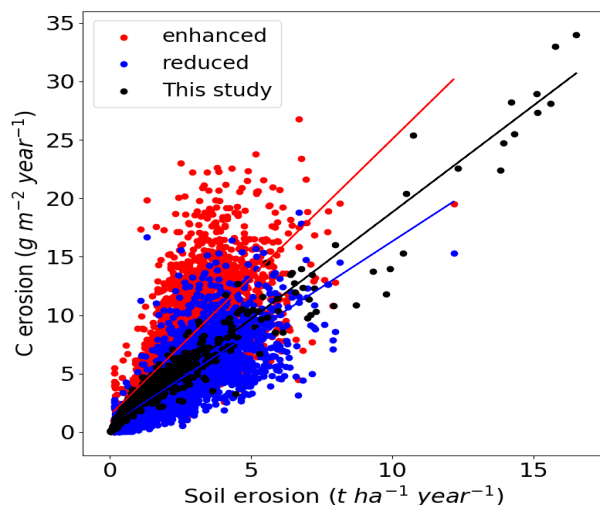

871

872

873 **Figure 5:** (A) Hillslope C erosion rates and, (B) C deposition rates, compared to the enhanced erosion scenario from
874 Lugato et al. (2018). (C) Hillslope C erosion rates and, (D) C deposition rates, compared to the reduced erosion scenario
875 from Lugato et al. (2018).

876

877 **Figure 6:** The relationship between soil erosion and C erosion of simulation S2 (black points) in comparison to the erosion
878 scenarios from the study of Lugato et al. (2018) with enhanced (red points) and reduced erosion (blue points), respectively.
879 The straight lines are the trendlines of the linear regression between soil and C erosion.

880

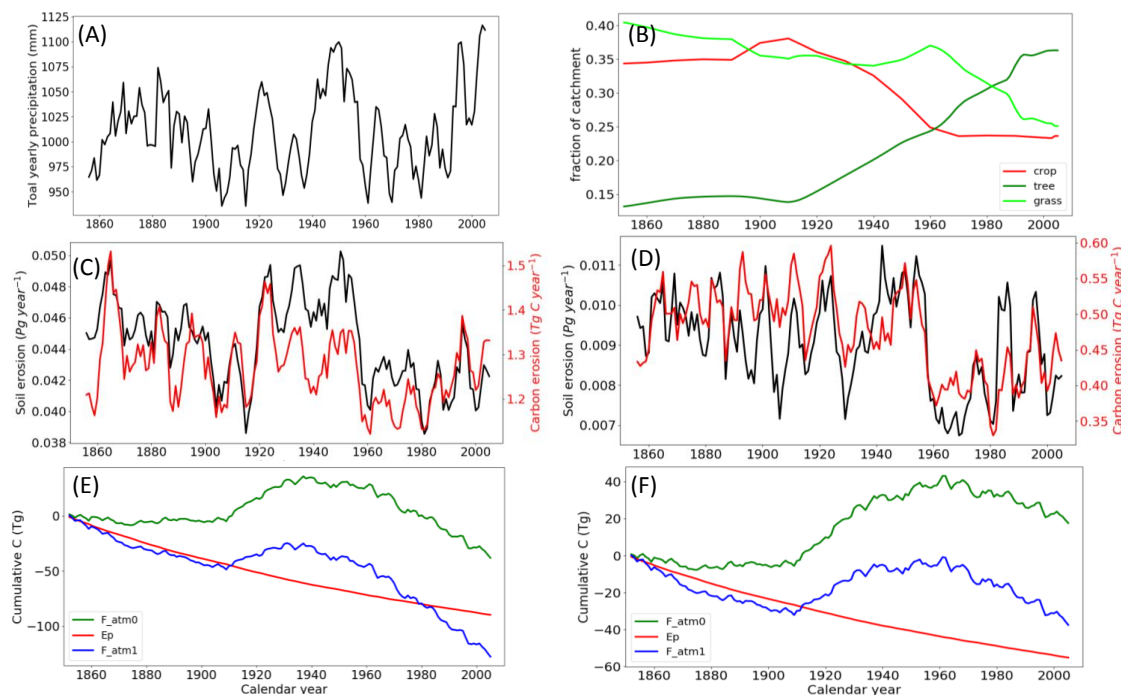

881 **Figure 7:** Comparison of total SOC stocks per land cover type between the simulation without erosion (red boxes), the
 882 simulation with erosion (black boxes) and the LUCAS data (green boxes). The red horizontal lines are the medians, the
 883 blue stars are the means, the dashed vertical lines represent the range between the minimum and maximum, and the black
 884 dots are the outliers.

889 **Figure 8:** Timeseries of (A) the 5-year average yearly precipitation of the entire Rhine catchment (mm), (B) changing land
 890 cover fractions of the entire Rhine catchment, (C): 5-year average of the total gross soil erosion (Pg year^{-1}) and C
 891 erosion rates (Tg C year^{-1}) of the **entire Rhine** catchment, (D): 5-year average of the total gross soil erosion (Pg year^{-1}) and C
 892 erosion rates (Tg C year^{-1}) of the **non-Alpine region** of the Rhine. Erosion on bare soil is not taken into account here. (E)
 893 Cumulative C emissions from the soil to the atmosphere under land use change and climate change without soil erosion
 894 (F_{atm0}), with soil erosion (F_{atm1}), due to additional respiration or stabilization of buried soil and photosynthetic
 895 replacement of C under erosion (E_p) of the **entire Rhine** catchment. (F) Cumulative C emissions from the soil for the **non-**
 896 **Alpine part** of the Rhine catchment. Positive values indicate net C emissions to the atmosphere and negative values
 897 indicate net C uptake from the atmosphere by the soil.

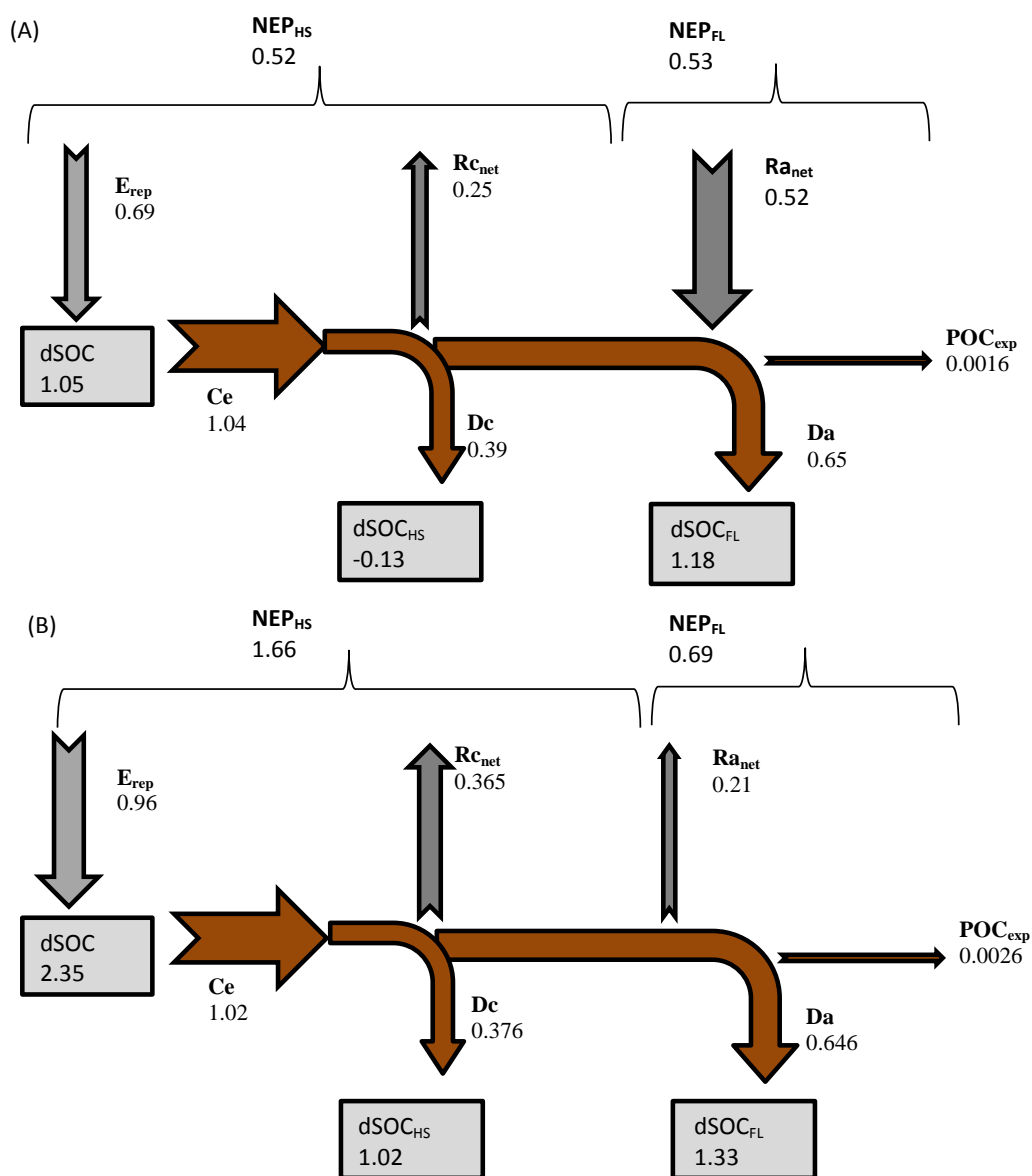

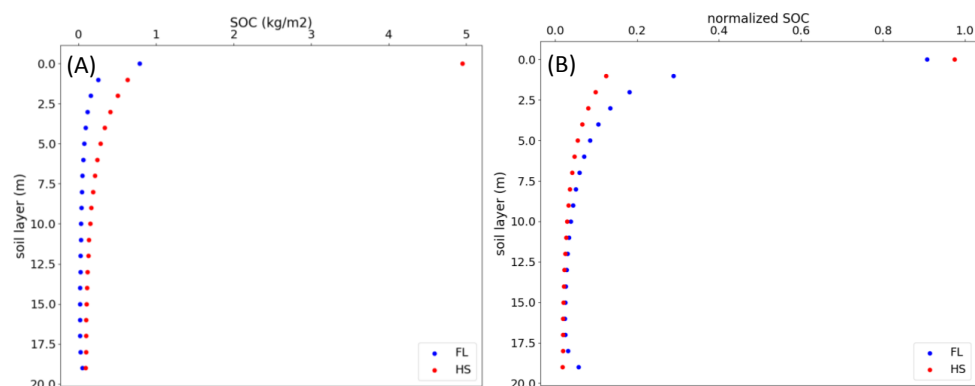

Figure 9: (A) C budget of the entire Rhine for the period 1851-1861, and (B) for the period 1995-2005. The budget shows the net exchange of C ($Tg\ C\ year^{-1}$) between the soil and atmosphere as a result of accelerated soil erosion rates. Grey arrows are the erosion-induced yearly average vertical C fluxes, while the brown arrows are the erosion-induced yearly

929 average **lateral** C fluxes. The grey boxes represent yearly average changes in SOC stocks for the specific time period as a
930 result of land use change, climate change, erosion and deposition. Dc: Deposition of C on hillslopes; Da: Deposition of C
931 in floodplains; POC_{exp}: net POC export flux; NEP_{HS}: Net ecosystem productivity of hillslopes; NEP_{FL}: Net ecosystem
932 productivity of floodplains; dSOC: Yearly average change in the total SOC stock; dSOC_{HS}: Yearly average change in the
933 hillslope SOC stock; dSOC_{FL}: Yearly average change in the floodplain SOC stock.

935
936 **Figure 10:** (A) Vertical distribution of hillslope (red) and floodplain (blue) SOC stocks (kg m^{-2}) with depth averaged over
937 the whole Rhine catchment, and (B) the vertical distribution of normalized hillslope (red) and floodplain (blue) SOC stocks
938 (dimensionless) with depth averaged over the whole Rhine catchment.
