Concerns: Model Description Article for submission to Geoscientific Model Development

Dear Editor,

It is our pleasure to submit a revised version of our manuscript:

**FORHYCS v1.0: A spatially distributed model combining hydrology and forest dynamics**

by Matthias Speich, Massimiliano Zappa, Marc Scherstjanoi and Heike Lischke

We are grateful for the two thorough reviews of our manuscript and believe that we were able to address all of the reviewers’ concerns. The manuscript now also includes model runs with meteorological forcing from the climate models of the EURO-CORDEX experiment. Also, to comply with GMD’s guidelines, the model code is now publicly accessible on a permanent repository. Finally, the reviewers have pointed out several incomplete and unclear formulations, which we have now corrected and clarified.

Please find, in this document, our point-by-point response to the two reviewers and a marked version of our manuscript, tracking all modifications from the previous version.

We are looking forward to reading your response.

Kind regards from Switzerland, on behalf of all authors

Matthias Speich
matthias.speich@wsl.ch
Response to the comments of Reviewer #1

This is an update to the response submitted to the comments of Reviewer #1 in the interactive discussion. This version also describes how the changes were included in the revised manuscript. All changes to the original response document are marked in italic. Page and line numbers of the new manuscript refer to the marked version.

We would like to thank the reviewer for their thorough response to our manuscript. Their comments will be very helpful to improve our manuscript. We are glad to take the opportunity of this discussion format to address the points they raise.

My first comment is more a question out of curiosity, as the overestimation of LAI by the model intrigues me. It will strongly depend on the formulation of leaf area dynamics in Eq. 1, so how confident are you that this equation (or more the parameterization of this equation) is correct? How many trees were for example used to derive the allometric relations? Besides, the species specific parameters (like SLA, and a1,a2 ) are not reported, also not in the Supplement, so can you add these? So in general, could your leaf area formulation be the reason for the observed over-estimation?

The equation for leaf area and its parameterization are taken directly from the original TreeMig. They have originally been parameterized by Bugmann (1994, 1996) for the gap model FORCLIM, which shares many process formulations with TreeMig. The basis for the parameterization is the dataset collected by Burger (1945 - 1953), consisting of measurements of tree height, diameter and leaf area on 583 trees of five species or species groups. Tree species not represented in the dataset are assigned to one of the represented species, still following Bugmann (1994). The number of trees for each species, and specific parameters are given in the appendix of Bugmann (1994). Since this document is not widely available, we will repeat this information in a new version of the Supplement.

Section 1.3 of the Supplement now contains the parameter values for the allometric leaf area function, as well as some background information on the data source.

I am also a bit confused by equation 3. The fractional cover in LSM’s or remote sensing products is often related related to LAI by the Lambert-Beer relation: FC = 1 – exp( -K * LAI), where LAI is the total leaf area index (or crown index), FC is fractional cover, K is an extinction coefficient, (e.g. Bréda, 2003; Choudhury, 1987; Monsi, 2004). The extinction coefficient is a function of leaf inclination and often set to 0.5. Here, this seems to be set to 1 for all species, which seems a bit high, is that correct? In addition, why are the exponents summed? Shouldn’t you just add up the different final fractional covers of the species when the area stays the same? This is also what you describe on page 17 (if I am not mistaken), where you take the cumulative sums of the classes.

The calculation of fractional cover in FORHYCS is independent from the calculation of LAI. Instead, it is based on crown area, which is calculated from tree height using species-specific empirical relationships (the formula and its species-specific coefficients are reported in the supplementary material of Zurbrüggen et al. (2014), Section B5). This way, it is not necessary to estimate an extinction coefficient.
The procedure used here and in Zurbriggen et al. (2014) was originally developed by Crookston and Stage (1999). It is based on the assumption that trees are randomly distributed in space (which is consistent with the way light penetration is calculated in TreeMig) and accounts for overlap between crowns. On page 17, the same procedure is applied. For example, applying Eq. 3 to the upper 3 height classes will return the fractional cover for the trees belonging to these classes, accounting for overlap between them. This assumes that shading of lower parts of the crowns by smaller trees can be neglected.

In a revised version of the manuscript, these two assumptions (random distribution and no shading by shorter trees) will be explicitly stated in Section 2.2.3 (currently p. 17). In addition, to clarify that the same procedure is being used, a modified version of Eq. 3 will be introduced in the same section:

\[
 f_{c,i} = 1 - \exp \left( -1 \times \sum_{sp=1}^{n_{sp}} \sum_{hc=i}^{n_{hc}} \left( n_{sp,hc} / 833 \right) \times CA_{sp,hc} \right),
\]

where \( f_{c,i} \) is the fractional cover of the \( i \) upper height classes.

In the new manuscript, it is pointed out explicitly that LAI and fractional cover are calculated independently from each other (p8 l23). Also, the calculation of cumulative fractional cover by height class and the assumptions behind it are explicitly described, as discussed above (p18 l23).

In addition, LAI and fractional cover are compared by two newly developed error measures, which only compare on one specific moment in time. However, getting the seasonality right in these models is quite important, and one of the minimum things the model should be able to represent is the seasonal signal. Did you compare the timeseries of simulated and observed LAI? It’s rather simple to do, and, in my view, provides much more information then the error measures as presented by the authors. So how well is the seasonality captured by the model?

Indeed, these metrics focus on the canopy structure at full foliage cover. This is intentional, as their purpose is to evaluate the forest structure and improvements over stand-alone TreeMig (hence the comparison with TreeMig in Fig. 7 and 8). An evaluation of the intra-annual variations in leaf area was not carried out for the following reasons:

- As seen on Fig. 6, the observed and simulated distribution of species do not match well (for the reasons discussed in Section 4.2, p. 34 l4-9). Therefore, a good fit to phenological observations is not to be expected.
- In another study (Speich et al., 2018a), the sensitivity of a water-balance model (corresponding to the surface water balance part of FORHYCS) to vegetation properties was assessed. It was found that long-term water partitioning was not very sensitive to growing season length (defined as the number of days with full foliage), as compared to LAI at full foliage. As long-term annual streamflow is the main hydrological output of interest in this case study, we chose not to evaluate simulated phenology in detail.
- While they do not constitute a validation, the error metrics obtained during the calibration of the phenology submodel (reported in Tables S3 and S4 in the Supplement) give an indication of its strength. As discussed in the Supplement, spring phenology can be reproduced reasonably well in most cases, whereas
I am also a bit confused on how the effect of elevated CO2 is studied. How can you evaluate the effect of elevated CO2 if you switch off the stomatal response to high CO2 (P22.L3)? Do you mean you keep the conductance the same? It would be much more interesting to keep the feedbacks in place, so why do you do this? However, later on in the manuscript, the stomatal conductance is discussed, so can you clarify what you do exactly?

Our formulation here may indeed be unclear. In most simulation runs, the effect of elevated CO2 on stomatal resistance (Eq. 12) is active, i.e. stomatal resistance is impacted by atmospheric CO2 concentration. As this is a new addition (there is no CO2 effect either in PREVAH or in the water balance model described in Speich et al. (2018a)), the purpose of the NCS runs is to test the strength of this effect. Therefore, in the NCS runs, the stomatal effect of CO2 is switched off, i.e. Eq. 12 is set to 1. Comparing the NCS runs with the standard runs will give an indication of how strong the CO2 effect in the model is.

This is now clarified (p21 l20).

I am not too familiar with PREVAH, unfortunately, but the authors state that the model structure is similar to HBV. That would mean there are also several parameters that do not relate to vegetation (such as recession parameters, routing, snow parameters), so how are these determined? It can also be seen in Figure 5 that snow melt and recessions are quite off compared to the observations, which is probably just due to the remaining parameters. It may also affect the conclusions based on the climate change scenarios, as the snow melt is highly affected by the temperature changes.

Indeed, there are various parameters related to non-vegetation aspects. Some of these parameters are constant for the whole study area; others are spatially variable and have a different value for each grid cell. The spatially variable parameter values were determined in a previous study (Zappa and Bernhard 2012) based on the regionalization method of Viviroli et al. (2009). The spatially constant parameters were also taken from previous studies. As a different dataset for soil water holding capacity was used in this study (see Section 2.2.2), some parameters were manually adjusted to improve the optical fit of the streamflow lines. Due to the proof-of-concept nature of this study, a full calibration was not undertaken.

In a revised version, we will provide the reference for the spatially variable parameter values, as well as the values used for the spatially constant parameters, in the Supplement.

The source for the parameter values used is now given in Section 1.7.2 of the Supplement (referred to from p.17 l.5 in the main text).

My last, but most important comment is on several key-findings which do not seem to be (entirely) supported by data. For example, one of the key findings presented in the manuscript concerns the effect of the climate change scenarios on streamflow. However, the result of only one specific catchment is shown in
Figure 10, how do the results for the other catchments look like? Similarly, an analysis on elevated CO2-levels is described, but no results are shown in any of the graphs. Please add some graphs and evidence to support the statements you make here.

We agree that these figures are necessary to give the full picture. At the end of this document, we include the future streamflow projections and differences between model configurations (equivalent to Fig. 10) for the other four catchments, as well as the differences in streamflow for model runs with and without CO2 effect on stomatal resistance. In a revised version, we will include these figures in the Supplement and refer to them in the Discussion.

The Supplement now contains figures for mean annual streamflow under future scenarios for subcatchments 2-5 (S18-S21), and for a comparison of streamflow with and without the effect of CO2 concentration (S22).

Minor comments

I would like to suggest to change names of the modelling scenarios into more meaningful names, or add clarifications in the text when discussing a certain scenario. Names like Succ_TM_BEK, or T6_P10, are not very informative and make it hard to understand what happens without looking at the table all the time.

We welcome this comment, as this may indeed be a factor that makes it difficult to follow the text. We will take this into consideration when submitting a new version, and modify the text and figures accordingly.

The names of runs have been revised (Table 1) and the use of run names is now consistent throughout the manuscript. Also, a new paragraph explains the nomenclature for the different model runs (p.19 l.19).

P8.L8-9. In this way, the equation does not seem consistent in units. What is the unit of Pd,sp?

The phenological status p_d,sp is dimensionless and ranges from 0 to 1. Its purpose is to scale leaf area when the foliage is not fully developed (in autumn, winter and spring). We forgot to specify the unit [-] for this variable in the text and will correct this in a revised version.

This has been clarified (p.8 l.10).

P8.L10. This seems a rather arbitrary number to me, why 833 m2?

This number has its origin in the gap model FORCLIM (Bugmann 1994, 1996), from which many process formulations of TreeMig were taken. In FORCLIM, 833 m² is the reference area of a simulated forest plot (roughly equivalent to the crown area of a large, dominant tree).

This has been clarified (p.8 l.12).
How does crown area relate to leaf area?

As noted in our response to the second comment, leaf area and crown area are calculated independently from each other, both using empirical relationships with tree size.

So the used transpiration values are model outputs, correct?

Yes, both actual and potential transpiration are simulated in the surface water balance part of the model.

This has been clarified (p.9 l.29).

Is fDS not a single yearly value, as DI is a single year value too? What do you use to calculate the geometric mean in that case?

Indeed, there is some information missing here to properly follow. Modeled tree growth depends on an environment-dependent function ranging from 0 (maximum stress) to 1 (unstressed conditions). This function is the geometric mean of three functions:

- The drought stress function fDS (Eq. 6)
- The effect of degree-day sum (Eq. S8 in the supplement)
- A stress function describing the effect of nitrogen supply

The last function is not mentioned in the manuscript, as the nitrogen supply is kept constant over the whole study area and period. Nevertheless, as this part of the model cannot be described without this function, it will be included into the supplement.

The description of the stress functions has been corrected and clarified in the main text (p.10 l.11 and following) and in the Supplement (Section 1.2).

“i.e. with a decrease...is at kDT”, I am not sure I follow, can you please clarify?

There is a mistake in this sentence – this is not about LAI, but tree height. The correct version is (also modified for additional clarity): “The former is parameterized following Rasche et al. (2012), i.e. species-specific maximum tree height may be reduced as a function of the bioclimatic indices DI and DDEGS. The parameter \( k_{red,max} \), which is also species-specific, indicates the fraction of maximum height that can be attained by trees if one of the environmental vitality functions is at its minimum. The more severe of the two reductions (drought or degree-days) is applied.”

The text has been clarified as described above (p.10 l.23 and following).

Why did you use these numbers? Seems a bit arbitrary.
First, we noticed that there was a mistake in the way Eq. 12 is reported. The parameter \( j_c \) is equivalent to \((1-a)\) in Medlyn et al. (2001) (their Eq. 5). Therefore, the correct version of Eq. 12 is:

\[
f_5 = \left(1 - j_c \left(\frac{\min(C_{a(700)})}{350}\right) - 1\right)^{-1}.
\]

The values for \( j_c \) were set based on the results reported by Medlyn et al. (2001): coniferous species had a value of \((1-a)\) between 0 and 0.2, whereas broadleaves had values up to 0.4. Therefore, for conifers, a value of 0.1 was selected. For broadleaves, as there seemed to be some acclimation for trees growing in elevated \( \text{CO}_2 \), a more conservative (than 0.4) value of 0.25 was chosen. The value for mixed forests corresponds to the arithmetic mean of the two.

*The text has been corrected and clarified as described above (p.12 l.7 and following).*

**P13. So PPo includes the carbon costs? What are these values based on?**

This variable is described in Speich et al. (2018b), and combines the plant-specific characteristics of Eq. 13 as follows:

\[
PP_o = \frac{\gamma_{r,20} b_r}{L_w p_h}
\]

where \( \gamma_{r,20} \) is the root respiration rate at 20 °C. The actual root respiration rate is dependent on annually averaged temperature via a \( Q_{10} \) function, as described in Speich et al. (2018b). These details are indeed important, and will be included in the new version.

*The description of the rooting depth module has been completed (p.13 l.21 and following).*

**P16.L1-5. If a large amount is diverted by pipelines, can you compare modelled and observed discharge? Which sub-catchments are affected by this?**

The streamflow data used in this study was obtained from the company operating the power plants and includes the amount of water diverted through the different pipelines. From this, time series of natural streamflow were reconstructed, which were used as observations.

*The text has been completed as described above (p.17 l.23 and following).*

**P16.L27. “As the sampling plots... a larger area.” This sentence is a bit unclear to me, what do you mean?**

Here, we explain why it does not make sense to compare simulations and observations at the scale of single inventory sampling plots (which is sometimes still being done). New formulation to clarify: „As the sampling plots of the NFI are distributed on a regular grid, each plot is randomly selected from all forest plots in that region, and may not be considered representative for a larger area. It is therefore not sensible to compare simulated and observed biomass at the scale of single inventory plots. Instead, the 245 NFI plots in the study area were aggregated to seven classes based on aspect and elevation,
with four elevation bands for North-facing plots and three for South-facing plots. This way, each class has a sample size of at least 30 plots, which ensures that the averages are representative."

*The text has been clarified as described above (p.17 l.28 and following).*

**P17.L19. Please correct reference**

Thank you for catching this.

**P22.L31 The plot only shows Acer spp., so how can I see this?**

This is indeed not visible on Fig. 6. However, it seems that differentiating between the three Acer species will add little value to the figure (especially as the Acer spp. band is quite thin in all plots), while making the plots harder to read. We will rephrase the text to make it clear that this is not visible on the plots.

*The text has been clarified as discussed above (p.26 l.1).*

**P24.L21. This sounds a bit counter-intuitive, wouldn’t you expect a higher biomass when there is no LAI-reduction? What is the reason for this?**

An important point to keep in mind (which should be made clearer in the manuscript) is that TreeMig/FORHYCS does not explicitly simulate carbon cycling/allocation (see also response to the next point). Hence, there is no direct effect of LAI reduction on biomass. Such effects are implicitly simulated through the environmental stress functions such as Eq. 6.

Two main effects happen in the model as a result of LAI reduction: the drought index (Eq. 5) is lower than it would be without LAI reduction; and the light distribution is modified, i.e. lower height classes get more light than they would get without LAI reduction. These two effects both promote tree growth, which explains why the model simulates higher biomass. This higher growth also eventually leads to greater mortality, after the number and size of trees have grown fast for some years. This explains the more dynamic pattern when LAI reduction is activated (Fig. S9).

These effects indeed need to be discussed in the text, and will be included in Section 4.2 (Effect of coupling on forest simulations) in a revised version.

*The text now points out that there is no direct link between the assimilation partitioning described in Eqs. 8-11 and simulated biomass (p.11 l.17). The effects discussed above are now part of the Discussion in Section 4.2 (p.37 l.10 and following).*

**P29.L10-11. Is this not counter-intuitive too? You would expect (also because of equations 7 and 8, where additional carbon is allocated for roots under stress) that the roots will go deeper in case of drier scenarios, and that LAI would go down, correct?**

As noted in the response to the previous comment, there is no simulation of carbon uptake and allocation in the model. Eqs. 7 and 8 have no (direct) influence on the development of roots – they only influence the LAI reduction (which is switched off on the simulation described here). These equations were included because they represent a
sound and plausible way to parameterize reduction of leaf area due to environmental stress. This comes at the price of inconsistent formulations between Eqs. 7-11 (where carbon allocation fraction to roots is calculated as an auxiliary variable to determine the degree of leaf area reduction) and Eq. 13 (which determines rooting depth). As the allocation fractions of Eqs. 7-11 are not used anywhere else, we argue that this inconsistency can be tolerated. However, in a new version of this manuscript, we will need to make it clearer that Eqs. 7-11 only affect leaf area. The rooting depth scheme used in FORHYCS assumes that plants dimension their rooting systems to optimize for net carbon gain. In this scheme, rooting depth does not necessarily increase with a drier climate. In some cases (like the low-elevation regions under drying scenarios, as discussed here), it may not be worth it for the plants to invest more carbon into roots. This is a point that should be included in the discussion (where a link can be made to Speich et al. (2018b), where the behavior of this rooting depth scheme was examined under various environmental conditions).

The part of the Discussion relating to coupled modeling under climate change (Section 4.3) has been expanded to include a discussion of rooting depth (p.38 l.27 and following).

**P31.L4-5. You described earlier that Eq. 12 was set to 1, correct?**

Only in the NCS runs – in all other runs, the effect of CO2 concentration on stomatal resistance is activated (see our response to the corresponding point above).

**P32.L4-14. How different are the landuses eventually at the end of the runs? Are the differences mainly due to different forest covers under the different scenarios?**

There is no other mechanism for land cover change in the model than forest growth or retreat. In the runs with land-cover change enabled, the forest biomass in the cells initially belonging to the „potentially forested“ land cover classes reaches up to 150 t/ha at the end of the simulation (these values vary with climate scenario and elevation band). This information is indeed important to follow the presentation and discussion of these results, and will be included in the new version.

This information is now given in the Results section (p.33 l.24); it was mentioned in the Discussion in the previous version.

**P33.L14. Based on the data as shown, you cannot claim that the sensitivity of streamflow to vegetation properties varies spatially. This would also mean you need to have the same vegetation in different places and observed different changes in streamflow, but I believe that is not the case.**

This sentence was indeed formulated in an ambiguous/misleading way, and this is not the point that we wanted to make here (the sensitivity of water balance to absolute values of vegetation properties was the subject of another of our studies (Speich et al. 2018a)).

Rather, the point here is that the effect of model coupling (i.e. of dynamically varying the values of vegetation properties) varies spatially. This statement (which will be corrected/clarified in the new version) is directly based on the results discussed immediately before.
This sentence has now been clarified (p.36 l.1).

P37.L7-8. “the greatest effects occurred at low elevations, and in regions currently above the treeline”, where do you show this? Please back this up with some evidence in the main manuscript, especially when it is a key-finding.

This is directly linked to the statement discussed in the previous point, with the greatest changes in streamflow occurring in the Chippis subcatchment (Fig. 10 and its equivalents for the other subcatchments, to be included in the supplement) and in the currently unforested, high-elevation subcatchments if forest is allowed to grow there (Fig. 11).

Eq3. Please define all variables and subscripts

Table 1. There two Succ_noHmax-scenarios, please correct.

Table 2. Please describe the abbreviations in the caption or replace them with a description.

Fig 1a. Please define SFC also in the figure.

OK to all

Fig 5. There are a couple of things that seem a bit odd to me in this plot. In Fig 5a, Prevah seems to be much closer to the observations then the other two model set-ups, but in Table 2 the KGE-values are lower. Is that correct? In addition, Forhycs00 and Forhycs11 are on top of each other in Figure 5a, whereas Figure 5b suggests a difference of up to 0.3 m3/s.

What may create some confusion in this figure is that the lines in Fig. 5a are presented as 30-day rolling averages, while the line in Fig. 5b is not. For example, at the time of the greatest difference (Fig. 5b) in early 2005, the lines on Fig. 5a depart slightly but visibly from each other. If the lines on Fig. 5a were not presented as rolling averages, this difference would be more pronounced, but the plot would be more difficult to read.

The caption of Fig. 5 now mentions that Fig. 5b does not show rolling means.

Code availability: I would suggest to share your code on github or gitlab, instead of the supplement. Please also add links to the actual datasets used in the study.

It is feasible to create a public repository for the model code. However, due to the different levels and structure of documentation in the code of the original models, it may be rather difficult to study the model code. Due to restrictions from the provider of the meteorological data, it is unfortunately impossible to give access to the data used to drive the model.

As requested by GMD’s editors, the model code is now hosted in a permanent repository and publicly accessible.
Appendix A: Why is there an appendix in the main manuscript and also a supplement? Should Table A1 not just be part of the Supplement then?

This can be done, it is certainly a good idea to keep the main document as lean as possible.

This table is now part of the supplement

New Figures

2. Torrent du Moulin – uncoupled FORHYCS (Clim_00)

Equivalent to Fig. 10 for the Moulin subcatchment – to be added to the Supplement.

3. Vissoie – uncoupled FORHYCS (Clim_00)

Equivalent to Fig. 10 for the Vissoie subcatchment – to be added to the Supplement.
Equivalent to Fig. 10 for the Mottec subcatchment – to be added to the Supplement.

Equivalent to Fig. 10 for the Moiry subcatchment – to be added to the Supplement.
Modification of simulated mean annual streamflow if the effect of CO₂ concentration on stomatal resistance is enabled. To be added to the supplement.
Response to the comments of Reviewer #2

This is an update to the response submitted to the comments of Reviewer #1 in the interactive discussion. This version also describes how the changes were included in the revised manuscript. All changes to the original response document are marked in italic. Page and line numbers of the new manuscript refer to the marked version.

We would like to thank the reviewer for their thorough response to our manuscript. Their comments will be very helpful to improve our manuscript. We are glad to take the opportunity of this discussion format to address the points they raise.

My main concern about the research is, this study area is not an ideal watershed for doing the experiments. Since we are talking about coupling a forest model with a hydrological model, we better have a catchment that is covered with forest. The five subcatchments of Navizence, have 30% forested area in Chippis (but no streamflow data) and ~15% forested area in Vissoie. The other three catchments have negligible fraction of forested area. That might be part of the reason that we don’t see much hydrograph difference between uncoupled and coupled runs even in the most forested catchment Vissoie. In fact the uncoupled-coupled streamflow differences are smaller in the other less forested catchments

The relative fractions of currently forested, potentially forested and never-forested area are shown on Fig. 2. The fractions of forested area are higher than the numbers stated in the review: more than half of the Chippis subcatchment is currently forested (> 25 km² out of ~50 km²), and for Vissoie, this number is about 25% (~15 out of ~60 km²).

The abandonment of pastures and replacement with forests is an ongoing process in this region, and is expected to continue given current socio-economic trends (see Price et al. 2016). Therefore, the potentially forested area is also relevant, and the behavior of the model for this situation is also tested in this study. For the five subcatchments of this study, the fractions of currently and potentially forested area are ~ 90% (Chippis), 66% (Torrent du Moulin), 70% (Vissoie), 25% (Mottec), 33% (Moiry/Lona).

Considering also the other reasons for selecting this study region, listed in Section 2.2 (p.14f) (strong ecological and hydro-climatic gradient due to elevation differences), we argue that this is a suitable study region for testing the model. Another study is planned in which we apply FORHYCS to several catchments representing different hydro-climatic regions of Switzerland.

It would be great if authors could acquire downscaled meteorological data from latest climate modeling scenarios and test the FORHYC with those time series data. It’s not that the delta method (e.g. ±degrees and/or precipitation) isn’t scientifically sound, but the climate modeling data provides more variation and insight to the change of climate.

In the framework of an ongoing study, we have acquired the CH2018 scenarios (NCCS 2018), based on the EURO-CORDEX simulations. Given the scope of this study, it does not seem necessary to run FORHYCS with all 39 model chains. Instead, we suggest providing results for the three chains selected by Brunner et al. (2019) as representative for dry, medium and wet conditions (in addition to the delta runs).
The study now includes simulations with meteorological forcing from three GCM-RCM chains. These model chains are presented in Section 2.2.4 (p.21 l.23 and following). The Supplement shows how precipitation and temperature develop in these three model chains (Fig. S2-S5). The output from the FORHYCS simulations with meteorological forcing has been added to Figs. 9 and 10.

P1L12-13: give names of the two new metrics.

The names for these metrics (dH95 and 1-ABC) are introduced in Section 2.2.3.

P2L22: what aspects of mountainous regions are sensitive to what type of global change?

We will be more specific on this in a revised version and mention the following aspects:

- Strong influence of snow storage on hydrology, which may change with warming.
- Warmer and drier conditions may alter species composition in temperature-limited ecosystems.
- Upwards shift of treeline.

This has been completed (p.2 l.24).

P8L7: explain Al, is it the stand leaf area?

Yes – we will include this in the text.

This has been clarified (p.8 l.8).

P9L3: define EDI, is it Evaporative Demand Index?

This is a remainder of an old version of the text, thank you for catching this. This refers to the drought index used in TreeMig, and described in the rest of the paragraph. The symbol “EDI” will be removed.

This has been corrected (p.9 l.25).

P10L5: again, define fDS.

Vitality reduction function due to drought stress. Based on the comments of Reviewer #1, this passage will need to be clarified. We will also consider this remark.

The description of the vitality reduction functions has been clarified (p.10 l.11 and following).

P14L7: forest minimum stomatal resistance at 180 s m-1 seems to be at the lower end of what has been reported. The stomatal/canopy resistance could be one of the most influential parameters when it comes to estimating transpiration (not sure about this PREVAH model). Why is a single number resistance superior to the previous “minimum canopy resistance for each land cover class”? In any case, the
number needs to be justified according to the region and species being applied in this particular study.

This concerns only uncoupled FORHYCS, i.e. a simultaneous run of the hydrological and forest parts of the model without any transfer of information between them. For coupled FORHYCS, minimum stomatal resistance is parameterized according to species and tree height, as described in Section 1.3.2 of the Supplement (which we forgot to reference from the main text – this will be fixed in a new version).

Uncoupled FORHYCS is not meant to represent an improvement from stand-alone PREVAH. Rather, its purpose here is to provide a comparable baseline against which to assess the effect of the coupling. This was not done directly against stand-alone PREVAH for the reason stated in Section 2.1.7 (PREVAH uses a different dataset for soil water storage capacity which is incompatible with the new water balance module).

In another study (Speich et al. 2018a), we found that RSMIN was a rather influential vegetation property for simulated annual water balance (though not as influential as soil water storage capacity or LAI). This was one of the motivations for coupling the models. For uncoupled FORHYCS, the value of 180 s/m was selected as a standard value from the literature (see the cited reference of Guan and Wilson 2009, who base their choice on the review by Körner (1994)). For comparison, in another study in a region nearby (Peters et al. 2019), stomatal resistances of 128 s/m and 285 s/m were found for Larix decidua and Picea abies, respectively.

P22L9-23: I’ve got confused by the streamflow simulations. How was the model calibrated to generate these KGE scores? I assume the PREVAH/FORHYCS were “tuned” to their best performance before the series of experiment. It seems three modeling runs generated model efficiencies that vary from catchment to catchment. Would some other combinations of parameterization make the results look differently?

As Reviewer #1 had a similar comment, here is our answer to their question regarding calibration:

Indeed, there are various parameters related to non-vegetation aspects. Some of these parameters are constant for the whole study area; others are spatially variable and have a different value for each grid cell. The spatially variable parameter values were determined in a previous study (Zappa and Bernhard 2012) based on the regionalization method of Viviroli et al. (2009). The spatially constant parameters were also taken from previous studies. As a different dataset for soil water holding capacity was used in this study (see Section 2.2.2), some parameters were manually adjusted to improve the optical fit of the streamflow lines. Due to the proof-of-concept nature of this study, a full calibration was not undertaken. In a revised version, we will provide the reference for the spatially variable parameter values, as well as the values used for the spatially constant parameters, in the Supplement.

P23-Figure 5: I’d suggest giving PREVAH a solid light grey line to make it easier to read the difference between FORHYCS00 and FORHYCS11 (which matters more).
labels from different simulations need to be unified. For example, Succ_TM_BEK is BEK in the Figure 8?

Based on comments from Reviewer #1, we will reconsider the naming of the different runs. We will also take this comment into account.

The names of runs have been revised (Table 1) and the use of run names is now consistent throughout the manuscript. Also, a new paragraph explains the nomenclature for the different model runs (p.19 l.19).

looks like a large part of the reason that uncoupled and coupled modeling runs were making rather subtle differences is, the catchment areas are not forested enough for the forest model to pass signals back to the hydrology module. If we look at the hydrologic modeling performance for catchments, Vissoie has more vegetated areas (other than Chippis, which has no observations), thus has the lowest KGE score. The other three catchments, none with meaningful forest fraction, perform much better without interplay with the forests.

It is plausible that the degree of forest cover had some influence for the KGE scores. However, I would also see it in the view of the different soil parameterizations used in PREVAH and uncoupled FORHYCS. Those differ in currently and potentially forested areas, so that lower performance is to be expected in those areas.

It is also worth considering that streamflow from the Mottec and Moiry subcatchments stems to a large extent from the glaciers, the water balance of which the model is able to simulate relatively well.

**Abstract.** We present FORHYCS (FORests and HYdrology under Climate Change in Switzerland), a distributed ecohydrological model to assess the impact of climate change on water resources and forest dynamics. FORHYCS is based on the coupling of the hydrological model PREV AH and the forest landscape model TreeMig. In a coupled simulation, both original models are executed simultaneously and exchange information through shared variables. The simulated canopy structure is summarized by the leaf area index (LAI), which affects local water balance calculations. On the other hand, an annual drought index is obtained from daily simulated potential and actual transpiration. This drought index affects tree growth and mortality, as well as a species-specific tree height limitation. The effective rooting depth is simulated as a function of climate, soil and simulated above-ground vegetation structure. Other interface variables include stomatal resistance and leaf phenology.

Case study simulations with the model were performed in the Navizence catchment in the Central Swiss Alps, with a sharp elevational gradient and climatic conditions ranging from dry inneralpine to high alpine. In a first experiment, the model was run for 500 years with different configurations. The results were compared against observations of vegetation properties from national forest inventories, remotely sensed LAI and high-resolution canopy height maps from stereo aerial images. Two new metrics are proposed for a quantitative comparison of observed and simulated canopy structure. In a second experiment, the model was run for 130 years under idealized climate change scenarios: daily temperature was increased by up to 6 K, and precipitation altered by 10 \%, with a gradual change over 35 years using both a delta change approach and meteorological forcing from downscaled GCM-RCM model chains.

The first experiment showed that model configuration greatly influences simulated vegetation structure. In particular, simulations where height limitation was dependent on environmental stress showed a much better fit to canopy height observations. Spatial patterns of simulated LAI were more realistic than for uncoupled simulations of the forest landscape model, although some model deficiencies are still evident. Under idealized climate change scenarios, the effect of the coupling varied regionally, with the greatest effects on simulated streamflow (up to 40 \( \text{mm y}^{-1} \) difference with respect to a simulation with static vegetation parameters) seen at the valley bottom and in regions currently above the treeline. This case study shows the importance of coupling hydrology and vegetation dynamics to simulate the impact of climate change on ecosystems. Nevertheless, it also
highlights some challenges of ecohydrological modelling, such as the need to realistically simulate plant response to increased CO₂ concentrations, and process uncertainty regarding future land cover changes.

1 Introduction

Of the manifold effects of climate change, many are expected to impact the interactions between the water cycle and forest dynamics. As a result of higher temperatures and shifts in precipitation regimes, an increase in the frequency and intensity of drought events is predicted (Allen et al., 2010), as experienced in Europe in 2003 and 2018. This may greatly affect tree growth and mortality, even in locations currently not subject to high water stress (Choat et al., 2012; Martin-Benito and Pederson, 2015). This affects hydrologically relevant vegetation properties such as leaf area index (LAI) (Tesemma et al., 2015), root depth or biomass (Bréda et al., 2006) and stomatal conductance, which vary with stand age or species composition (Ewers et al., 2005; Ford et al., 2011). These changes might affect streamflow, but also feed back on local conditions for growth by altering water availability. For example, various studies have shown that trees growing in thinner stands are subject to lower water stress, so that artificial thinning may mitigate drought effects on tree growth and mortality (Elkin et al., 2015) and increase water yield (McLaughlin et al., 2013). Also, hydrological sensitivity of catchments to climate change seems to depend on vegetation properties, with mixed forests showing a more stable water yield than catchments dominated by broadleaf or coniferous forests (Creed et al., 2014). Furthermore, increased atmospheric CO₂ is expected to impact hydrology through its effects on stomatal activity and plant productivity (Trancoso et al., 2017), although the long-term effects are still subject to high uncertainty and debate (Medlyn et al., 2011). Another ecohydrologically relevant component of global change is land-cover change, driven by change of human land use, but also by natural vegetation dynamics. Increases in forested area usually reduce streamflow (Andréassian, 2004; Bosch and Hewlett, 1982), although the magnitude of such changes varies strongly with catchment characteristics such as climate, soil and forest age (Andréassian, 2004). Also, catchment response is often non-stationary, especially in the case of afforestation or reforestation, where streamflow strongly depends on stand age (Farley et al., 2005). Recent model developments have aimed at improving predictions by including transient vegetation parameters to simulate the transition between forest and non-forest (Du et al., 2016; Nijzink et al., 2016).

Mountainous regions are particularly sensitive to global change. Among the main effects are the changing significance of seasonal snow storage (Speich et al., 2015), altered species composition in temperature-limited ecosystems (Mayor et al., 2017) and an upwards shift of the treeline (Gehrig-Fasel et al., 2007). Given the high significance of mountains for large-scale water supply (Viviroli et al., 2003), it is crucial to estimate how the factors affecting water supply will change in the future. In Switzerland, mountains make up two thirds of the territory and are of high importance for nature conservation, energy production, tourism and farming, among other sectors (SCNAT, 2012). Modeling studies predict a change in runoff regime due to increased temperatures, changing precipitation seasonality and glacier melt (Rössler et al., 2014), with important, but locally varying consequences for hydropower generation (Gaudard et al., 2014) and farming (Milano et al., 2015). Climate impacts on forests also vary locally, with an increase of drought stress predicted at lower elevations and improved growth conditions in energy-limited high-altitude forests (Bugmann et al., 2014), leading to shifting spatial patterns of species composition, tree
biomass and canopy cover (Bugmann et al., 2014; Fuhrer et al., 2006). The increased frequency of extreme droughts will probably be a more important factor than a change in long-term averages (Fuhrer et al., 2006). Additionally, abandonment of high-mountain pastures, driven by socio-economic processes, is an important factor of land-use change (Price et al., 2016), interacting with climate change to allow the tree line shift upwards (Gehrig-Fasel et al., 2007). These developments and predictions highlight the need for an integrated simulation of hydrology, forest dynamics and land use change in Switzerland.

1.1 Coupled models of hydrology and forest dynamics

Interactions between hydrology and vegetation dynamics are included in various types of dynamic models, with widely different areas of application, levels of complexity, and spatial and temporal resolutions (Fatichi et al., 2016). One such domain are land surface models (LSMs), which represent land surface processes in climate models (e.g. CLM; Lawrence et al., 2011). The main role of vegetation in these models is the partitioning of energy between sensible and latent heat fluxes. The latter consist of evaporation and transpiration, thus representing the coupling between vegetation, hydrology and the atmosphere. Over time, the representation of vegetation and evaporative fluxes in LSMs grew increasingly complex, moving from a simple vegetation-independent bucket model in early applications to a detailed description of vegetation processes, in particular physiological processes such as photosynthesis, carbon assimilation and nutrient cycling (see review by Seneviratne et al., 2010). For a representation of vegetation dynamics, climate models are sometimes coupled with dynamic global vegetation models (e.g. LPJ; Sitch et al., 2003), which can also be used for offline simulations. Although the primary objective of these models is to simulate vegetation patterns, they usually include a representation of terrestrial water balance, and are able to simulate river discharge (Gerten et al., 2004).

While these models typically operate at the global scale, and for computational efficiency simplify vegetation to a single average individual per plant type and coarse grid cell, some ecosystem models have been developed to depict vegetation structure, such as the dynamic vegetation model LPJ-GUESS (Smith et al., 2001), which is based on individual plants. Like LPJ, this model contains a soil hydrology module that can be used to calculate discharge, but such predictions were greatly improved by adding a coupling to a routing scheme (Tang et al., 2013). A sensitivity analysis by Pappas et al. (2013) pointed out that, despite of its detailed mechanistic representation of transpirational demand and stomatal closure that affects carbon uptake, water stress effects are represented inaccurately in LPJ-GUESS. As the various effects of water shortage on trees are well documented (McDowell et al., 2008), this may be seen as a weakness of LPJ-GUESS, especially since important plant functions, like cavitation or leaf area reduction under drought conditions are not implemented yet (Pappas et al., 2013; Manusch et al., 2014).

Another type of models representing the interface of hydrology and vegetation are forest water balance models. These usually simulate local water balance of forest stands to predict the influence of climatic change or forest management practices on growth conditions for trees. Examples include WAWAHAMO (Zierl, 2001) or BILJOU (Granier et al., 1999). These models may be coupled with dynamic forest models (Lischke and Zierl, 2002; Seely et al., 2015), or run with vegetation parameters assimilated from forest inventories (Zierl, 2001; De Cáceres et al., 2015) or remote sensing (Chakroun et al., 2014). Moreover,
most forest dynamics models include a water balance module (Bugmann and Cramer, 1998; Seidl et al., 2012). However, its role is usually restricted to quantifying soil moisture stress, and it is seldom used to predict streamflow.

Various hydrological models operating at catchment scale have been used to evaluate the effect of land use change, and the resulting change in vegetation, on streamflow. Such models include distributed models with a high spatial resolution, allowing for a detailed mapping of static vegetation parameters, e.g. DHSVM (Wigmosta et al., 1994). Other models include a simple vegetation growth module, such as SWAT (Watson et al., 2008) or SWIM (Wattenbach et al., 2005). More complex models include a detailed representation of average plant biomass growth, carbon and nutrient cycling, and hydrological processes, such as RHESSys (Tague and Band, 2004), or Tethys-Chloris (Fatichi et al., 2012).

Furthermore, the impact of vegetation dynamics on streamflow has also been studied with models that were not originally developed to this effect. For example, Sutmöller et al. (2011) used the physically-based, distributed hydrological model WaSiM-ETH (Schulla, 2015) to perform hydrological simulations with vegetation parameters derived from an individual based forest model driven by different forest management scenarios, which influence forest structure and species composition. Also, Schattan et al. (2013) applied the semi-conceptual hydrological model PREVAH (Gurtz et al., 1999) with vegetation parameters obtained from the forest landscape model TreeMig (Lischke et al., 2006). In the original versions of both these hydrological models, vegetation parameters were parameterized as a function of season and land cover class only. This one-way coupling impacted mean annual streamflow by about 10 mm year$^{-1}$ in two large catchments in Switzerland, whereas the effect on local water balance reached 40 mm year$^{-1}$ in individual cells. Similarly, a modeling experiment by Köplin et al. (2013) showed that including transient land cover changes, such as forest cover increase or decrease or glacier retreat, could substantially affect water balance predictions. Such experiments highlight the importance of considering the dynamics and spatial variability of vegetation properties in hydrological simulations.

So far, most of the models combining hydrology and vegetation processes have a strong biogeochemical focus, whereas successional dynamics and interspecific competition are rarely considered. Couplings between models that explicitly simulate forest dynamics and hydrological models have so far mostly been the object of experimental studies. The results from these experiments show that coupling these processes may substantially alter model results and behavior (Sutmöller et al., 2011; Schattan et al., 2013). This gives an opportunity to increase the confidence in simulated impacts of climate change on forested ecosystems. For reliable, country-level predictions of long-term climate impacts on water resources and forest structure and composition in a mountainous country such as Switzerland, a model should:

- explicitly simulate the feedbacks between forest properties and hydrology;
- return estimates of streamflow and (evapo)transpiration as well as tree species distribution and biomass;
- operate at a spatial resolution fine enough to account for the great variability in climate, topography and land cover;
- be able to simulate the hydrology of non-vegetated areas such as glaciers, bare rock or built-up
- take into account the possibility of forest expansion and retreat
- not be too complex, so that it can be run for large areas and long periods at a reasonable computational cost.
None of the models discussed above fulfil all these criteria. This motivated the development of a spatially distributed model combining hydrology and forest dynamics, presented below.

### 1.2 Aims of this work

In this paper, we present a newly developed distributed ecohydrological model, FORHYCS (FORests and HYdrology under Climate change in Switzerland). This model combines two existing models, the hydrological model PREVAH (Gurtz et al., 1999) and the forest landscape model TreeMig (Lischke et al., 2006). FORHYCS is spatially distributed and operates on a grid of regular cells. The model outputs are hydrological quantities, such as catchment-integrated streamflow and maps of runoff, transpiration, evaporation or snow cover, and maps of forest properties, such as biomass, leaf area index (LAI), species distribution and tree density. In FORHYCS, the two source models are run simultaneously, and exchange information through shared variables. FORHYCS may be run in uncoupled mode (i.e. parallel simulations of hydrology and forest dynamics, without any transfer of information between the two source models), with a one-way coupling (transfer of information from the forest landscape model to the hydrological model, or vice-versa), or in fully coupled mode.

Like its parent models, FORHYCS may be described as semi-conceptual. Hydrological processes (evaporation, transpiration, soil moisture dynamics and runoff generation) and forest dynamics (growth, mortality, establishment and migration of tree species) are based on physical and ecological theory as well as empirical approaches. Thus, the degree of complexity of FORHYCS is lower than other coupled ecohydrological models, such as RHESSys (Tague and Band, 2004). Also, unlike these models, the focus of the ecological part is on forest dynamics, similarly to the addition to SWIM proposed by (Wattenbach et al., 2005). However, FORHYCS differs from the latter approach in that growth and mortality are simulated at the level of species and size classes, instead of a single biomass pool per cell. Both TreeMig and PREVAH were designed for applications at an intermediate spatial resolution, with a cell size between 100 m and 1 km.

The goal of this paper is to explore the interplay of hydrology and forest dynamics in a coupled model. The questions to be answered are (1) How does the coupling impact the behavior and the performance of both TreeMig and PREVAH, compared to uncoupled simulations? (2) Which aspects of the forest-hydrology coupling are of greatest importance for simulation results? (3) What are the implications of model coupling for simulations under climate change?

The model is tested in five subcatchments of the Navizence catchment (27 to 87 km$^2$), located in the Swiss Central Alps. To answer the first question, a full forest succession is modeled for the period 1500-2015, starting from bare soil. The forest model is run in uncoupled mode to serve as a reference simulation. For the coupled runs, various configurations are tested, with different aspects of the coupling between hydrology and forest dynamics switched on and off. The outputs are then compared to forest inventory data, as well as gridded datasets of leaf area index (LAI) and canopy height. To assess the effect of the coupling on hydrological predictions, simulated streamflow from coupled and uncoupled model runs is compared against a time series of daily measurements. Furthermore, to assess the behavior of the coupled and uncoupled model under climate change, the model is run for a century under artificial climate change scenarios. In these future model runs, the significance of two further aspects of the forest-hydrology coupling are examined: the effect of elevated CO$_2$ on stomatal resistance, as well as the potential forest expansion into high-elevation meadows as a result of climate and land-use change.
2 Methods and Data

2.1 FORHYCS model description

The two original models operate at a different temporal resolution: while TreeMig simulates forest dynamics with an annual time step, PREVAH calculates daily values, with an internal time step of one hour. Both original models are run simultaneously over the same domain and exchange information through shared variables. Figure 1 a) shows the flow of a simulation: hydrology is simulated on a daily basis with vegetation properties given by the forest model for the previous year. This is based on the assumption that effects of current-year water balance on the forest structure and composition are negligible. An annual drought index, influencing tree growth and mortality (Sect. 2.1.3), is calculated in each cell from the transpiration simulated in the hydrological model over the whole simulation year (Sect. 2.1.4). Based on the number of trees per species and height class in each cell, annual maximal values of Leaf Area Index (LAI) and fractional canopy cover (FCC) are calculated. These values are converted to daily values using a temperature-dependent phenology module (Sect 2.1.2). The root-zone water storage capacity (SFC) is updated annually as a function of long-term climate (Sect. 2.1.5). Furthermore, the model includes the effects of snow-induced mortality for some species using an additional mortality function based on snow cover duration (Sect. 2.1.6).

2.1.1 Source models

The semi-conceptual hydrological model PREV AH (Gurtz et al., 1999) in its fully distributed form (Schattan et al., 2013; Speich et al., 2015) solves the water balance of each grid cell by calculating evapotranspiration, soil water balance and runoff generation at a sub-daily time step. The core of PREV AH is based on the structure of the widely used model HBV (Bergström, 1992), combined with a conceptual runoff routing scheme (Gurtz et al., 1999). Successive model developments enabled or improved the treatment of interception (Menzel, 1996), snowpack dynamics (Zappa et al., 2003), glacier runoff (Klok et al., 2001) and groundwater runoff (Gurtz et al., 2003). PREV AH was used, among other applications, to estimate the impact of climate change on discharge (Zappa and Kan, 2007). Climate impact studies were also conducted using the distributed outputs of PREV AH (Speich et al., 2015).

The spatially explicit forest landscape model TreeMig (Lischke et al., 2006) simulates forest establishment, growth and mortality, as well as seed dispersal. Originally based on a gap model (Lischke et al., 1998), TreeMig calculates the number of trees per species and height in each cell, and operates at an annual time step. Inter- and intra-specific competition is represented through light distribution within the canopy, which depends on the distribution of trees of different height within a stand, and thus on leaf area (Lischke et al., 1998). TreeMig was used to predict climate impact on tree species distribution in Switzerland (Bugmann et al., 2014), as well as to simulate forest response to land abandonment (Rickebusch et al., 2007) and the feedbacks between forests and avalanches (Zurbriggen et al., 2014). Abiotic drivers of forest dynamics are represented by three bioclimatic indices: mean temperature of the coldest month, degree-day sum and drought (see Sect. 2.1.3 for the latter).
Figure 1. (a) Flow of a FORHYCS simulation starting in the example year 1971. The initial state can be loaded from a file, or a spin-up can be performed. The hydrological calculations are performed daily. At the end of the simulation year, bioclimatic indices are calculated, and passed to TreeMig, which simulates forest dynamics with an annual time step. Long-term climate statistics are updated at the end of the year based on the daily calculations, and the effective rooting depth module is run with the updated climate indices. The forest model returns an annual maximal LAI value. To be used in hydrological calculations, this value is converted to daily values based on simulated leaf phenology. Another important interface variable is the rooting zone storage capacity SFC. (b) Schematic overview of the couplings between climate, above-ground forest structure and the rooting zone in TreeMig (left) and FORHYCS (right). TreeMig’s forest structure (species-size distribution) depends on its previous state, and is influenced by the annual bioclimatic indices. Unlike the other indices, which depend on meteorological input only, the drought index DI further depends on a constant soil moisture storage capacity (“bucket size”). In FORHYCS, the drought index further depends on canopy structure, through its influence on potential transpiration (PT). Additional optional couplings in FORHYCS are the dynamic simulation of a climate-dependent storage capacity of the rooting zone (through varying effective rooting depth), a limitation of maximum tree height under dry conditions, as well as a drought-dependent reduction of leaf area.
2.1.2 Canopy structure and leaf phenology

Leaf Area Index (LAI) is calculated in TreeMig to account for mutual shading and competition for light (Lischke et al., 1998). In FORHYCS, LAI is passed to the hydrological model, replacing the land cover-specific parameterization in PREVAH. The allometric equations of Bugmann (1994) relate leaf area to diameter at breast height ($D$ [cm]). As $D$ is allometrically linked to tree height, leaf area is calculated for each group of trees of the same species and height class, then summed to obtain the value for the whole stand:

$$A_l = \sum_{sp=1}^{nsp} \sum_{hc=1}^{nhcl} SLA_{sp} \times a_{1,sp} \times D_{sp,hc}^{a_{2,sp}} \times p_{d,sp},$$

(1)

where $A_l$ is total, all-sided stand leaf area [$m^2$], $nsp$ the number of species (30 in FORHYCS), $nhcl$ the number of height classes (16), $SLA_{sp}$ specific leaf area [$m^2$ kg$^{-1}$], $a_{1,sp}$ [kg cm$^{-1}$] and $a_{2,sp}$ [-] are species-specific allometric parameters (Bugmann, 1994), and $p_{d,sp}$ is a dimensionless reduction term accounting for seasonal variations in leaf area, ranging from 0 to 1 (see below and in the supplement). The reference area in TreeMig is the size of a forest plot, assumed to be set to 833 m$^2$ (1/12 ha), which is the reference area in many gap models (e.g. Bugmann, 1994), so that:

$$LAI = A_l k_c / 833,$$

(2)

where $k_c$ is a factor to convert from true to projected leaf area, set to 0.5 for broadleaves and 0.4 for conifers following Hammel and Kennel (2001). Fractional canopy cover $f_c$ is also calculated from the number of trees per species and height class, using the equation of Zurbriggen et al. (2014):

$$f_c = \left[ 1 - \exp \left( -1 \times \sum_{sp=1}^{nsp} \sum_{hc=1}^{nhcl} \left( n_{sp,hc} / 833 \right) \times CA_{sp,hc} \right) \right],$$

(3)

where $CA_{sp,hc}$ is the total crown area for trees of each species and height class:

$$CA_{sp,hc} = (k_{a1,sp} \times h_{hc}^2 + k_{a2,sp} \times h_{hc}) \times n_{sp,hc},$$

(4)

Minimum values for LAI and $f_c$ are set to 0.2 and 0.1, respectively, to account for a minimal cover by grass and herbs, as well as bare stems. Annual maximum LAI may be reduced as a function of drought stress of the previous years, as described below in Section 2.1.3. It is worth noting that leaf area and crown area are calculated independently from each other, both using empirical relationships with tree size.

To obtain daily values for LAI and $f_c$, a leaf phenology module has been implemented. The variable $p_{d,sp}$ reflects the phenological status of species $sp$ in a given cell, and varies between zero (no leaves) and one (full foliage). This module also
defines the start and end of the growing season in each cell, which is required to calculate the climatic indices for the rooting depth module (Sect. 2.1.5). In each cell, the growing season lasts as long as $p_{d,sp}$ is greater than 0.5 for the dominant species. Daily values of $p_{d,sp}$ are simulated in spring with the model of Murray et al. (1989), which depends on the number of chill days in winter and of accumulated growing degree days in summer. When $p_{d,sp}$ reaches one, the foliage is assumed to be fully developed. The onset of leaf senescence in autumn is simulated using the model of Delpierre et al. (2009), which depends on temperature and photoperiod. For broadleaves, the end of the growing season is set 14 days after the onset of senescence, and $p_{d,sp}$ is linearly reduced from one to zero during this period. Although the leaf area is not varied throughout the year for evergreen conifers, $p_{d,sp}$ is still simulated to define the start and end of the growing season. For these species (as well as for the deciduous conifer *Larix decidua*), the development of $p_{d,sp}$ following the onset of senescence is calculated using the formulation of Scherstjanoi et al. (2014). The parameters for the empirical models of Murray et al. (1989) and Delpierre et al. (2009) were calibrated against phenological observations across Switzerland (Defila and Clot, 2001). The species-specific parameters and a description of the calibration procedure are given in the supplement.

### 2.1.3 Drought and its effects on forest growth, mortality and structure

The drought index used in TreeMig is based on the ratio of annual to potential evapotranspiration, as calculated with a module modified from Thornthwaite and Mather (1957). This scheme requires monthly precipitation sum and temperature average for each cell, as well as the plant-available water storage capacity. Evaporative demand is calculated using an empirical, temperature-dependent approach, and monthly soil water balance is simulated based on water supply and demand, after accounting for interception (see Bugmann and Cramer, 1998, for a full description of this scheme). This approach has a number of drawbacks. First, it does not consider the effect of variations in vegetation properties on evaporative supply and demand, thus neglecting feedbacks between vegetation density, transpiration and drought (see e.g. Kergoat, 1998). Also, the Thornthwaite-Mather routine does not account for snow-related processes, which can lead to large errors in the estimation of evapotranspiration, diminishing the representativeness of the index for growth conditions (Anderegg et al., 2013). Furthermore, empirical evapotranspiration formulations such as the Thornthwaite-Mather formula rely to a large extent on calibrated values. These may not be transferrable to climatic conditions that differ from the calibration period (Bartholomeus et al., 2015), limiting the ability of the model to make predictions under a changing climate. For these reasons, the **EDI** this abiotic drought index was replaced by a relative transpiration index (Speich et al., 2018a). This index is similar to the evapotranspiration deficit index presented above, but is based on transpiration rather than evapotranspiration:

$$DI = 1 - \frac{\sum_{d=de}^{ds} E_{T,act,d}}{\sum_{d=de}^{ds} E_{T,pot,d}},$$  \hspace{1cm} (5)$$

where $de$ and $ds$ are the first and last day of the period for which the drought stress is calculated, and $E_{T,pot,d}$ and $E_{T,act,d}$ are modeled daily canopy transpiration sums [mm/day]. Here, $DI$ is calculated for the entire year, so that $de = 1$ and $ds = 365$. Furthermore, to account for delayed effects of drought on tree physiology (Hammel and Kennel, 2001), the average of the last three years is used here. Transpiration is reduced from potential rate through the effect of low soil moisture or high
atmospheric vapor pressure deficit (VPD) on stomatal resistance (Eq. 14 in Speich et al. (2018a)). The rationale behind this index is based on the fact that stomatal closure is one of the first responses of a plant to water deficit. Therefore, the time during which stomatal resistance is increased due to drought is the time during which adverse physiological effects of water shortage (e.g. cavitation, reduced carbon uptake) are likely to occur, and DI serves as a proxy for all these processes. The effect of VPD was included to account for the effects of high evaporative demand on plant-internal hydraulics (Zierl, 2001). The drought stress function in TreeMig \( f_{DS} \) determines the relative drought-induced limitation of annual growth (Bugmann, 1994):

\[
f_{DS} = \sqrt{\text{max}(0, 1 - \frac{DI}{k_{DT}})},
\]

where \( k_{DT} \) is a species-specific drought tolerance parameter, indicating the value of \( DI \) at which growth is completely suppressed. This growth reduction function can take values between zero (complete growth suppression) and one (unstressed conditions). Annual growth of the trees of the same species and height class is the product of a species-specific maximal growth, and an environmental reduction function \( f_{env} \), and a further reduction term accounting for shading. This reduction function is the geometric mean of \( f_{DS} \) and two other stress functions, representing the effects of temperature and shading nitrogen availability (Bugmann, 1994). While the effects of temperature are taken into account in this study, nitrogen availability is kept spatially and temporally constant. These two environment-dependent stress functions are further described in Section 1.2 of the Supplement (for a description of the effects of light competition and shading, we refer to Lischke et al. (2006)). The same reduction function is used to simulate mortality in addition to background mortality, and applies if it is more severe than mortality caused by low productivity. Lischke and Zierl (2002) parameterized \( k_{DT} \) for the 30 tree species represented in TreeMig by overlaying modelled \( DI \) with inventory-derived maps of species distribution. The values range between 0.27 and 0.5. However, this parameterization did not lead to satisfactory simulations of species composition in the case study of this paper. Therefore, species-specific \( k_{DT} \) was defined based on a combination of the rankings by Lischke and Zierl (2002) and Niinemets and Valladares (2006). Table A1S7 in the supplement lists the \( k_{DT} \) values used in this study.

FORHYCS accounts for two additional effects of drought stress: a limitation of maximum height and a reduction of annual maximal LAI. The former is parameterized following Rasche et al. (2012), i.e. with a decrease of LAI with \( DI \) down to a species-specific parameter \( k_{redmax} \), indicating the fraction of species-specific maximum height that can be attained by a species if \( DI \) is at \( k_{DT} \). The same is done for annual degree-day sum, and the more severe of the two reductions is applied. The former is parameterized following Rasche et al. (2012), i.e. species-specific maximum tree height may be reduced as a function of the bioclimatic indices \( DI \) and DDEGS. The parameter \( k_{redmax} \), which is also species-specific, indicates the fraction of maximum height that can be attained by trees if one of the environmental vitality functions is at its minimum. The more severe of the two reductions (drought or degree-days) is applied. Unlike in the formulation of Rasche et al. (2012), where the reduction is a linear function of the bioclimatic indices, the impact functions (Eq. 6 for drought and S8 for degree-day sum) are used here.

The LAI reduction function follows the formulation of Landsberg and Waring (1997), where the fraction of carbon allocated to roots increases under stress, whereas allocation to foliage and stem decreases. Since allocation is not explicitly simulated in
FORHYCS, the following formulation is purely phenomenological. For all size classes of a given species, leaf area is scaled by the ratio of the foliage allocation coefficient under current $\eta_l$ and unstressed conditions $\eta_{l,u}$. Eq. 1 is thus modified as follows:

$$A_l = \sum_{sp=1}^{nsp} \sum_{hc=1}^{nhcl} SLA_{sp} \times a_{1,sp} \times D_{sp,hc}^{a_{2,sp}} \times p_{d,sp} \times \eta_{l,sp}/\eta_{l,u,sp}, \quad (7)$$

The allocation coefficients for foliage are calculated as:

$$\eta_l = 1 - \eta_r - \eta_s, \quad \text{and} \quad \eta_{l,u} = 1 - \eta_{r,u} - \eta_{s,u}, \quad (8)$$

where $\eta_r$ and $\eta_{r,u}$ are the allocation coefficients to roots, and $\eta_s$ and $\eta_{s,u}$ he the allocation coefficients to the stem, under current and unstressed conditions, respectively. Following Landsberg and Waring (1997), $\eta_{r,u}$ is set to 0.229, and $\eta_r$ increases with increasing stress by the following relation:

$$\eta_r = \frac{0.8}{1 + 2.5(1 - f_{env})}, \quad (9)$$

where $f_{env}$ is the geometrical mean of the drought and low temperature stress functions (Eqs. 6 and S8). The carbon allocated to the stem is related to $\eta_r$ as follows:

$$\eta_s = (1 - \eta_r)/(p_{l,s} + 1), \quad \text{and} \quad \eta_{s,u} = (1 - \eta_{r,u})/(p_{l,s} + 1), \quad (10)$$

where $p_{l,s}$ is the ratio of the growth rates of leaves and stems, in terms of their change in relation to diameter at breast height $D$. In FORHYCS, $p_{l,s}$ is calculated using the allometric equations used to calculate leaf and stem biomass:

$$p_{l,s} = \frac{dwl/dD}{dw/dD} = \frac{k_{l,1}D^{k_{l,2}}}{k_{s,1}D^{k_{s,2}}}, \quad (11)$$

where $k_{l,1}$ and $k_{l,2}$ are allometric parameters for leaf biomass, and $k_{s,1}$ and $k_{s,2}$ are allometric parameters for stem biomass (Bugmann, 1994). It is important to stress that FORHYCS does not explicitly simulate carbon assimilation. Hence, Eqs. 9 and 10 are used only to determine a reduction factor for leaf area (Eq. 8) and have no direct influence on simulated tree growth, stem biomass and rooting depth.

### 2.1.4 Partitioning of transpiration and soil evaporation

The implementation of the new drought index (see Sect. 2.1.3 above) required some changes to the evapotranspiration routine in the hydrological model. While the relative transpiration index is based on estimates of actual and potential transpiration, PREVAH does not explicitly differentiate between transpiration and soil evaporation. Therefore, a new local water balance routine was implemented, based on the stand-alone model FORHYTM (Speich et al., 2018a). This module combines the soil water balance formulation of the HBV model (Bergström, 1992), which is also implemented in PREVAH, with the transpiration
and evaporation scheme of Guan and Wilson (2009) and a Jarvis-type (Jarvis, 1976) parameterization of canopy resistance. A full description is given in (Speich et al., 2018a).

The parameterization of canopy resistance differs from the original formulation in two ways. First, the effect of atmospheric vapor pressure deficit (VPD) on stomatal conductance is represented with a negative exponential function instead of a linear function. Second, an additional canopy resistance modifier \( f_5 \) was implemented, to account for the effect of atmospheric \( CO_2 \) concentration \( (C_a [\mu mol mol^{-1}]) \). This function is based on the results of Medlyn et al. (2001):

\[
\begin{align*}
    f_5 &= \left( 1 - (1 - j_c) \left( \frac{\min(C_a,700)}{350} - 1 \right) \right)^{-1}, \quad ***WRONG\ VERSION***
    \\
    f_5 &= \left( 1 - j_c \left( \frac{\min(C_a,700)}{350} - 1 \right) \right)^{-1}, \quad (12)
\end{align*}
\]

where \( j_c \) represents the fractional change in conductance in response to an increase in \( C_a \) from 350 to 700 \( \mu mol\ mol^{-1} \), and was set to 0.1 for coniferous forests, 0.25 for broadleaf forests and 0.18 for mixed forests (the forest type in each cell is determined based on the relative share of above-ground biomass belonging to conifers and broadleaves). These values were set based on the results reported by Medlyn et al. (2001): coniferous species had a value of \( j_c \) between 0 and 0.2, whereas broadleaves had values up to 0.4. Therefore, for conifers, a value of 0.1 was selected. For broadleaves, as there seemed to be some acclimation for trees growing in elevated \( CO_2 \), a more conservative (than 0.4) value of 0.25 was chosen. The value for mixed forests corresponds to the arithmetic mean of the two. This affects both potential and actual transpiration, so that with all other factors kept constant, increases in \( C_a \) will reduce the level of drought stress. The rationale for implementing this new water balance scheme is to account for the effect of variations in vegetation properties (e.g. LAI) on physiological drought in forests. As FORHYCS includes the possibility of changing land cover classes in a cell, some non-forested cells may become forested over the course of a simulation. As vegetation parameters (such as LAI and effective rooting depth) are prescribed as a function of land cover for non-forested cells, this shift inevitably introduces an artificial discontinuity in the simulation. To reduce this discontinuity, the new water balance scheme is also used for potentially forested land cover types. On the other hand, for land cover types that cannot become forested, the original water balance scheme of PREVAH (Gurtz et al., 1999) is applied.

### 2.1.5 Rooting zone storage capacity

The rooting zone water holding capacity, SFC, is calculated as the product of effective root depth \( Z_e \) and soil water holding capacity \( \kappa \) (Federer et al., 2003). While \( \kappa \) is assumed to remain constant, \( Z_e \) is assumed to vary as a function of vegetation characteristics and climate. The approach used to parameterize \( Z_e \) is the carbon cost-benefit approach of Guswa (2008, 2010). This approach rests on the assumption that plants dimension their rooting systems in a way that optimizes their carbon budget. The optimal rooting depth is the depth at which the marginal carbon costs of deeper roots (linked to root respiration and construction) starts to outweigh the marginal benefits (i.e. additional carbon uptake due to greater availability of water for
transpiration). The implementation of this model in FORHYCS follows the procedure described by Speich et al. (2018b). Effective rooting depth, expressed as an average over the whole cell, is calculated for both overstory (trees) and understory (shrubs and non-woody plants). The storage volume SFC for a given cell is defined as the sum of these two area-averaged rooting depths, multiplied with soil water holding capacity $\kappa$. A full description of this implementation is given in Speich et al. (2018b). The underlying equation is:

$$\frac{\gamma_r \times D_r}{L_r} = w_{ph} \times f_{seas} \times \frac{d\langle T \rangle}{dZ_e},$$

(13)

where $\gamma_r$ is root respiration rate [mg C g$^{-1}$ roots day$^{-1}$], $D_r$ root length density [cm roots cm$^{-3}$ soil], $L_r$ specific root length [cm roots g$^{-1}$ roots], $w_{ph}$ photosynthetic water use efficiency [g C cm$^{-3}$ H$_2$O], $f_{seas}$ growing season length [fraction of a year] and $\langle T \rangle$ mean daily transpiration [mm day$^{-1}$] during the growing season. The left hand side represents the marginal cost of deeper roots, and the right hand side the marginal benefits, and solving for $Z_e$ gives the optimal rooting depth. Any equation can be used to relate $d\langle T \rangle$ to $dZ_e$. In this implementation, the probabilistic models of Milly (1993) and Porporato et al. (2004) are used for the understory and overstory, respectively. These two models reflect the differing water uptake strategies of grasses and trees (Guswa, 2010). Both models estimate transpiration based on soil water holding capacity $\kappa$ and long-term averages of climatic indices. Evaporative demand is represented by potential transpiration, and rainfall is represented as a marked Poisson process characterized by the frequency ($\lambda$ [events day$^{-1}$]) and mean intensity ($\alpha$ [mm event$^{-1}$]) of events. In FORHYCS, these variables are calculated as rolling means with a window of 30 years, including only the growing seasons. Potential transpiration for the understory and overstory are taken from the calculations of the local water balance module (Sect. 2.1.4), and the rainfall characteristics are taken from modeled effective precipitation (i.e. after accounting for interception). The start and end of the growing season are determined based on the phenology module (Sect. 2.1.2). In addition, mean daily air temperature is calculated over the growing season to adjust respiration rate. The plant-specific parameters in Eq. 13 are summarized in the variable $PP_o$, defined as follows:

$$PP_o = \frac{\gamma_{r,20} D_r}{L_r w_{ph}},$$

(14)

where $\gamma_{r,20}$ is the root respiration rate at 20 °C. The actual root respiration rate is dependent on annually averaged temperature via a $Q_{10}$ function. For further details, please refer to Speich et al. (2018b). A higher value of $PP_o$ indicates a greater difficulty for the plant to develop additional roots. In FORHYCS, $PP_o$ was set to $1.263 \times 10^{-4}$ for conifers and $1.01 \times 10^{-4}$ for broadleaved species. At cell level, $PP_o$ was averaged based on the relative share of aboveground biomass belonging to conifers and broadleaves. For the understory, the corresponding parameter $PP_u$ is set to $1.512 \times 10^{-4}$. 

2.1.6 Snow-cover induced seedling mortality

For seedlings of the high-mountain species \textit{Larix decidua}, \textit{Pinus cembra} and \textit{P. montana}, the model also includes the effect of snow-induced fungal infections via the variable \(FDSA\) (final day of snow ablation), as described by Zurbriggen et al. (2014). An additional mortality term is calculated:

\[ \mu_s = a \times FDSA^2 + b \times FDSA + c, \]  

(15)

where \(a\), \(b\) and \(c\) are empirical parameters fitted by Zurbriggen et al. (2014) for \textit{Larix decidua} and for the two aforementioned \textit{Pinus} species. If \(\mu_s\) is greater than background mortality or the mortality term integrating light, temperature and water stress, it is applied instead for the seedlings of these species. This aspect of the model was implemented to examine the feedback between forest dynamics and avalanches on a small spatial scale (Zurbriggen et al., 2014), but was never tested on landscape scale. Here, FDSA is defined as the last day of the year with more than 5 mm snow water equivalent.

2.1.7 Uncoupled mode and one-way coupling

The methods have so far described the model FORHYCS in its fully coupled version. It is also possible to run FORHYCS in uncoupled mode (without any information transfer between the hydrological and forest models), or with a one-way coupling (information transfer from the forest model to the hydrological model only). An uncoupled FORHYCS run consists essentially of a PREV AH run and a TreeMig run, happening independently from each other. Uncoupled FORHYCS differs from other PREV AH implementations mainly through the parameterization of soil and surface properties. As mentioned in Sect. 4.2, previous applications of PREV AH in Switzerland have used soil depth and water holding capacity from the agricultural suitability map BEK (BfR, 1980). Preliminary analyses in this project have shown that this parameterization gave implausible results when used with the newly implemented water balance module (Sect. 2.1.4). Therefore, to ensure comparability between coupled and uncoupled runs, all FORHYCS runs use the soil parameterization from Remund and Augustin (2015) (see Sect. 2.2.2) in forested cells. In uncoupled runs, it is assumed that the rooting depth of forests is 1 m. As this dataset was developed based on forest soil profiles, values for cells outside currently forested areas are not reliable (Jan Remund, Meteotest, pers. comm.). To simulate forest expansion under climate and land use change scenarios, it was nevertheless assumed that cell values of the RA2015 (Remund and Augustin, 2015) dataset represent the water storage capacity for 1 m of soil depth. To account for shallower rooting of non-forest vegetation types, a land cover-dependent rooting depth parameter was introduced. The parameter values for different land cover types are given in Table S6. Non-vegetated land cover classes (e.g. built-up, bare rocks) use the same standard soil parameters as in original PREV AH (Gurtz et al., 1999). Another difference between FORHYCS and PREV AH is the parameterization of canopy resistance. Whereas PREV AH gives a minimum canopy resistance for each land cover class (i.e. normalized by leaf area index), the new water balance module requires a minimum stomatal resistance. Following Guan and Wilson (2009), minimum stomatal resistance was set to 180 s m\(^{-1}\) for forests, 130 s m\(^{-1}\) for meadows and grasslands, and 210 m\(^{-1}\) for shrubs.
One-way coupling is similar to the modeling experiment of Schattan et al. (2013): vegetation variables from TreeMig are passed to PREVAH, but there is no feedback from the hydrological to the forest model. This configuration uses the abiotic drought index calculated with FORCLIM-E (Bugmann and Cramer, 1998). In this study, TreeMig was run with two soil datasets (BEK and RA2015; see below). In all cases, the hydrological part of the model uses the RA2015 dataset. In this study, rooting zone storage capacity SFC of the hydrological model was kept constant in one-way coupled mode, assuming a rooting depth of 1 m. Enabling climate-dependent adaptation of SFC in this mode would impact simulation results for the hydrology part, but not for the forest.

2.2 The Navizence case study

2.2.1 Catchment description

The Navizence catchment is located in the central Swiss Alps and covers an area of 255 km². To enable the future migration of tree species that are currently not represented in the catchment, the modeling area extends beyond the catchment to form the rectangular area shown on Fig. 2 (1079 km²). The catchment is characterized by a sharp elevational gradient, with elevations ranging from 522 to 4505 m asl. Like in its neighboring valleys, this gradient is reflected in the hydro-climatic conditions. Due to the shielding effect of mountain ranges, the Rhône valley, where the catchment outlet is located, is the driest region of Switzerland, with mean annual precipitation (MAP; 1981-2010) at Sion totaling 603 mm (MeteoSwiss, 2014). However, the valley presents a strong altitudinal precipitation gradient, with MAP exceeding 2500 mm at 3000 m asl, most of it falling as snow (Reynard et al., 2014).

Tree species composition shows a rather clear altitudinal zonation, with drought-resistant species (*Pinus sylvestris* and *Quercus spp.*) dominating at lower elevations, whereas *Picea abies, Larix decidua* and *Abies alba* dominate the subalpine stage and the treeline is formed by *Larix decidua* and *Pinus cembra*. The landscape is heavily influenced by human activity, with a large fraction of land occupied by settlements, cropland, vineyards and pastures. Furthermore, nearly all forests in the area are subject to management in various forms and degrees of intensity, with a considerable impact on forest dynamics. Specifically, many forests were clear-cut between the Middle Ages and the nineteenth century, mostly for fuel (Burga, 1988). In the first half of the twentieth century, the quantitatively most important anthropogenic disturbance factors were litter collecting and wood pasture by goats (Gimmi et al., 2008). Nowadays, these practices have been largely abandoned, and timber harvesting plays a limited role in the region. As a result of past and current anthropogenic factors, the main deviations from potential natural forest composition are (1) silvicultural practices favoring certain species, such as *Pinus sylvestris* and *Larix decidua* (2) Effects of litter removal and grazing and (3) a replacement of *L. decidua* and *Pinus cembra* by mountain pastures (Büntgen et al., 2006) and dwarf shrubs (Burga, 1988) near the treeline.

Currently, three major hydropower plants are operational in the valley, with a total installed capacity of 164 MW and a mean net annual production of 570 GWh. The main reservoir is the artificial lake Lac de Moiry, located in a lateral valley, with a storage capacity of 77 mio m³. A system of pipelines has been built to divert water from the Navizence, as well as from a neighboring catchment, into the lake.
Figure 2. Map of the study area, including the Navizence catchment and the subcatchments used in this study. Streamflow measurements are available for the subcatchments 2 through 5. As the lowest part of the Navizence catchment (subcatchment 1) differs greatly from the others in terms of elevation and current land cover, modeled streamflow is also examined for this subcatchment, although no measurements are available. Forest-related model outputs are evaluated over the entire currently forested area, inside and outside the catchment. Streams are drawn for reference only.
2.2.2 Input data

Three kinds of spatial data are needed to run the model: daily meteorological data, time-invariant physiographic data, and spatially distributed model parameters for PREVAH. These parameters represent environmental factors not related to vegetation, such as snow, glacier and runoff generation processes. Further information on the parameterization of PREVAH is given in Sect. 1.7 of the Supplement. The model is driven by daily values for precipitation [mm], air temperature [°C], global radiation \([W \text{ m}^{-2}]\), wind speed [m s\(^{-1}\)], relative air humidity [%] and sunshine duration SSD [h], provided by the Swiss Meteorological Office MeteoSwiss (Begert et al., 2005).

Physiographic data consists of information on soil, topography and land cover. Soil is represented in terms of water holding capacity \(\kappa\) [mm water depth mm\(^{-1}\) soil depth] and soil depth. Two different datasets are used for soil properties. In previous applications in Switzerland, both PREVAH and TreeMig used grids of \(\kappa\) and soil depth from a country-wide agricultural suitability map (BfR, 1980; hereafter referred to as "BEK"). The resulting rooting zone storage capacities (SFC [mm]) in the forested cells of the study region range between 3.75 and 110 mm. As this dataset was not specifically developed for use in forests, and some values are implausibly low, Remund and Augustin (2015) generated a new country-wide dataset (RA2015) of rooting zone storage capacity, on the basis 1234 forest soil profiles throughout Switzerland, combined with a lithological map. This dataset gives the volume of water that can be stored in the soil for a depth of up to 1 m, with lower values in cells where soil is assumed to be shallower. SFC in the new dataset ranges from 71 to 223 mm in forested cells of the study region. Figure S1 shows the rooting zone storage capacity in forested cells of the study region for both soil parameterizations. For coupled simulations, only the RA2015 parameterization is used. To facilitate comparison with results from previous studies, the parent models PREVAH and TreeMig are also run with the BEK parameterization.

2.2.3 Comparison data and metrics of agreement

This section describes the data against which model outputs were compared, including three datasets of vegetation properties and one dataset of streamflow measurements. These datasets are used to plausibilize model outputs and serve as a basis for the choice of model configuration. Daily streamflow was obtained from the operator of the power plants. This data includes an accounting of the amount of water diverted through the different pipelines. From this, time series of natural streamflow were reconstructed, which were used as observations.

The simulated stem numbers and above-ground biomass were compared against data from the first Swiss National Forest Inventory (NFI; Bachofen et al., 1988). As the sampling plots of the NFI are distributed on a regular grid, each plot is a randomly selected from all forest plots in that region, and may not be considered representative for a larger area. It is therefore not sensible to compare simulated and observed biomass at the scale of single inventory plots. Instead, the 245 NFI plots in the study area were aggregated to seven classes based on aspect and elevation, with four elevation bands for North-facing plots and three for South-facing plots. This way, each class has a sample size of at least 30 plots, which ensures that the averages are representative. For comparison with inventory data, simulated biomass was also averaged over the same strata.
Simulated LAI was compared to the remotely sensed LAI dataset provided by Copernicus at 300 m resolution (Copernicus Service Information, 2017). This dataset uses measurements of the satellite Proba-V and its temporal coverage starts in January 2014. The LAI 300m rasters were resampled to match the resolution and extent of the model input and output, then stratified as described above. For each cell of the original LAI 300m grids, the maximum value of the 10-day periods contained between May and July of the years 2014 through 2016 was used as an estimate of maximum LAI, independent of intra-annual fluctuations. As forest properties are also shaped by local processes not represented in the model (e.g. disturbance, forest management), a direct cell-by-cell correspondence of simulated and observed values is not expected. Furthermore, cells of the remote sensing dataset are spatially heterogeneous and may include non-forested parts. However, it was still assumed that over larger domains, a good correspondence between simulated and observed LAI would be indicative of good model performance. Therefore, the simulations and observations were also stratified by elevation and aspect. As the number of cells is relatively large, smaller elevation bands were chosen than for inventory data. The cells are divided between North and South facing aspects, then binned into nine elevation bands. These elevation bands have a fixed width of 200 m, except the lowest (< 700 m asl) and highest (> 2100 m asl). Each zone contains between 100 and 714 forested cells. Model outputs and observations are only evaluated over the areas classified as forests or shrubland in the model input.

The recently developed Switzerland-wide vegetation height dataset at 1 m resolution of Ginzler and Hobi (2016), derived from stereo aerial images, was compared against simulated canopy structure. To compare the level of agreement between observed and simulated canopy structure, two novel metrics were introduced. The rationale behind these metrics is illustrated in Figure 3. Both measures are based on the discrete height classes used in TreeMig, and use the cumulative fractional cover of each height class, starting from the highest class. In the illustrative example of Fig. 3 a), the cumulative fractional cover of the height class “5-10 m” corresponds to the visible crown area of the height classes “5-10 m” and “10-15 m”, divided by the potentially vegetated area (i.e. excluding the area occupied by a road, shown in grey). In each cell of the model grid, the fractional cover of each height class is calculated from simulated species-size distribution using the procedure described in Eqs. 3 and 4. For each height class \( i \), the cumulative fractional cover \( f_{c,i} \) is defined as follows:

\[
 f_{c,i} = \left[ 1 - e^{x(-1 \times \sum_{sp=1}^{nspc} \sum_{hc=i}^{nhcl} (n_{sp,hc}/833) \times CA_{sp,hc})} \right].
\]  

The procedure used to calculate fractional cover is based on the assumption that trees are randomly distributed in space and accounts for overlap between crowns. For example, applying Eq. 16 to the upper 3 height classes will return the fractional cover for the trees belonging to these classes, accounting for overlap between them. This assumes that shading of lower parts of their crowns by smaller trees can be neglected.

As can be seen on the examples in Fig. 3 c) and d), each cell from the model grid covers 200x200 cells of the observations grid. Therefore, for each model cell, the observed fractional cover is calculated from the relative number of high-resolution cells belonging to each height class. Observed cells with a height of zero represent non-vegetated surfaces such as roads, water bodies or buildings and were excluded from the analysis. Indeed, as the model does not contain any land-cover information on subgrid level, these elements are an irreducible source of disagreement between observations and simulations. On the other hand, observation cells with a height between zero and 1.37 m are assumed to be covered by ground vegetation, and decrease...
the total fractional canopy cover in a coarse cell. The first cell-level measure of agreement is the difference in observed and simulated H95, i.e. the lowest height class for which the cumulated fractional cover (starting from zero) equals or exceeds 95% of the total fractional cover. Figure 3 b) shows the H95 of the observations, at the level of model cells. The second measure of agreement is illustrated in Fig. 3 e) and f). The cumulative fractional cover of each class (starting from the top) is plotted for observations and simulations. The better the agreement, the closer the curves are to each other. Therefore, the second measure of agreement, termed 1-ABC (where ABC stands for “Area Between the Curves”), is defined as the fraction of the plot area not contained between the curves. The plot in Fig. 3 e) applies this to the cell shown in Fig. 3 c), and represents a case with a poor agreement between simulations and observations. Indeed, this area was devastated by a wildfire, and is thus currently very sparsely forested. As this fire is not represented in the model, the simulations indicate a fully developed forest. Even in this extreme case, the ABC does not exceed 40% of the plot area. Therefore, a 1-ABC score of 0.6 can be considered a poor fit. On the other hand, the sample cell in Fig. 3 d) and f) shows a good agreement between observations and simulations, with 1-ABC exceeding 0.99. These two measures of agreement can be used to evaluate the performance of a model by examining their distribution over the whole simulation domain. A better performing model will have a higher proportion of cells with a dH95 close to zero and a 1-ABC close to one. Furthermore, the spatial distribution of dH95 and 1-ABC may give insight into the factors that contribute to agreement or disagreement between simulations and observations.

2.2.4 Simulation experiments

To evaluate the behavior of the coupled model FORHYCS and the importance of the different forest-hydrology couplings implemented, two series of simulation experiments have been conducted. An overview of the different simulation runs is given in Table 1. In a first series of experiments, the simulations start with no forest, and a full succession is modeled. The names for these simulations start with "S". The second part of the name indicates whether these experiments were conducted in fully coupled mode ("F") or in one-way coupled mode ("T"). The next part indicates which couplings are switched on and off, as per Table 1. Finally, for the one-way coupled runs, the fourth part of the name indicates the source of the soil water holding capacity ("BEK" or "RA15", see next paragraph). In a second series of experiments, starting with "C", the model was run with several climate change scenarios (see below). In this set of experiments, the model was run in uncoupled ("U"), one-way coupled ("T") and fully coupled mode ("F"). In addition, a simulation with stand-alone PREVAH was run ("P"). For the fully coupled simulations, two additional experiments were run (see below), testing the effect of CO2 ("_NCS") and land cover change ("_LC").

In the first series of simulation experiments, the simulations start with no forest, and a full succession is modeled. The simulations span a period of 515 years, where the last 45 years are the years 1971 to 2015. For the first 470 years, the meteorological forcing consists of years bootstrapped from the period 1981 to 2000. In two cases (S_T_BEK and S_T_RA15), the model is run in uncoupled mode, and only the forest output is evaluated. This is equivalent to a standard TreeMig run. The difference between the two runs is the parameterization of the rooting zone storage capacity for the (abiotic) drought stress module (FORCLIM-E; Bugmann and Cramer, 1998). In the first case, the storage capacity in each cell is given by the soil depth and water holding capacity given in the Swiss soil map for agricultural suitability (referred to as "BEK"; BfR, 1980),
Figure 3. (a) Schematic representation of the canopy division into discrete height classes, as used in the model-data comparison. The cumulative fractional cover of a height class is the total visible crown area of that and higher classes, divided by the total vegetated area. In this example, a road (in grey) crosses the cell, which reduces the total vegetated area. (b) For each 200x200 m cell, the shade of green represents the lowest height class for which 95% of the 1x1 m cells are lower or equal (H95). (c) An example of a very sparsely vegetated 200x200 m cell. The shade of green shows the height of each 1x1 cell. Cells with a height of zero are assumed to be bare and are marked black. This cell is located in an area disturbed by a wildfire in 2003. (d) An example of a mountain forest, located at 2000 m asl. The bare areas in this cell are mostly covered by rocks. (e) and (f) An illustration of the 1-ABC index of agreement between observed and simulated forest structure, applied to the cells shown in c) and d). The open dots and solid lines show the cumulative sum of 1x1 cells belonging to each discrete height class, starting from the right (i.e. from the highest class), normalized by the area of the 200x200 m cell which is not bare. The full dots and dashed lines represent the cumulative relative coverage of each height class as simulated by FORHYCS. As the wildfire is not reflected in the model, the simulation shows a fully developed forest in the cell shown in c), leading to a poor match between simulated and observed canopy structure. On the other hand, the forest simulated in the cell shown in d) corresponds well to the observed structure, leading to a high 1-ABC score.
as in previous TreeMig applications in Switzerland (e.g. Bugmann et al., 2014). In the second case, the parameterization of Remund and Augustin (referred to as "RA15"; 2015) is used. As noted in Sect. 2.2.2, the soil water holding capacity is much larger in the RA2015 dataset for most cells. As a result, the (abiotic) drought index also shows great differences between the two model runs. Figure S1 c) and d) shows the difference in mean annual drought index (1971-2015), and maximum annual drought index between the BEK and RA2015 parameterizations. Due to the considerable effect of maximum height reduction (Sect. 2.1.3) on the coupled model, two additional TreeMig runs were performed with this effect enabled, to facilitate the comparison between coupled and uncoupled runs.

In coupled mode, FORHYCS is run with different configurations, with the various couplings described in Sect. 2.1 switched on or off (maximum height reduction, stress-induced leaf area reduction, dynamically varying rooting depth, and snow-induced seedling mortality). Based on pilot study results, the configuration S_F_noLAre (all couplings switched on, except leaf area reduction) was selected as the best configuration, and the other configurations in Table 1 differ from S_F_noLAre by only one process switched on or off.

The configuration S_F_noLAre is also used for the second set of model runs, which starts in the year 1971 and ends in 2100. In this second the "delta" set of model runs, the sensitivity to a ramp-shaped climate change is evaluated (see Fig. 4). In the period 1971-2015, observed forcing is used. From 2016 to 2100, years are randomly selected from the period 1981-2015 (excluding the abnormally dry and hot year 2003). Furthermore, from 2016 on, daily temperature is incremented by a given amount of degrees dT, and daily precipitation is scaled by a given factor dP. The values of these factors are given in Table 1. To emulate a gradual progression of climate change, these factors are scaled linearly between zero and their full value between 2016 and 2050. The runs C_F_NCS test the impact of the CO₂ effect on stomatal closing, implemented through Eq. 12. In these runs, the CO₂ response function is always set to one, i.e. stomatal response to high CO₂ is switched off, whereas in all other runs, this effect is active. In all the runs presented so far, forest growth is restricted to the currently forested cells. In the runs C_F_LC, forest is allowed to grow in all potentially forested land cover classes. Thus, the potential ecohydrological consequences of land abandonment and rising treelines are examined. In addition to the runs with delta change, three runs were performed with meteorological forcing from downscaled regional climate simulations, generated in the CH2018 project (National Centre for Climate Services, 2018). CH2018 contains the output of climate model runs from the EURO-CORDEX initiative (Kotlarski et al., 2014) , downscaled to a 2 x 2 km grid. While there are 39 climate model chains available in the CH2018 dataset, running FORHYCS with each of them would be beyond the scope of this study. Instead, the three chains selected by Brunner et al. (2019) to represent dry, intermediate and wet conditions were used. The characteristics of the three chains are given in Table 2. For more information on the model chains, we refer to Brunner et al. (2019). It is worth noting that precipitation in the GCM-RCM chains is higher than in the observations for this region. Mean annual precipitation differs by 300 to 600 mm year^-1, depending on period and subcatchment (see Fig. S2 in the Supplement). Due to these differences, a comparison of the absolute model outputs between delta change runs and GCM-RCM chain runs is of little value. Therefore, the analysis shall focus on the difference between coupled and uncoupled runs for the different scenarios. Precipitation also differs in terms of event frequency (Fig. S3) and mean intensity (Fig. S4): the latter is consistently higher for the three GCM-RCM chains, whereas for the former, observed values lie between the two extreme values of the model chains. The model chains also

Figure 4. Workflow of the various simulation experiments conducted in this study. The Succession runs (S_) use bootstrapped meteorological forcing for 470 years, followed with observed forcing for the period 1971-2015. FORHYCS is run with several configurations, as described in Table 1. The output from each run is then compared against observations, based on which one configuration is selected for the runs under idealized climate change (C_). The modifiers for temperature and precipitation (red line) are scaled linearly between zero and their maximum in the period 2016-2050. Atmospheric \( CO_2 \) concentration \( C_a \) (blue line, approximate illustration) has no effect on the temperature and precipitation modifiers, but impacts the canopy resistance.

differ with regard to temperature: the mean annual and seasonal (May-October) temperatures in two arbitrarily selected grid cells (one in the bottom of the Rhone valley at 667 m asl and one near the treeline at 2160 m asl) are shown on Fig. S5.

3 Results

3.1 Plausibilization of simulated streamflow

To evaluate model efficiency, the Kling-Gupta efficiency (Gupta et al., 2009, KGE,) was applied to daily streamflow for the period April 2004-December 2008 in subcatchments 2 to 5 (Table 2). The scores were calculated for three different model runs: uncoupled FORHYCS (C_U), fully coupled FORHYCS (C_F), as well as a run with original PREVAH (C_P; the version used in Speich et al., 2015) for reference. There is little difference between the scores of these three runs, and no model version consistently outperforms the others. The last four columns of Table 2 show the observed and simulated mean annual streamflow for the period 2005-2007 (the years for which there are no gaps in the observations). The sums simulated by PREVAH are consistently greater than for FORHYCS, with differences between PREVAH and uncoupled FORHYCS ranging between 40 (Moiry) and 172 mm year$^{-1}$ (Chippis). The values simulated with coupled FORHYCS are somewhat higher than with the uncoupled version at the lower elevation subcatchments (35 mm year$^{-1}$ in subcatchment 1 and 6 mm year$^{-1}$ in subcatchment 2), but almost equal in the two high-elevation catchments 4 and 5. Figure 5 a) shows the daily values (30-day rolling means) for subcatchment 3 (Vissoie; analogous figures for the other gauged subcatchments are given on Fig. S6-S8). The main differences between PREVAH and the FORHYCS runs occur in late summer and autumn, where streamflow simulated by PREVAH is consistently higher. The differences between the two FORHYCS versions are shown on Fig. 5 b). The greatest differences occur in winter and early spring, with some peaks in spring 2005 an 2006, and consistently higher streamflow in the winters 2006-2007 and 2007-2008.

3.2 Forest spin-up with different model configurations

3.2.1 Biomass and species composition

Figure 6 shows the aboveground biomass simulated with FORHYCS using the configuration S_F_noL_Ared (analogous figures for the other configurations are provided in S2 the Supplement; Fig. S9 to S16). In addition, the bar shows the average aboveground biomass of trees in plots of the first Swiss national forest inventory (1982-1986; Bachofen et al., 1988). The simu-

Figure 5. (a) Observed vs. simulated daily streamflow for subcatchment 3 (Vissoie) for the period 2004-2008. For clarity, the plot shows rolling averages with a 30-day window. The plot shows results for two FORHYCS runs, uncoupled (C_U) and fully coupled (C_F). For reference, the results obtained with standard PREVAH (C_P) are also shown. (b) Difference in simulated daily streamflow between the coupled and uncoupled versions of FORHYCS. Unlike in a), values are not shown as rolling averages. Streamflow simulated with coupled FORHYCS is usually higher than for the uncoupled version, and the greatest differences occur in winter and spring.
lations start in 1500 with no trees. Biomass increases quickly at the beginning, so that in most zones, values close to 100 t ha\(^{-1}\) are reached within the first 40 years. The initial species composition consists of various broadleaf species, among which the maple species *Acer campestre* and *A. pseudoplatanus*. The former is more prevalent at lower elevations, and the latter at higher elevations (to avoid overloading the figure, the maple species are grouped together). After this initial state, *Pinus sylvestris* (mainly at lower elevations) and *Larix decidua* (mainly at higher elevations) start developing. Finally, *Quercus* species (lower elevations, mainly *Q. pubescens* and *Q. petraea*), *Abies alba* (north-facing slopes) and *Picea abies* develop, with the latter becoming dominant at higher elevations. At the end of the simulation, the forest seems to have reached a state in which the relative importance of species changes little over time. At lower elevations, the state at the end of the simulation is close to that reached after the first 100 or 200 years. By contrast, at high elevations, the replacement of *L. decidua* by *P. abies* occurs over a much longer time.

At low elevations, simulated biomass is higher than the inventory value, especially on north-facing slopes. By contrast, simulated biomass is lower than the observed value at intermediate elevations. Unlike in simulations, for slopes reaching below 1346 m, there is almost no *Quercus* and *Acer* biomass in the inventory data, and the share of other broadleaves is also much smaller. Also at intermediate elevations, FORHYCS simulates a higher biomass for *Acer* and other broadleaves. However, *L. decidua* makes up one third of observed biomass in that elevation band, while it is practically non-existent in the simulations. Also at higher elevations, the simulated biomass of *L. decidua* is much lower than in the inventory data.

The results of S_T_noHmax_BEK (Fig. S9) differ greatly from those on Fig. 6. *Pinus sylvestris* is dominant at intermediate elevations, whereas high elevations are dominated by *L. decidua*. *P. abies* is hardly represented, and simulated biomass for broadleaves is very low. Fluctuations of simulated biomass are also much higher, with increases or decreases of up to 70 t ha\(^{-1}\) within 20 years. For S_T_noHmax_RA15 (Fig. S10), biomass equals or exceeds 200 t ha\(^{-1}\) in all strata except at the highest elevations. The mesophilous species *Abies alba* and *P. abies* dominate at all elevations. For TreeMig runs with maximum height reduction (S_T_Hmax_BEK and S_T_Hmax_BEK; Figs. S11 and S12), species composition is similar to the results of standard TreeMig, but with much lower biomass.

The configuration S_F_Full differs from S_F_noLAred in that LAI is reduced as a function of drought or low temperatures. Biomass simulated with this configuration (Fig. S13) is markedly higher than with S_F_noLAred, especially at lower and intermediate elevations, while species composition is similar. Biomass also fluctuates more for S_F_Full at lower and intermediate elevations. For S_F_noHmax (Fig. S14) and S_F_cSFC (Fig. S15), biomass is also higher than for S_F_noLAred. In the former case, species composition is similar to S_F_noLAred, whereas for S_F_cSFC, the share of relatively drought intolerant species is larger at lower elevations (e.g. higher share of *P. abies* and lower share of *Pinus sylvestris*). Biomass simulated with S_F_noSmort (Fig. S16) shows no apparent difference from S_F_noLAred.

### 3.2.2 Canopy structure

The distribution of the two metrics of agreement between observed and simulated canopy structure, is shown on Fig. 7. The distribution of $\Delta H_{95}$ shows large differences between the model configurations. While S_T_noHmax_RA15 has its maximum count of $\Delta H_{95}$ at 25.2 m and overestimates H95 in almost all cells, S_T_noHmax_BEK shows a much flatter distribution,
**Figure 6.** Aboveground tree biomass simulated with FORHYCS using the configuration S_noLAre (Table 1). The graphs show annual values, averaged over seven clusters of cells. The bar shows the aboveground biomass in the same area, from the first Swiss national forest inventory (1982-1986; Bachofen et al., 1988). The limits of the elevation bands were set so that each cluster contains at least 30 forest inventory plots. The dashed line marks the year 1971, from when meteorological data are available. Simulation years before 1971 use meteorological data bootstrapped from the years 1981-2000.
with a large number of under- and overestimations. By contrast, the TreeMig runs with maximum height limitation have their maximum count at 0 m, suggesting a better fit. Most of the FORHYCS runs show a similar pattern, with a peak close to 0 m, and most values contained between -16.8 and 21 m. S_F_noHmax, however, has its maximum at 16.8 and overestimates H95 in almost all cells. The distribution of the 1-ABC scores, shown in the lower plot, also sets apart the two configurations with the largest overestimation of H95, S_T_noHmax_RA15 and S_F_noHmax. These runs have their highest density at a lower value than the other configurations. The other FORHYCS runs all have their highest density around 0.95. While S_F_Full shows a distribution of dH95 that is very similar to S_F_noLAred and S_F_noSmort, its density distribution for 1-ABC differs from that of the other 2 configurations. S_F_Full has a lower density around 0.95, but a higher density between 0.7 and 0.85, indicating a lower degree of agreement between observations and simulation for this configuration.

3.2.3 Leaf Area Index

Figure 8 shows a comparison of the Copernicus 300m LAI and values simulated with the different TreeMig and FORHYCS configurations listed in Table 1. For the observations, the averages for the different elevation and aspect classes range approximately between 2 and 4. The lowest values occur on south-facing slopes below 700 m asl (i.e. close to the bottom of the Rhône valley). LAI of the south-facing slopes increases steadily with elevation up to 1700-1900 m asl, where it reaches a value of 4. For cells over 2100 m asl, LAI is again somewhat smaller. LAI is generally higher on north-facing slopes. There is little difference among the elevation bands between 700 and 2100 m asl. Average LAI is always around 4 in that elevational range. Smaller values occur only in the lowest and highest elevation bands. The two standard TreeMig runs differ greatly in the range and pattern of simulated LAI. For S_T_Hmax_BEK, parameterized with available water capacity (AWC) from the soil suitability map (BfR, 1980), the values range between 2 and 6. The highest values occur in the lowest elevation band and, for north-facing slopes, at 1700-1900 m asl. Except for the lowest elevation band, LAI on north-facing slopes is markedly higher than on south-facing slopes, with differences of up to 2.5. By contrast, for S_T_Hmax_RA15, which uses the AWC from Remund and Augustin (2015), the absolute values are much higher and the variability much lower. For all elevation bands, values range between 6.5 and 7.5. The results for TreeMig runs with height limitation are almost equal to the standard version.

There is little less difference in patterns and absolute values among the FORHYCS runs. The absolute values range from 4 to 7. Spread is lowest for the two highest elevation bands, where all configurations give a value of approximately 6, for both north- and south-facing slopes. At lower elevations, there is a clear difference between the two aspect classes, with consistently higher values for the north-facing slopes. The difference between configurations increases with decreasing elevation, and is somewhat higher on south-facing slopes. The configuration S_F_cSFC consistently returns the largest values. On north-facing slopes, the values are lowest for S_F_noLAred. This is also the case at higher elevations on south-facing slopes, whereas at lower elevations, S_noHmax returns the lowest values. In most cases, the results of S_F_Full and S_F_noLAred are similar. Up to 1300-1500 m asl on north-facing slopes, S_F_Full gives somewhat higher values, whereas on south-facing slopes, the value for S_F_noLAred is higher. In all cases, the symbols for S_F_noSmort are indistinguishable from S_F_noLAred.
Figure 7. Distribution of the two goodness-of-fit metrics for canopy structure described in Sect. 2.2.3 over all forested cells of the simulation domain (n=7138). The upper graph shows the distribution of $\Delta H_{95}$ (difference between $H_{95}$ for simulated and observed data) for the different model configurations listed in Table 1. More values closer to zero indicate a better agreement between observed and simulated canopy structure. As $H_{95}$ uses the height classes of TreeMig, the results are given as discrete values with an interval of 4.2 m. The lower graph shows the density distribution of the 1-ABC scores (bandwidth=0.0075). The better the agreement between observed and simulated canopy structure, the more values are close to one.
Figure 8. Observed and simulated Leaf Area Index (LAI), averaged over elevation bands and aspect classes. The observed values show the average of cell-level maximum LAI of the period 2014-2016. The simulated values correspond to the averages of the largest annual maximum LAI values in the last three years of the succession runs (2013-2015). The top graph shows LAI simulated with TreeMig, using two different parameterizations for soil moisture storage capacity. The purple symbols show results of TreeMig runs parameterized with the soil suitability map (BfR, 1980), whereas the green symbols correspond to TreeMig runs parameterized with the dataset of Remund and Augustin (2015). The bottom graph shows the results of the various FORHYCS succession runs, with the configurations listed in Table 1.
### 3.3 Climate change runs

#### 3.3.1 Differences between uncoupled, one-way coupled and fully coupled model runs

Figure 9 shows how area-averaged LAI and rooting zone storage capacity SFC change for all idealized climate change scenarios (the results are shown here as rolling means with a 30-year window; a version without smoothing is given in Fig. S17). LAI and SFC are averaged over two of the strata used in Fig. 6, the lowest stratum of south-facing cells (Fig. 9 a) and c)) and the highest stratum of north-facing cells (Fig. 9 b) and d)). Fig. 9 a) shows the results of the coupled run for the low-elevation south-facing cells. At the end of the succession run, LAI is approximately 6, and over the next century, the values range between 3.5 and 6.5 for all runs except the dry GCM-RCM chain. Long-term average LAI is lower for warmer and drier scenarios runs. In particular, under the dry GCM-RCM chain, LAI starts to decrease sharply around 2050, with values less than 2 at the end of the simulation (Fig. S17). The plot of annual values (Fig. S17) shows that under warmer scenarios, the variability of LAI is much higher, with LAI decreasing much more in certain years than in less warm scenarios. In other years, annual LAI values strongly converge between scenarios. For SFC, values decrease for drying scenarios and increase for wetting scenarios, with consistently higher values for the GCM-RCM chains than for the delta change runs. The high-elevation north-facing cells (Fig. 9 b), Fig. S17 b)) also show a decrease in long-term average LAI and an increase in variability under drying and warming scenarios. Also here, the dry GCM-RCM chain stands out, with a sharp decrease in LAI from the middle of the century. SFC initially increases in all scenarios. Around 2050 (when the temperature and precipitation modifiers reach their maximum), SFC starts decreasing, with a faster decrease in drying scenarios delta change runs.

Due to the similarity of LAI simulated by TreeMig with and without height reduction (cf. Fig. 8), only the results for the version without height reduction are shown. LAI differs greatly between the two TreeMig simulations, especially for the low-elevation south-facing cells (Fig. 9 c), Fig. S17 c)). With TM_BEK, LAI is approximately at 3.5 at the end of the succession run, and decreases to less than 1.5 in the warmest and driest scenario (T6_P-10). Unlike with fully coupled FORHYCS, the dry GCM-RCM chain leads to values within the range of the delta runs at the end of the simulations. By contrast, under TM_RA2015, LAI decreases from 6.5 to 5 in the T6_P-10 scenario. Here, as for the fully coupled runs, the dry GCM-RCM chain leads to substantially lower values than the other runs. Inter-annual variability increases with TM_RA2015, but not with TM_BEK (Fig. S17 c)). In the high-elevation north-facing cells, the LAI trajectories diverge between the two TreeMig runs parameterizations. Under TM_BEK, as for the lower elevation cells, LAI decreases under the T6_P-10 scenario while inter-annual variability increases. On the other hand, with TM_RA2015, LAI increases under all warming scenarios delta change runs. LAI also decreases noticeably under the dry GCM-RCM chain, but remains around 5.5 at the end of the simulation.

Figure 10 a) shows simulated annual streamflow (30-year rolling means) for subcatchment 1 (Chippis), as simulated with uncoupled FORHYCS (equivalent graphs for the other subcatchments are provided in Fig. S18 to S21 in the Supplement). From initially 550 mm year$^{-1}$, streamflow decreases by about 50% under the most extreme warming and drying delta scenario (temperature increase of 6K and precipitation decrease by 10 %). The three GCM-RCM chains show little difference to each other, no clear trends and consistently lead to higher mean annual runoff than all delta change runs. Figure 10 b), c) and d) show the difference in annual streamflow to the uncoupled run (Fig. 10 a)), for the one-way coupled runs (C_T_BEK and
**Figure 9.** (a) Annual maximum LAI (top) and rooting zone storage SFC (bottom) under idealized climate change scenarios, simulated using coupled FORHYCS (C_F). LAI and SFC are averaged over the cells belonging to the lowest elevation class with south-facing slopes (same stratification as for Fig. 6). The results are shown as 30-year rolling means. In the delta change runs, both LAI and SFC generally increase under wetting scenarios, and decrease under drying scenarios, although trends are not always monotonous. While the wet and medium scenarios are in the same range as the delta runs, the dry scenario leads to a marked decrease from about 2050. (b) Same as a), but for the highest elevation class with north-facing slopes. Also here, LAI increases under wet scenarios and decreases under dry scenarios. SFC trajectories show large differences between scenarios. (c) LAI simulated with TreeMig, with the two different soil parameterizations (C_T_BEK and C_T_RA15). Note the different scales on the y-axis. LAI simulated with C_T_BEK is markedly lower than for C_F, whereas the C_T_RA15 values are somewhat higher. (d) Same as c), but for the highest elevation class with north-facing slopes.
C_T_RA15) and the fully coupled FORHYCS runs (C_F), respectively. In all cases, streamflow is higher in the coupled runs. For C_T_BEK, the difference is approximately 30 mm year\(^{-1}\) at the end of the succession and increases under idealized climate change. The increase is greater for warmer scenarios, with a difference of 60 mm year\(^{-1}\) for the warmest delta change scenarios (T6_Py) at the end of the simulation. For the GCM-RCM chains, the difference is usually smaller than for most delta change runs. The difference in annual streamflow is much less for C_T_RA15, and ranges between 5 and 20 mm year\(^{-1}\). Here, the difference in streamflow decreases with idealized climate change, with a more pronounced decrease for the warmer delta change scenarios. For the fully coupled runs, the initial difference is around 30 mm year\(^{-1}\), which is similar to the initial difference for C_T_BEK. During idealized climate change, the difference does not increase as much as for C_T_BEK: the largest difference in the order of 40 mm year\(^{-1}\). The only exception is the dry GCM-RCM chain, where streamflow difference starts increasing sharply around 2050 to reach 60 mm year\(^{-1}\) at the end of the simulation. Unlike for TM_BEK, the delta change scenarios with the greatest difference by the end of the simulation are the three warming and drying scenarios.

### 3.3.2 Effect of CO\(_2\) concentration

The increase of stomatal resistance due to increased CO\(_2\) concentration (Eq. 12) has a minimal effect on streamflow and area-averaged forest properties (not shown) (see Fig. S22 in the Supplement). In C_F_NCS (the runs in which Eq. 12 is set to one), streamflow is consistently lower than in the C_F runs. The greatest difference occurs towards the end of the simulation period in the Chippis subcatchment, with differences of up to 10 mm year\(^{-1}\). The differences are largest in the simulations with a precipitation increase. Regarding vegetation properties, the differences in LAI and SFC, averaged over the strata used in Fig. 6, never exceed 0.05 m\(^2\)m\(^{-2}\) and 1 mm, respectively.

### 3.3.3 Effect of land-use change

Figure 11 shows the difference in annual streamflow (30-year annual means) between a fully coupled run without land-use change (C_F) and a run in which forest is allowed to grow in all cells with a "potentially forested" land cover type (see Fig. 2). The three subcatchments shown here differ by elevation and distribution of land cover classes. Chippis is the lowest subcatchment and has few cells belonging to the “potentially forested” land cover classes. By contrast, the high-elevation subcatchments Mottec and Moiry are barely forested (Mottec) or have no forest cells at all (Moiry). In the warmest scenarios, LAI and rooting zone storage capacity reached values of 5.5 and 120 mm, respectively, by the end of the simulation even in the highest elevation band of meadows (cells above 2700 m asl). In all cases, allowing land-cover change leads to a decrease in streamflow. The magnitude of this change depends greatly upon the warming scenario. When no warming is assumed, the difference in streamflow relative to the simulation without land cover change is approximately 10 mm year\(^{-1}\). In all three subcatchments, the difference is greatest under warmer and wetter scenarios. The difference increases rapidly until 2050 (when the temperature and precipitation modifiers reach their maximum), whereas the increase is slower or partially reversed between 2050 and 2100.
Figure 10. (a) Simulated annual streamflow (30-year rolling means) in the Chippis subcatchment (lowest elevation, most forested). In the warmest dry delta change scenario (T6_P-10), annual streamflow is reduced approximately by half, from 550 to less than 300 mm/year. (b) and (c) Difference in annual streamflow in the runs with one-way coupling in the warm and dry scenarios, relative to the uncoupled run. (d) Difference in annual streamflow in the fully coupled FORHYCS run, relative to the uncoupled run. In all coupled runs, streamflow is greater than in the uncoupled version, due to lower LAI (see Fig. 8 and 9; the standard PREVAH value for forest LAI is 8) and, for the fully coupled version, smaller rooting zone storage capacity SFC.
Figure 11. Difference in simulated annual streamflow (30-year rolling means) between the standard fully coupled runs (C_F) and the coupled runs with land abandonment (C_F_LC) for three contrasting subcatchments. In the land abandonment scenario, forest is allowed to grow in all cells classified as "meadows" and "alpine vegetation". The Chippis subcatchment has relatively few meadows, whereas they occupy about a third of the high-elevation catchment Moiry (see Fig. 2). Forest expansion leads to streamflow reduction due to the higher leaf area, and potentially deeper roots. As most meadows are located at high elevations, the effect of forest expansion on streamflow greatly depends on the warming scenario.

4 Discussion

4.1 Effect of coupling on hydrological simulations

The plausibilization of simulated streamflow (Sect. 3.1) showed that PREV AH in its original version, as well as coupled and uncoupled FORHYCS yielded similar goodness-of-fit scores in the four gauged subcatchments of this study. The differences between standard PREV AH and the two FORHYCS versions are much larger than between coupled and uncoupled FORHYCS. As noted in Sect. 2.1.7, the main difference between standard PREV AH and uncoupled FORHYCS is the parameterization of rooting zone storage capacity SFC. As this difference is considerable (see Fig. S1), the differences in daily streamflow seen on Fig. 5 are to a large extent due to the differing SFC parameterizations. Due to the small differences between the results of coupled and uncoupled FORHYCS, it is not possible to conclude whether varying vegetation properties has led to an improvement of model performance. In the fully coupled version, simulated LAI is quite close to the default values in PREV AH (cf. Fig. 8; standard summer LAI for forests in PREV AH is 8). As seen on Fig. 8, LAI is smaller when simulated with TM_BEK in most elevation bands. A comparison of the simulated streamflow shown in Sect. 3.1 with output from a one-way coupled simulation with TM_BEK (not shown) shows differences of only 3 mm year$^{-1}$ between one-way and two-way couplings, except in the ungauged catchment 1 (Chippis), where the difference is 24 mm year$^{-1}$. This suggests that the sensitivity of
The relatively modest effect of the coupling on simulated streamflow, especially in the high-elevation subcatchments, is consistent with the findings of Schattan et al. (2013), whose study domain also included the Navizence catchment. They found a differential effect of transient vegetation parameters on simulated streamflow, with the greatest effects at low elevations (where LAI is much lower than the generic parameter value of the hydrological model) and above the current treeline (where the forest may expand in the future). The issue of scale is also of relevance: as forested cells make up a relatively small fraction of each subcatchment (Fig. 2), even an important change in the water balance of some forested cells will have little influence on catchment-integrated streamflow. The most extreme example of change in vegetation parameters in this study in the runs using meteorological forcing from the GCM-RCM model chain representing dry conditions. In this run, forest LAI greatly decreases throughout the study region (Fig. 9), leading to a difference in simulated streamflow of up to 60 mm year$^{-1}$ between the coupled and uncoupled runs (Fig. 10). This shows the value of including vegetation dynamics for hydrological modeling under severe change.

In addition, while leaf area and rooting depth are among the most sensitive vegetation parameters for surface water partitioning (Milly, 1993; Nijzink et al., 2016; Speich et al., 2018a), FORHYCS does not represent all possible impacts of forest dynamics on hydrological processes. For example, forest properties have been related to hydrological model parameters relating to snow (Seibert, 1999) or soil properties (Johst et al., 2008). Badoux et al. (2006) found that forest site type was a good indicator of the dominant runoff processes. While this does not imply a causal relationship between forest characteristics and runoff generation in all cases, some of the differences between runoff processes could be explained by forest properties, such as hydrophobicity of conifer needle litter, which promotes fast runoff processes. On the other hand, forest soils are often associated with low runoff coefficients. Johst et al. (2008) parameterized the soil moisture recharge BETA as a function of land cover type. This parameter, which controls the partitioning of precipitation between plant-available soil moisture and runoff generation, is also used in the local water balance modules of PREVAH and FORHYCS (see Speich et al., 2018a). Speich et al. (2018a) found that BETA was a relatively sensitive parameter for the physiological drought index of FORHYCS. Currently, snow and runoff generation parameters are static in PREVAH and FORHYCS. As they have been obtained through regionalization, it may be challenging to relate their values to specific forest properties. However, representing the effects of forest dynamics on these processes might further reduce the dependence on calibrated and regionalized parameter values.

### 4.2 Effect of coupling on forest simulations

To assess the effect of various forest-hydrology couplings on the performance of the forest models, several outputs and state variables were compared against observations. For various reasons, a perfect match between simulated and observed vegetation properties cannot be expected. First, the model simulates the potential natural vegetation dynamics, without considering forest management or disturbances such as fire or avalanches, which again have impacts on stand age. Second, the succession is modeled using bootstrapped meteorological forcing data, which do not contain any trends and may differ greatly from the actual climate in past centuries. Third, the spatial scales of model outputs and observations are not the same. For all these reasons,
the comparison against observations serves as a plausibilization rather than a rigorous validation of the model. Nevertheless, it is assumed that when aggregated to a larger scale, a qualitative comparison with observations can still give some indication of the model’s skill. The fully coupled FORHYCS gave reasonable results for biomass, species composition and stand structure (simulated LAI is discussed in the next paragraph). It is important to remember that the coupled and uncoupled forest simulations used two different drought indices, one that depends on transfer variables from PREVAH equations, and one that is calculated before the simulations, respectively (see Sect. 2.1.3). These indices require two different sets of species-specific drought tolerance parameters. Therefore, it is difficult to assess to what extent the differences in model outputs are due to the coupling, or to the different parameterization. In any case, representing the effect of water availability (and low temperatures) on maximum height greatly improved the simulation of canopy structure, also in uncoupled models. By contrast, reducing leaf area as a function of stress leads to poorer results regarding canopy structure, as well as unrealistic biomass fluctuations. Two main effects happen in the model as a result of LAI reduction: the drought index (Eq. 5) is lower than it would be without LAI reduction; and the light distribution is modified, i.e. lower height classes get more light than they would get without LAI reduction. These two effects both promote tree growth, which explains why the model simulates higher biomass. This higher growth also eventually leads to greater mortality, after the number and size of trees have grown fast for some years. This explains the more dynamic pattern when LAI reduction is activated (Fig. S13).

Simulated leaf area index (LAI) varies greatly between the TreeMig and FORHYCS runs (Fig. 8). The pattern of LAI simulated with TM_BEK across elevation bands follows the distribution of soil moisture storage capacity (Fig. S1). The flat areas at the bottom of the Rhône valley are the only areas where storage capacity exceeds 100 mm. Therefore, LAI is high for the lowest elevation band. By contrast, storage capacity on the slopes is much lower, so that LAI initially sharply decreases with elevation. With TM_RA2015, water is hardly limiting, so that LAI is high at all elevations. LAI simulated with FORHYCS shows a similar pattern as the remotely sensed data, with an initial increase with elevation, and consistently higher values on north-facing than on south-facing slopes, except at the highest elevations. The absolute values, however, are consistently higher than the observations, sometimes offset by a factor of two. Various factors hinder a direct, quantitative comparison of measured and simulated LAI. First, the 300-by-300 m cells of the remotely sensed dataset may contain non-forested surfaces, such as pastures, clearings, roads or water bodies, even if the cell is classified as forest. The model does not consider this type of spatial heterogeneity. This is especially relevant in regions with a high spatial variability of land cover, as is the case in this study region. Second, remotely sensed LAI is subject to some uncertainty, due for example to the clumping of needles in coniferous forests (Garrigues et al., 2008). Despite a good overall performance, the authors of the validation report for the Copernicus LAI 300 product (Camacho et al., 2016, p.83) note that forests were under-represented in the validation dataset. Therefore, it is difficult to say to what extent FORHYCS overestimated LAI in this study. Schleppi et al. (2011) measured LAI at 91 forested sites across Switzerland and used a regression against stand parameters to predict LAI in forests throughout the country. Their measured values range between 1 and 7. They noted a decrease of LAI with elevation, as well as a limitation of LAI due to water availability for sites with annual precipitation below 1000 mm. The values simulated by FORHYCS thus appear plausible at intermediate elevations, where the effects of both water availability and low temperatures are moderate. By contrast, terrestrial LAI measurements at the bottom of the Rhône valley (Dobbertin et al., 2010) are between 2 and 2.5. Despite the presence of
patches with more mesic forest types, especially in the proximity of water bodies (personal observation), such values can be taken as representative for the xeric forests in the Rhône valley. The values simulated by TreeMig and FORHYCS are much higher than this for this elevation band. At high elevations, the decrease in LAI is not as pronounced in the simulations as in the observations (Fig. 8). These results suggest that the spatial variability of LAI is somewhat underestimated by the model, especially where an environmental factor is particularly limiting.

4.3 Effect of coupling on model behavior under climate change

The models used in this study are very similar to those used in the simulation experiment of Lischke and Zierl (2002). In that experiment, they coupled the gap model DisCForM, from which TreeMig was later derived, with a point-scale water balance model which is conceptually similar to the new local water balance module of FORHYCS. They found that the coupling of forest dynamics and water balance had a stabilizing effect on the simulated system under climate change. In their experiment, coupled simulations converged towards low LAI and lower levels of physiological drought. This effect is not visible to the same extent in the simulations conducted here. The effect of warming on forests is less pronounced in the fully coupled runs, as evidenced by the evolution of streamflow differences on Fig. 10. However, it cannot be excluded that this is due to the different drought tolerance parameters, or to the lesser sensitivity of the FORHYCS drought index to changes in temperature.

In contrast to the study of Lischke and Zierl (2002), FORHYCS includes some additional mechanisms through which the system can react to changes in climate, such as the adaptation of rooting depth and maximum tree height. Some processes may even have a destabilizing influence on the system, such as the high fluctuations in biomass introduced by the stress-induced leaf area reduction.

An exception to the generally resilient behavior of forests under climate change are the GCM-RCM runs representative for dry conditions. In these runs, the forest greatly deteriorates throughout the study region, even under the C_F configuration (Fig. 9). Interestingly, under this meteorological forcing, precipitation is higher than in the delta change scenarios, where this severe reduction of forest LAI does not occur (see Sect. 2.2.4 and Fig. S2). Therefore, the high stress causing this LAI reduction must have been caused mainly by changes in potential evaporation or temporal precipitation distribution. While this study has shown a range of possible model behaviors under various climate change scenarios, future research should examine more formally the effect of different bioclimatic factors on the behavior of forest models under climate change. For example, understanding the physiological significance of bioclimatic drought indices is important to interpret how a forest model responds to different scenarios (Speich, 2019). Also, rooting depth has been shown to be an important interface variable for the coupling of hydrology and vegetation dynamics. In the runs presented in this study, ecoregion-integrated rooting zone storage capacity fluctuated by up to 30 mm over the course of a simulation covering 130 years. The rooting depth formulation used in FORHYCS responds to bioclimatic and edaphic conditions in complex and nonlinear ways (Guswa, 2008, 2010; Speich et al., 2018b). As the inclusion of this variable is rather new in dynamic models, its magnitude and dynamics should be plausibilized against empirical evidence, using e.g. inverse modeling (Nijzink et al., 2016)
4.4 Effect of additional processes

4.4.1 $CO_2$ concentration

Results of this modeling experiment have shown that an increase in atmospheric $CO_2$ concentration has almost no effect on hydrological processes and vegetation dynamics as modeled by FORHYCS. In this implementation, the physiological effect of elevated $CO_2$ concentration is represented by an additional modifier function to the stomatal resistance parameterization. All else being equal, an increase in $C_a$ leads to an increase in stomatal resistance, and thus to a decrease in potential and actual transpiration. This slows down canopy water use, and thus leads to lower levels of simulated physiological drought. This formulation does not account for other physiological impacts of elevated $C_a$, such as enhanced photosynthetic rates, or possible acclimation effects. The physiological effect of increased $C_a$ is a source of uncertainty in forest models, due to widely differing process formulations among models (Medlyn et al., 2011). For example, our results contrast with the simulations of Scherstjanoi et al. (2014), who applied a modified version of LPJ-GUESS and found a crucial influence of $C_a$ on simulated future forest biomass in Switzerland. These differences between models are partly due to the knowledge gaps regarding the underlying processes. According to Medlyn et al. (2011), models that do not consider the physiological effects of $C_a$ at all are likely to underestimate future forest productivity, whereas some other models are likely to yield overestimates due to an improper representation of other limiting factors. From an ecohydrological point of view, the large-scale effects of increased $C_a$ have been the object of a number of recent studies. For example, Trancoso et al. (2017) found that decreases in streamflow in Australian catchments were caused by vegetation greening, which was in turn driven by elevated $C_a$. These studies suggest that the stomatal effects of increased $C_a$ (transpiration reduction) are more than offset by enhanced vegetation growth. This is not the case in this study, where the only visible effect was an increase in streamflow, whereas vegetation properties were not affected at all.

4.4.2 Land cover change

In this simulation experiment, allowing the forest to grow in areas currently covered by meadows caused a reduction of streamflow of up to 60 mm year$^{-1}$ at subcatchment level (Fig. 11). This is a substantially greater effect than in the simulation experiment of Schattan et al. (2013), who found a change in annual runoff in the order of 10 mm year$^{-1}$ in regions currently above the treeline as they become forested under simulated climate change. Under the scenario used in their study, temperature was projected to increase by 3-4 K by the end of the century. A major difference with this study is that they only varied LAI, whereas in this study, the development of both LAI and rooting depth were simulated. In the warmest scenarios, LAI and rooting zone storage capacity reached values of 5.5 and 120 mm, respectively, by the end of the simulation even in the highest elevation band of meadows (cells above 2700 m asl). Both of these variables probably had a major impact on simulated streamflow. These spectacular results must be considered in the light of several potential sources of uncertainty in the model formulation. First, FORHYCS does not account for competition by other vegetation types, which may slow down the expansion of forests. Also, other factors that make the current treelines an extreme environment are not considered by FORHYCS, such as the steep slopes and shallow soils. For example, it was shown that during the warmest period of the Holocene, only
stunted trees were able to establish at high elevations, although the climate would have allowed a forest to grow (Theurillat and Guisan, 2001). Another aspect to consider is that at the beginning of the simulation, meadows and alpine vegetation types were parameterized with a prescribed rooting depth of 22 cm. This value was set arbitrarily, and if it was actually higher for these vegetation types, the hydrological impact of forest expansion would be exaggerated in the simulations.

5  Conclusions and Outlook

This study presented a proof-of-concept for a dynamic, spatially distributed model combining hydrological processes and forest dynamics. The main interface variables are leaf area index, rooting depth, as well as a physiological drought index. This model was applied in a case study in a valley with a sharp topographical and hydro-climatic gradient.

The motivation behind developing this model was to apply it to climate change impact studies in which the spatio-temporal forest dynamics and water balance of Switzerland are simulated together. The closer integration of these ecosystem processes would increase the confidence in these model projections, compared to uncoupled models that do not account for changes in the environment besides climate. The research questions were (1) how model coupling impacts the results of simulated water balance and forest dynamics, (2) which aspects of the coupling were particularly relevant, and (3) how model coupling affects simulation results under climate change. From the hydrological point of view, the coupling had only a modest effect on catchment-integrated streamflow, although this effect was not uniform in space: the greatest effects occurred at low elevations, and in regions currently above the treeline. Regarding forest simulations, model results were compared against multiple data sources to examine model behavior and pinpoint potential weaknesses. In a comparison with a new high-resolution canopy height dataset, two new indices of agreement between observed and simulated forest structure were developed. This comparison confirmed the importance of specifying an environmental limitation on maximum tree height, as this greatly improved the realism of simulated canopy structure and biomass. Also, a dynamic parameterization of rooting depth led to better model performance. In combination with remotely sensed LAI data, this model-data comparison showed that the coupled model was better able to reproduce observed spatial patterns, although it also highlighted potential deficiencies in the way drought impacts are represented. Under (idealized) climate change, the forests in the coupled model show greater resilience, which translates into a reduced sensitivity of mean annual streamflow to changes in temperature and precipitation. In some cases, the behavior of the model seems exaggerated, but demonstrates the importance of explicitly modeling relevant processes. This was the case with regard to the possible expansion of forests above the current treeline. On the other hand, the effects of increased CO₂ concentration on plant physiology are less than what observations suggest, highlighting the challenges of incorporating physiological principles into phenomenological models. As these areas are the object of active research, it is expected that new analyses will give the opportunity to test model behavior under these novel conditions, and possibly to improve process formulations.
Code availability. Due to the dependency on specific, internally defined data formats, the model cannot be easily transferred to a new environment. For verification purposes, the Fortran code for the processes described in this paper is provided in the supplement. The model code for FORHYCS is accessible under https://www.envidat.ch/dataset/forhycs-v-1-0-0-model-code (DOI: 10.16904/envidat.93). Please note that due to restrictions from the data provider, the meteorological forcing data cannot be made public. For research purposes, this data can be obtained directly from the Swiss Federal Office of Meteorology MeteoSwiss.

Appendix A

Author contributions. HL and MZ designed the study. MJRS and MS wrote the new model code for the integration of PREVAH and TreeMig. MJRS executed the experiments and drafted the manuscript, under supervision from HL and MZ.

Competing interests. The authors declare that they have no competing interests

Acknowledgements. This research was funded by the Swiss National Science Foundation (no. 153544) and the Swiss Federal Office for the Environment (no. 15.0003.PJ/Q104-0149). The authors would like to thank James Kirchner (ETH Zurich) and Giorgio Vacchiano (University of Milan) for helpful comments on a previous version of this paper. Furthermore, we would like to thank Esther Thürig for providing the forest inventory data, and Christian Ginzler for providing the canopy height data. Streamflow data was obtained from Forces Motrices de la Gougra SA. We would like to thank the two anonymous reviewers for their helpful comments on an earlier version of this manuscript.
### Table A1. THIS HAS BEEN MOVED TO SUPPLEMENT

Values for the species-specific drought tolerance parameter $k_{DT}$ used in this study (last column). The parameter values were obtained by mapping the drought tolerance scores of Niinemets and Valladares (2006) (second column) on the range of values used by Lischke and Zierl (2002). Some of the parameter values were adjusted manually to improve modeled species composition. The parameters of Lischke and Zierl (2002) and of this study indicate the drought index DI at which the drought stress function (Eq. 6) becomes zero. The scores of Niinemets and Valladares (2006) take values between 1 (low tolerance) and 5 (high tolerance) and were obtained based on climatic characteristics at sites where each species was observed. Species marked with an asterisk were excluded from the simulations presented in this paper.
