**Abstract.** The roughness sublayer (RSL) is one compartment of the surface layer (SL) where turbulence deviates from Monin–Obukhov similarity theory. As the computing power increases, model grid sizes approach to the gray zone of turbulence in the energy containing range and the lowest model layer is located within the RSL. In this perspective, the RSL has an important implication in atmospheric modeling research. However, it has not been explicitly simulated in atmospheric mesoscale models. This study incorporates the RSL model proposed by Harman and Finnigan (2007, 2008) into the Jiménez et al. (2012) SL scheme. A high-resolution simulation performed with the Weather Research and Forecasting model (WRF) illustrates the impacts of the RSL parameterization on the wind, air temperature, and rainfall simulation in the atmospheric boundary layer. As the roughness parameters vary with the atmospheric stability and vegetative phenology in the RSL model, our RSL implementation reproduces the observed surface wind, particularly over tall canopies in the winter season by reducing the root mean square error (RMSE) from 3.1 to 1.8 m s<sup>-1</sup>. Moreover, the improvement is relevant to air temperature (from 2.74 to 2.67 K of RMSE) and precipitation (from 140 to 135 mm month<sup>-1</sup> of RMSE). Our findings suggest that the RSL must be properly considered both for better weather and climate simulations and for the application of wind energy and atmospheric dispersion.

## 1 Introduction

The Planetary boundary layer (PBL) is important for the proper simulation of weather, climate, wind energy application, and air pollution. Turbulence plays a critical role in the spatio-temporal variation of the PBL structure through the turbulent exchanges of momentum, energy, and water between the atmosphere and Earth's surface. Because turbulent eddies in the PBL are smaller than the typical grid size in mesoscale and global models, their impacts must be properly parameterized for atmospheric models. The surface layer (SL) occupies the lowest 10% of the ABL, where the shear-driven turbulence is dominant. In the SL, Monin–Obukhov similarity theory (MOST), which is a zero-order turbulence closure, provides the relationships between the vertical distribution of wind and scalars and the corresponding fluxes in a given stability condition (Obukhov, 1946; Monin and Obukhov, 1954). The typical numerical weather prediction (NWP) and climate models are applied

25

30 for the SL parameterization based on MOST to parameterize the subgrid-scale influences of the turbulent eddies in the PBL (e.g., Sellers et al., 1986, 1996).

The SL has two parts: inertial sublayer (ISL) and roughness sublayer (RSL). The ISL is the upper part of the SL, where MOST is valid and vertical variation of the turbulent fluxes is negligible. The RSL is the layer near and within the surface roughness elements (e.g., trees and buildings). The turbulent transport in the RSL has a mixing layer analogy, and the atmospheric flow depends on the roughness element properties (Raupach et al., 1996). Accordingly, the flux–gradient relationships in the RSL deviate from the MOST predictions, and the eddy diffusion coefficients are larger than the values in the ISL (e.g., Shaw et al., 1988; Kaimal and Finnigan, 1994; Brunet and Irvine, 2000; Finnigan, 2000; Hong et al., 2002; Dupont and Patton, 2012; Shapkalijevski et al., 2016; Zhan et al., 2016; Basu and Lacser, 2017).

Traditionally, the RSL has not been explicitly considered in global and mesoscale models because the PBL in the model is coarsely resolved, and the lowest model layer is well above the roughness elements accordingly. As the computing power increases, the regional and global models can be simulated with a finer spatial resolution and the grid size of the NWP model moving toward the gray zone of turbulence (the scales on the order of the energy-containing range of turbulence). Nevertheless, studies on the impact of a fine vertical resolution have not been relatively performed. In this perspective, the RSL has an important implication in atmospheric modeling research. The lowest model layer is typically approximately 30 m high, and its vertical resolution continues to be better; hence, the models have more than one vertical layer in the RSL, which extends to 2–3 times of the canopy height. Furthermore, model outputs are sensitive to the selection of the lowest model level height (Shin et al., 2011), but its relation to the RSL has not yet been clearly investigated. Accordingly, turbulent transport in the RSL must be incorporated particularly in the mesoscale models if the vertical model levels are inside the RSL with an increase in the vertical model resolution.

The RSL function is a popular and simple method of incorporating the effects of the RSL in the observation and model (e.g., Raupach, 1992; Physick and Garratt, 1995; Wenzel et al., 1997; Mölder et al., 1999; Harman and Finnigan, 2007, 2008; de Ridder, 2010; Arnqvist and Bergström, 2015). The RSL function is defined as the observed relationship between the vertical gradient of wind and scalar variables and their corresponding fluxes in the RSL. Accordingly, simple relationships are appropriate for the land surface model in the climate model and for the mesoscale model (Physick and Garratt, 1995; Sellers et al., 1986, 1996). Despite the importance of the RSL, the Weather and Research Forecasting (WRF) model (Skamarock et al., 2008), which is one of the widely used models in the operation and research fields, does not consider the effects of the RSL for the regional weather and climate simulations. Harman and Finnigan (2007, 2008) and Harman (2012) (hereafter, HFs) recently proposed a relatively simpler RSL function that can be used in a wide range of atmospheric models. The RSL function of the HFs is based on a theoretical background and applicable to a wide range of atmospheric stabilities by succinctly satisfying the continuity of the vertical profiles of fluxes, wind, and scalars both at the top of the RSL and at the top of a canopy. The parameterization of HFs has recently been incorporated in a one-dimensional (1D) PBL model and a land surface model (Harman, 2012; Shapkalijevski et al., 2017; Bonan et al., 2018).

Based on the abovementioned background, this study incorporates the RSL parameterization based on the RSL function of the HFs into the WRF model (version 3.7.1). For this purpose, we reformulate the HFs' RSL parameterization to implement it in the SL parameterization in the WRF model and then discuss the impacts of the RSL parameterization on the regional weather and climate simulations in terms of meteorological conditions near the Earth surface. To the best of the authors' knowledge, our study is the first extensive attempt to incorporate the RSL parameterization into the WRF model and to validate it for regional climate simulations. Section 2 is a brief discussion of the RSL parameterization of HFs and the implementation procedures into the WRF model. Section 3 explains the experimental and observational descriptions. Section 4 presents the impacts of the RSL parameterization. Section 5 ends the study with the concluding remarks.

## 2 RSL theory of the HFs

The roughness sublayer parameterization by HFs is adopted herein along with an explanation of the core of the HF model, and the relevant details on this parameterization can be found in Harman and Finnigan (2007, 2008) and Harman (2012). Appendix A lists the symbols and variables used in this study in alphabetical order.

We first define the coordinate alignment for its application to the WRF. The revised MM5 SL scheme in the WRF model defines the vertical origin by the conventional zero-plane displacement height ( $d_0$ ). The same coordinate system is also applied herein. The vertical coordinates  $z$  and  $\tilde{z}$  in this coordinate system are defined as the distance from  $d_0$  and from the terrain surface, respectively; therefore, their relation is  $z = \tilde{z} - d_0$  (Fig. 1). Note that a vertical origin in the HFs is at the canopy height ( $h$ ). MOST says that a variable ( $C$ ), such as wind speed ( $u$ ) and temperature ( $T$ ), has the logarithmic vertical profile:

$$\frac{k}{C_*} (C(z) - C_0) = \ln\left(\frac{z}{z_0}\right) - \psi_c\left(\frac{z}{L}\right) + \psi_c\left(\frac{z_0}{L}\right), \quad (1)$$

where  $k$  is von Kármán constant;  $C_*$  is a  $C$  scale;  $C_0$  is  $C$  at  $z_0$ ;  $z_0$  is the roughness length;  $\psi_c$  is the integrated similarity function of  $C$ ; and  $L$  is the Obukhov length. The  $C$  profile based on the RSL function of the HFs is divided into two layers depending on the relative distance between the canopy height ( $h$ ) and the redefined zero-plane displacement height in the HFs ( $d_t = h - d_0$ ): the upper-canopy layer ( $z > d_t$ ), where the influence of additional mixing by the canopy exists, and the lower-canopy layer ( $z < d_t$ ), where the canopy is the direct source and sink for drag and heat. The vertical profile in the upper-canopy layer is described as follows:

$$\frac{k}{C_*} (C(z) - C_0) = \ln\left(\frac{z}{z_0}\right) - \psi_c\left(\frac{z}{L}\right) + \psi_c\left(\frac{z_0}{L}\right) + \int_z^\infty \frac{\phi_c(1-\hat{\phi}_c)}{z'} dz', \quad (2)$$

where  $\phi_c$  is the similarity function of  $C$  and  $\hat{\phi}_c$  is an RSL function of  $C$ . In the  $z \rightarrow \infty$  limit,  $\hat{\phi}_c$  is equal to 1 and the wind speed converges to the MOST prediction. The last term in the right-hand side represents the additional mixing caused by the roughness element due to the coherent canopy turbulence, and can be replaced by  $\hat{\psi}_c$ , which is an integrated RSL function of  $C$ . The vertical profile from the HFs for the RSL deviates from that of MOST because of  $\hat{\psi}_c$ , thereby adjusting the logarithmic profile. The  $\hat{\phi}_c$  is introduced as follows:

$$\hat{\phi}_c = 1 - c_1 \exp\left[-c_2 \frac{\beta}{l_m} z\right]. \quad (3)$$

$c_1$  and  $c_2$  are then determined from the continuity of  $\hat{\phi}_c$  at the canopy top and the RSL function,  $\hat{\phi}_c$  exponentially converges to zero above the RSL. In the lower canopy layer,  $C$  has the following exponential form:

$$C(z) - C_0 = (C_h - C_0) \exp\left(f \frac{z-d_t}{2d_t}\right), \quad (4)$$

The RSL functions vary with atmospheric stability through  $\beta$ ,

$$\beta = \begin{cases} \frac{\beta_N}{\phi_m(z=d_t)} & \frac{L_c}{L} > -0.15 \\ \frac{k}{2\phi_m(z=d_t)} + \frac{\frac{\beta_N}{\phi_m(z=d_t)} - \frac{k}{2\phi_m(z=d_t)}}{1+2\left|\frac{L_c}{L}+0.15\right|^{1.5}} & \frac{L_c}{L} \leq -0.15 \end{cases}, \quad (5)$$

where  $L_c$  is a canopy penetration depth defined as:

$$L_c = (c_d a)^{-1} = \frac{4h}{LAI}. \quad (6)$$

95 where  $c_d$  is a drag coefficient at the leaf scale and  $a$  is the leaf area density. The parameter  $d_t$  and  $z_0$  also depend on the stability because of their dependence on  $\beta$ :

$$d_t = h - d_0 = \frac{l_m}{2\beta} = \beta^2 L_c, \quad (7)$$

$$z_0 = d_t \exp\left[-\frac{k}{\beta}\right] \exp\left[-\psi_m\left(\frac{d_t}{L}\right) + \psi_m\left(\frac{z_0}{L}\right)\right] \exp\left[\int_{d_t}^{\infty} \frac{\phi_m(1-\hat{\phi}_m)}{z'} dz'\right]. \quad (8)$$

### 3 Incorporation of the roughness sublayer parameterization into the WRF model

The RSL parameterization of the HFs described above is implemented in the Jiménez et al. (2012) revised MM5 surface layer scheme and Noah land surface model in the WRF (hereafter called the Yonsei University surface layer (YSL) scheme) because  
100 of theoretical consistency between the HFs and PBL parameterization. To incorporate the RSL parameterization, it is necessary to modify the SL scheme and the land surface model as follow (Fig. 1): the first step is to compute the bulk Richardson number at the lowest model layer,  $Bi_b$ , by the original equation of Jiménez et al. (2012) [Eq. (9) in their study]:

$$Bi_b = \frac{g}{\theta_a} \frac{\theta_{va} - \theta_{vg}}{[u(z_r)]^2} z, \quad (9)$$

The second step is to iteratively calculate the atmospheric stability ( $z_r/L$ ) as follows with an accuracy of 0.01:

$$\frac{z_r}{L} = Bi_b \frac{\left[\ln\left(\frac{z_r}{z_0}\right) - \psi_m\left(\frac{z_r}{L}\right) + \psi_m\left(\frac{z_0}{L}\right) + \hat{\psi}_m\right]^2}{\left[\ln\left(\frac{\rho c_p k u_*^{n-1} z_r + z_r}{c_s} - \psi_h\left(\frac{z_r}{L}\right) + \psi_h\left(\frac{z_l}{L}\right) + \hat{\psi}_h\right)\right]}, \quad (10)$$

where  $u_*^{n-1}$  is the friction velocity ( $u^*$ ) at previous time step. Equation (10) is different from Eq. (23) of Jiménez et al. (2012)  
105 by the RSL functions (i.e.,  $\hat{\psi}_m$  and  $\hat{\psi}_h$ ). After  $z_r/L$  is determined, the third step is to iteratively update  $d_t$  and  $\beta$  using Eqs. (5)

and (7) with an accuracy of 0.0001 because they are inter-correlated with each other. Subsequently,  $z_0$  is iteratively achieved with an accuracy of 0.0001 using Eq. (8) at the given  $z_r/L$ ,  $\beta$ , and  $d_t$ . The  $u$  profile is determined using Eqs. (2) and (4). Following Jiménez et al. (2012), the profile of a scalar, such as  $T$ , is determined by

$$\frac{k}{c_*}(C(z) - C_0) = \ln\left(\frac{\rho c_p k u_*^{n-1} z_r}{c_s} + \frac{z_r}{z_l}\right) - \psi_c\left(\frac{z}{L}\right) + \psi_c\left(\frac{z_0}{L}\right) + \int_z^\infty \frac{\phi_c(1-\hat{\phi}_c)}{z'} dz', \quad (11)$$

for the upper-canopy layer. Equation (4) is used for the lower-canopy layer. Finally,  $u_*$  is given to

$$u_* = \frac{ku(z_r)}{\left[\ln\left(\frac{z_r}{z_0}\right) - \psi_m\left(\frac{z_r}{L}\right) + \psi_m\left(\frac{z_0}{L}\right) + \hat{\psi}_m\right]} \quad (12)$$

and the aerodynamic conductance from  $z=0$  to  $z=z_r$  ( $g_a$ ) in the RSL are given to

$$\begin{aligned} 1/g_a &= \int_0^{z_r} \frac{dz}{K_h(z)} \equiv 1/g_{a1} + 1/g_{a2} + 1/g_{a3} \\ 1/g_{a1} &\equiv \int_0^{z_l} \frac{dz}{K_h(z)} = \int_0^{z_l} \frac{dz}{ku_* z + \frac{c_s}{\rho c_p}} = \frac{1}{ku_*} \ln\left[\frac{ku_* z_l}{c_s/\rho c_p} + 1\right] \\ 1/g_{a2} &= \int_{z_l}^{d_t} \frac{dz}{K_h(z)} = \frac{S_c}{\beta^2 u_h} \left[ \exp\left(\beta \frac{d_t - z_l}{l_m}\right) - 1 \right], \\ 1/g_{a3} &= \int_{d_t}^{z_r} \frac{dz}{K_h(z)} = \int_{d_t}^{z_r} \frac{\phi_h}{ku_* z} dz = \frac{1}{ku_*} \left[ \ln\left(\frac{z_r}{d_t}\right) - \psi_h\left(\frac{z_r}{L}\right) + \psi_h\left(\frac{d_t}{L}\right) + \hat{\psi}_h\left(\beta \frac{z_r}{l_m}\right) - \hat{\psi}_h\left(\beta \frac{d_t}{l_m}\right) \right]. \end{aligned} \quad (13)$$

- 110 Computing time increased only 8 % with 61 vertical layers in the YSL scheme despite more iterations in the YSL scheme compared to the revised MM5 SL scheme.

#### 4 Numerical experimental design

- 115 This study evaluated the YSL scheme by making a 1D offline and real case simulations. The 1D offline simulations were done to test the YSL scheme performance without feedback with the atmosphere. The 1D offline simulation consisted of the YSL and the revised MM5 SL schemes coupled with the Noah land surface model (i.e., offCTL and offRSL experiments) (Table 1). In the offline simulations, offCTL and offRSL indicate numerical experiments with and without the RSL parameterization, respectively and were driven by the idealized forcing data described in Table 1. The real case simulation consisted of two experiments: reproducing 1 month of winter (January 2016) with the revised MM5 SL scheme and the YSL scheme (hereafter referred to as the rCTL and rRSL experiments). The rCTL and the rRSL employed the same physics package, except for the SL scheme and the land surface model (Lee and Hong, 2016 and references therein). One-way nesting was applied herein in a single-nested domain with a Lambert conformal map projection to East Asia (Figure 3). A 9 km horizontal resolution domain
- 120

2 was then embedded in the 27 km resolution domain 1 with 61 vertical layers. The initial and boundary conditions were produced using the National Center for Environmental Prediction Final Analysis data ( $1^\circ \times 1^\circ$ ).

125

## 5 Observation data for the model validationevaluation

The model performance was examined against the surface wind speed, surface temperature and precipitation observed at 46 Automated Synoptic Observing System (ASOS) sites in Korea (Fig. 2). Quality control of the data includes gap detection, limit test, step test based on the standard of the World Meteorological Administration and Korea Meteorological Administration (KMA) (Zahumensky, 2007; Hong et al., 2013). For the model validationevaluation of the real case simulation, the three different measures of the correlation coefficients, centered root-mean-square differences (RSMD), and standard deviations of the model ( $\sigma_m$ ) normalized by that of the observation ( $\sigma_o$ ) are together shown in a Taylor diagram (Taylor, 2001). In the Taylor diagram, a point nearer the observation at a reference point (OBS) can be considered to give a better agreement with the observation. We also provide the root-mean-square error (RMSE) and the mean bias (MB) with the pattern correlation for the rainfall simulation validationevaluation.

135

## 6 Results

### 6.1 Offline simulations

Figure 4 shows the roughness parameters (i.e.,  $z_0$ ,  $d_t$ , and  $\beta$ ) as a function of the normalized atmospheric stability ( $L_c/L$ ) from the 1D offline simulation of the YSL scheme (offRSL). The offline YSL simulations reproduced the results of HFs. The roughness parameters varied with the atmospheric stability,  $L_c/L$ , and had peaks at weakly unstable conditions. These dependencies of the roughness parameters on the atmospheric stability are distinct from typical manner of dealing with the roughness parameters as a constant in atmospheric models. The roughness length is indeed constant based on the land cover in all the SL schemes in the WRF.

140

145

Figure 5 indicates that the impacts of the RSL are also function of  $L_c$ , which is a function of  $LAI$  and  $h$  (Eq. (6)), thus leading to both diurnal and seasonal variation of canopy roughness. Consequently, the roughness parameters showed daily and seasonal variations. Overall, the roughness length in the YSL was larger than the revised MM5 SL scheme, particularly in a smaller  $z/L$  (i.e., neutral and unstable conditions) and a larger  $L_c$  (i.e., small  $LAI$  and/or large  $h$ ). The roughness length in a stable condition showed relatively smaller changes with  $z/L$  and  $L_c$  compared to those in the unstable condition. Our findings suggest that a small  $LAI$  in the winter season makes a larger  $L_c$  because of the smaller  $LAI$ , thereby leading to relatively larger differences of  $z_0$  between the YSL scheme and the default WRF scheme. On the contrary, a similar value of  $z_0$  was observed in summer because of the larger  $LAI$ . Note that the revised MM5 SL scheme does not consider  $d_t$  and  $\beta$ .

150

The RSL function,  $\hat{\phi}_c$ , was introduced to consider the additional mixing caused by the roughness element. Accordingly,  $\hat{\phi}_c$  should asymptotically converge to the MOST profile (i.e.,  $\hat{\phi}_c \rightarrow 1$ ) as  $z$  increases with the continuous vertical profiles of the wind and the temperature. The YSL scheme reproduced these properties of  $\hat{\phi}_c$  and matched with the observed profiles inside canopies: the YSL scheme showed exponential profiles under the canopy top and logarithmic profiles above the canopy top (Fig. 6). The wind speed and the air temperature above the canopy top were smaller than predicted by MOST because  $\hat{\phi}_c < 1$  in the offRSL experiments. Furthermore, the YSL scheme produced wind and temperature within the canopy (i.e.  $\tilde{z} < z_0 + d_0$ ), thereby providing additional useful information on the atmospheric dispersion inside the canopy.

The roughness length changes in the YSL scheme eventually produced changes in the surface energy balance with the atmospheric stability (Fig. 7). In the 1D offline simulations based on the conditions in Table 1, the YSL scheme produced a larger  $z_0$  in the unstable and near-neutral conditions, but a smaller  $z_0$  in  $z/L > 3$  compared to the offCTL. The aerodynamic conductance ( $g_a$ ) in the YSL scheme was larger in all the stability conditions even in the stable conditions in which the YSL provided a smaller  $z_0$  because the additional term in Eq. (13),  $g_{a2}$ , dominated over the other effects in the  $g_a$  calculation. Accordingly,  $H$  and  $\lambda E$  in the YSL scheme were larger than those in the revised MM5 SL scheme. Our finding implies stronger fluxes from the YSL scheme when the gradient of quantity is the same. However, the impact of the increased  $g_a$  was asymmetrical in  $H$  and  $\lambda E$  depending on the soil moisture content. In this case simulation, an increase in  $\lambda E$  was dominant because the wet condition made more partitioning of the available energy into the latent heat flux first in the model. However, in the dry condition (i.e., less soil water content), the YSL produced a larger  $H$  without a substantial increase of  $\lambda E$  (Fig. S1). A significant increase in  $\lambda E$  was found along with a decrease in  $H$  in the strong unstable conditions (Fig. 7) because of the wet soil moisture of  $0.25 \text{ m}^3 \text{ m}^{-3}$  in the offRSL simulation in Table 1. The slight increase in the net radiation was mainly associated with the reduced outgoing longwave radiation caused by the smaller surface temperature in the offRSL.

## 6.2 Real case simulations

Figure 8 shows the real case simulation of the roughness length, 10 m wind speed ( $u_{10}$ ), and 2 m air temperature ( $T_2$ ). We discuss herein the real cases in the winter season because of stronger effect of the roughness sublayer. The results for the summer season can be found in the Supplementary Materials. The roughness length in the rCTL experiment was prescribed from the vegetation data table (i.e., VEGPARM table in the WRF model) and modified by the vegetation fraction (Fig. 8a).

Overall, the YSL scheme (rRSL experiment) produced 0.2–2.0 m larger  $z_0$  than the default values in the rCTL experiment over the tall canopies, where  $L_c$  was large. In contrast, the YSL scheme produced a similar or even slightly smaller  $z_0$  over the short canopies compared to the rCTL experiment. Importantly, the changes of  $z_0$  made direct impacts on the momentum fluxes and thus surface wind speed (Fig. 8b). The typical  $u_{10}$  in the rCTL was larger than approximately  $3 \text{ m s}^{-1}$ , and a much stronger wind ( $> 6 \text{ m s}^{-1}$ ) was observed along the mountains, making a positive bias against the observation. Overall, the YSL scheme reproduced the better observed diurnal variation by reducing the positive bias of the wind speed (Table 2, Fig. 9). Over the tall forest canopies,  $u_{10}$  in the rRSL was reduced by approximately 30%; however, the region of the increased wind speed

185 corresponded to the short canopies, where the roughness length increased (Figs. 8a and 8b). The YSL scheme particularly provided better RMSD and correlation coefficient, but less diurnal variability of wind speed because of a relatively larger reduction of the daytime wind speed (Fig. 9). MB and RMSE decreased from  $2.4 \text{ m s}^{-1}$  to  $1.0 \text{ m s}^{-1}$  and from  $3.1 \text{ m s}^{-1}$  and  $1.8 \text{ m s}^{-1}$ . The Taylor diagram shows that the overall performance of the YSL scheme is better than the default WRF simulation at all the 46 sites. In the Taylor diagram, the statistics moved toward the observation, except for one site, indicating an overall  
190 improvement of 2 m air temperature in the YSL scheme; however, the impact of the RSL was not as large as the wind speed (Table 2, Fig. 10).

Similar to the increases of the aerodynamic conductance in the offline simulations, the YSL scheme in the real case simulation (i.e., the rRSL simulation) simulated a larger  $g_a$ , particularly in the forest canopies and mountain regions (Fig. 11a). This larger  $g_a$  in the YSL scheme led to the increases of the latent heat fluxes by approximately  $20 \text{ W m}^{-2}$ , with an eventual  
195 reduction of the soil water content (Fig. 12a). The sensible heat fluxes in the rCTL experiments were generally approximately  $80 \text{ W m}^{-2}$ , except over the snow-covered region where  $H$  was approximately  $40 \text{ W m}^{-2}$ . As described in the offline simulation, the changing sign of  $H$  in the rRSL depended on the soil moisture content because evapotranspiration is limited in dry soils at given available energy (Figs. 11b and 12b). Consequently, the available energy ( $=H + \lambda E$ ) increased in the YSL scheme, and a larger  $\lambda E$  in the rRSL led to a cooler temperature than that in the rCTL experiment (Fig. 8c).

200 During the winter simulation period, precipitation was observed over an extensive area in the domain, and snow was dominant over the northeastern side of the domain (Figs. 12b and 13). The overall total precipitation in the YSL scheme increased, and the skill score indicated a better simulation of the total amount of precipitation (Table 2, Fig. 13). The pattern correlation of precipitation also increased from 0.972 to 0.978 in the YSL scheme based on 656 rain gauge stations, indicating a better match of the precipitation bands. Despite the increase in  $\lambda E$ , precipitation decreased in several regions (Figs. 11b and  
205 13b). The differences were not significant in the summer season, and the skill scores in the YSL scheme were similar to the default WRF simulation because our implemented RSL parameterization started to converge to the default WRF in a smaller  $L_c$  (i.e., larger  $LAI$  and/or smaller  $h$ ) and strong synoptic influences by the summer heavy rainy period (Table S1, Figs. S2–S6).

## 7 Summary and conclusion remark

Turbulent fluxes regulate the planetary boundary layer; thus, they are a crucial process for weather, climate, and air pollution  
210 simulations. Most of the NWP and climate models are commonly applied for MOST to compute the turbulent fluxes near the Earth's surface. MOST can be only applicable in the inertial layer and turbulence deviates from MOST in the roughness sublayer. Importantly, roughness sublayer, the important compartment of the SL, has not been properly parameterized in the model. Increasing the computing power enables us to use more vertical layers in the atmospheric models. Accordingly, the RSL must be incorporated into the model properly to simulate the atmospheric processes in the gray zone. This study proposed  
215 the YSL scheme, which incorporated the RSL into the WRF model, based on the RSL model proposed by Harman and Finnigan (2007, 2008) and Harman (2012). We also investigated the impacts of the RSL parameterization on the weather and climate

simulations. For these purposes, we designed a series of offline simulations with an idealized boundary condition and a real case simulation to evaluate the performance of the YSL scheme against the observation data.

The 1D offline simulation revealed that the YSL scheme successfully reproduced the features reported in various canopies.

220 The RSL function,  $\hat{\phi}_c$ , asymptotically increased to 1, and the vertical gradients of the wind speed and the temperature decreased in the RSL as  $z$  increased, thereby converging to the MOST prediction. Notably, unlike the typical assignment of the roughness parameters (i.e.,  $z_0$ ,  $d_t$ , and  $\beta$ ) as a constant, the roughness parameters are functions of the atmospheric stability ( $z/L$ ) and  $L_c$ . The roughness parameters had a maximum in the weakly unstable condition and in larger  $L_c$  (i.e., large  $h$  or small  $LAI$ ). In most conditions, the YSL scheme provided a larger roughness length, thereby producing a wind speed slower than that of the  
225 revised MM5 SL scheme. The YSL scheme simulated a colder surface temperature in the unstable conditions.

Meanwhile, the real case simulation showed that the RSL-incorporated WRF produced a larger  $z_0$  than the default WRF. This increase in  $z_0$  and its change with atmospheric stability eventually made substantial impacts on wind, and temperature near the surface, momentum transfer, surface energy balance, and precipitation. First, an increase of  $z_0$  produced larger momentum fluxes and a smaller 10 m wind speed when the YSL scheme was applied, leading to the mitigation of positive  
230 bias in the wind speed in the revised MM5 SL scheme. The larger  $z_0$  also made increases in the available energy. This increased available energy is related to the surface cooling caused by the increases in the latent heat fluxes in the wet surface conditions when the RSL parameterization is applied. As a result, these changes in the climate near the surface and the surface energy balance resulted in more precipitation, thereby giving a better simulation of the amount of precipitation and its spatial pattern.

Our results indicate that the RSL parameterization can be a promising option for resolving the typical overestimation of  
235 the surface wind speed of the WRF model, particularly in the tall vegetation and low  $LAI$ , with slight increase of computing time (e.g., Hu et al., 2010, 2013; Shimada and Ohsawa, 2011; Shimada et al., 2012; Wyszogrodzki et al., 2013; Lee and Hong, 2016). The improvement caused by the RSL parameterization is useful in air quality modeling and wind energy estimation by better weather and climate in the planetary boundary layer. A further study is necessary to evaluate the characteristics of the YSL scheme in various cases particularly at gray-zone resolutions.

240 *Code and data availability.* The source code of the Weather Research and Forecasting Model (WRF) is available at <http://www2.mmm.ucar.edu/wrf/users/downloads.html>. The source code of the YSL scheme and the modeling output presented in this study are available at Zenodo (<http://doi.org/10.5281/zenodo.3555537>). The National Center for Environmental Prediction Final Analysis data that was used as initial and boundary conditions is available at <https://rda.ucar.edu/datasets/ds083.2> (National Centers for Environmental Prediction, National Weather Service, NOAA, U.S.  
245 Department of Commerce, 2000). The observation data used for the model [validation/evaluation](#) can be downloaded at the Korea Meteorological Administration data portal (<https://data.kma.go.kr/data/grnd/selectAsosRltnList.do?pgmNo=36>) or are available upon request to the corresponding author ([jhong@yonsei.ac.kr](mailto:jhong@yonsei.ac.kr) / <http://eapl.yonsei.ac.kr>).

## Appendix A: List of symbols and definitions

Symbols	Definitions
$a$	Leaf are density
$Bi_b$	Bulk Richardson number, at the lowest model layer
$c_d$	Drag coefficient at the leaf level
$c_p$	Specific heat for air
$c_s$	Effective heat transfer coefficient for nonturbulent processes (Carlson and Boland, 1978; Jiménez et al., 2012)
$C$	Variable at $z$ , such as $u$ and $T$
$C_0$	$C$ at $z = z_0$
$C_h$	$C$ at $h$
$C_*$	Scale of $C$
$d_0$	Conventionally defined zero-plane displacement height
$d_t$	Redefined zero-plane displacement height in Harman and Finnigan (2007)
$f$	Parameter related the depth scale of the scalar profile ( $\equiv \frac{1}{2}(\sqrt{1 + 4r_c S_r} - 1)$ )
$g$	Gravitational acceleration
$g_a$	Aerodynamic conductance
$h$	Canopy height
$k$	von Kármán constant
$l_m$	Mixing length for momentum
$L$	Obukhov length
$L_c$	Canopy penetration depth ( $\equiv (c_d a)^{-1} = \frac{4h}{LAI}$ )
$LAI$	Leaf area index

$p$	Pressure at $z$
$q$	Water vapor mixing ratio at $z$
$r_c$	Canopy Stanton number
$SW$	Downward shortwave radiation
$S_c$	Turbulent Schmidt number
$S_m$	Soil moisture
$S_r$	Turbulent Schmidt number
$T$	Air temperature at $z$
$T_2$	Air temperature at 2 m
$T_{sk}$	Skin temperature
$u$	Wind speed at $z$
$u_{10}$	Wind speed at 10 m
$u_h$	Wind speed at $h$
$u_*$	Friction velocity
$u_*^{n-1}$	Previous time step value of $u_*$
$z$	Height from $d_0$
$\tilde{z}$	Height from terrain surface
$z_0$	Roughness length
$z_l$	Viscous sublayer depth =0.001 (Carlson and Boland, 1978; Jiménez et al., 2012)
$z_r$	Hight of the lowest model layer
$z_r/L$	Atmospheric stability
$\beta$	$u_*/u_h$

$\beta_N$	$\beta$ at neutral condition (=0.374)
$\theta_a$	Potential temperature of the air at $z_r$
$\theta_{va}$	Virtual potential temperature of the air at $z_r$
$\theta_{vg}$	Virtual potential temperature of the air at ground
$\rho$	Density of air
$\phi_C$	Similarity function of $C$
$\widehat{\phi}_C$	RSL function of $C$
$\psi_C$	Integrated similarity function of $C$
$\psi_h$	Integrated similarity function of heat
$\psi_m$	Integrated similarity function of momentum
$\widehat{\psi}_C$	Integrated RSL function of $C$
$\widehat{\psi}_h$	Integrated RSL function of heat
$\widehat{\psi}_m$	Integrated RSL function of momentum

---

*Author contribution.* JL and JH contributed to the code development for the YSL scheme, data analysis, and manuscript preparation. YN and PAJ contributed to the writing and editing of the paper and data analysis.

*Competing interests.* The authors declare that they have no conflict of interest.
