52 **Abstract.** The cloud Liquid Water Path (LWP), Ice Water Path (IWP), and precipitation simulated with uniform- and
53 variable-resolution numerical experiments using the Model for Prediction Across Scales (MPAS) are compared
54 against Clouds and the Earth's Radiant Energy System (CERES) and Tropical Rainfall Measuring Mission data. Our
55 comparison between monthly mean model diagnostics and satellite data focuses on the convective activity regions of
56 the Tropical Pacific Ocean, extending from the Eastern Tropical Pacific Basin where trade wind boundary layer clouds
57 develop to the Western Pacific warm pool defined by deep convective updrafts capped with extended upper-
58 tropospheric ice clouds. Using the scale-aware Grell-Freitas (GF) and Multi-Scale Kain-Fritsch (MSKF) convection
59 schemes with the Thompson cloud microphysics scheme, uniform-resolution experiments produce large biases
60 between simulated and satellite-retrieved LWP, IWP, and precipitation. Differences in the treatment of shallow
61 convection lead the LWP to be strongly overestimated when using GF while being in relatively good agreement when
62 using MSKF compared to CERES data. Over areas of deep convection, numerical experiments using MSKF lead to
63 increased IWP than those using GF, in conjunction with increased convective detrainment of cloud ice and ice
64 nucleation. Mesh refinement over the Western Pacific warm pool yields increased grid-scale condensation, LWP,
65 IWP, and cloudiness over the refined area of the mesh associated with increased grid-scale upward vertical motions.
66 Results underscore the importance of evaluating clouds, their optical properties, and the top-of-the-atmosphere
67 radiation budget in addition to precipitation when performing mesh refinement global simulations.

68 **1 Introduction**

69 Comparing simulated against observed global cloud liquid and ice water paths (LWP and IWP) remains challenging
70 because of uncertainties in parameterizing moist processes and cloudiness in global climate and numerical weather
71 prediction (NWP) models, and errors in retrieving the LWP and IWP from satellite measurements. Cloud simulations
72 from general circulation models (GCMs) involved in Phase 3 and 5 of the Coupled Model Intercomparison Project
73 (CMIP3; CMIP5; Meehl et al, 2007; Taylor et al., 2012) display a strong disparity in the simulated LWP (Jiang et al.,
74 2012; Li et al., 2018) and IWP (Li et al., 2012), producing annual mean LWP and IWP overestimated by factors of 2
75 to 10 when compared to satellite data. Satellite observations of the LWP and IWP from passive nadir viewing
76 instruments such as the Moderate-resolution Imaging Spectroradiometer (MODIS; Minnis et al., 2011), and profiling
77 radar such as the 94-GHz instrument on the CloudSat satellite (Stephens et al., 2002), also display major differences
78 among themselves, as discussed in Li et al. (2008) and Waliser et al. (2009). While models and satellite retrievals
79 agree that the LWP and IWP should be defined as the vertically-integrated liquid and ice water content, including all
80 nonprecipitating and precipitating hydrometeors, this is not always the case in practice, further challenging a clearly-
81 posed data-data and model-data comparison. Defining the LWP and IWP varies between models, depending on the
82 complexity of the parameterization of cloud microphysics processes and prognostic versus diagnostic treatment of
83 falling hydrometeors. Defining the measured LWP and IWP varies between satellite products, depending on the
84 sensitivity of the observing systems to detect large precipitating particles. While comparing simulated and observed
85 LWP and IWP may not be as straightforward as comparing the top-of-the-atmosphere (TOA) radiation budget (Dolinar
86 et al., 2015; Stanfield et al., 2015), it offers a different way to directly diagnose biases in simulated total cloud liquid

87 and ice water mass as a first step to help correct deficiencies in parameterizing global scale moist processes and
88 precipitation.

89 Before the launch of the CloudSat and Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation mission
90 (Stephens et al., 2002), global estimates of the LWP and IWP were retrieved principally from satellite radiance
91 measurements over different spectral intervals (e.g., Alishouse et al., 1990; Greenwald et al., 1993; Minnis et al., 1995;
92 Platnick et al., 2003). In their critical review of most common methods developed to retrieve cloud and precipitation
93 properties from satellite radiances, Stephens and Kummerow (2007) identify two main sources of errors. The first
94 source of errors originates from the mandatory classification between cloudy and cloud-free scenes, and between
95 precipitating and non-precipitating cloudy scenes. The second source of errors stems from using forward radiative
96 transfer models that lack details of the vertical distribution of cloudiness and precipitation as well as complexity in
97 specifying the optical properties of liquid water and ice particles. Estimating the LWP and IWP from CloudSat radar
98 reflectivities alone presents its own set of challenges for scenes that include precipitating cloud systems due to the
99 high sensitivity of radar reflectivities to the presence of large particles, for scenes that include mixed-phase and deep
100 convective clouds, and close to the surface due to ground clutter. Li et al. (2018) show that annual mean maps of
101 MODIS- and CloudSat-based LWP agree relatively well in tropical and subtropical regions if both data sets exclude
102 LWP observations for deep convective/precipitating clouds since MODIS is quite insensitive to precipitation.
103 Stephens and Kummerow (2007) advocate combining satellite-retrieved radar and radiance measurements to help
104 validate simulated cloud properties and precipitation. In addition to considering the impact of precipitating particles,
105 Waliser et al. (2009) demonstrate that a well-posed model-data comparison must include a consistent sampling
106 between model outputs and satellite data to reduce diurnal sampling biases and sensitivity of the sensor and retrieval
107 algorithm to the particle size when computing the simulated LWP and IWP.

108 Contemporary climate and NWP GCMs (Giorgetta et al., 2018; Molod et al., 2012; Kay et al., 2015, Skamarock
109 et al., 2012) categorize moist processes into three distinct parameterizations, one to simulate turbulent mixing in the
110 Planetary Boundary Layer (PBL) in response to surface forcing and forcing in the free troposphere, one to simulate
111 subgrid scale shallow and deep convection, and one to include grid-scale cloud microphysics. While coupling between
112 parameterizations varies between GCMs, it is an established practice to let detrained condensates from convective
113 updrafts serve as sources for non-convective grid-scale clouds, as precipitating anvils and cirrus outflow. We suggest
114 that uncertainties in parameterizing moist convection and impact on grid-scale clouds may explain a major part of the
115 differences in the LWP and IWP simulated between the CMIP3 and CMIP5 GCMs. In recent years, efforts have been
116 made to develop unified cloud parameterizations to represent all cloud types and alleviate the need to parameterize
117 complex interactions between stratiform, shallow convective, and deep convective clouds (Guo et al., 2015; Storer et
118 al., 2015; Thayer et al., 2015). Using the global Model for Prediction Across Scales (MPAS; Skamarock et al., 2012),
119 Fowler et al. (2016) discuss the sensitivity of simulated precipitation as spatial resolution increases from hydrostatic
120 to nonhydrostatic scales and suggest to further analyze the associated sensitivity of simulated clouds and TOA
121 radiation. Results show that as subgrid scale convective motions are increasingly resolved, diagnostic precipitation
122 from the scale-aware Grell-Freitas (GF; Grell and Freitas, 2014) deep convection scheme decreases while prognostic
123 precipitation from the WSM6 (Hong and Lim, 2006) cloud microphysics scheme increases over the refined area of

124 the variable-resolution mesh. Vertical profiles of the cloud liquid and ice water mixing ratios and cloud fraction
125 highlight the redistribution of cloud condensates and relative humidity with height in the refined area in response to
126 decreased contribution of convective detrainment of cloud liquid water and ice. However, Fowler et al. (2016) do not
127 further address if variations in the vertical profiles of cloud condensates lead to improved LWP, IWP, and cloud optical
128 properties against satellite-derived data.

129 The objectives of our research are threefold. First, we want to assert that our suite of PBL, deep and shallow
130 convection, and cloud microphysics parameterizations tested in MPAS at hydrostatic and nonhydrostatic scales for
131 medium-range spring forecasts over the Continental United States (Schwartz, 2019; Wong and Skamarock, 2016) can
132 also be used to produce month-long simulations of tropical convection, narrowing our analysis on the Tropical Pacific
133 Ocean. In order to broaden our research and possibly generalize our results, we implemented the scale-aware
134 MultiScale Kain-Fritsch (MSKF; Glotfelty et al., 2019; Zheng et al., 2016) parameterization of deep and shallow
135 convection in addition to GF. Second, we want to evaluate the ability of MPAS to simulate the LWP, IWP, cloudiness,
136 and TOA long- and short-wave radiation against the Clouds and the Earth's Radiant Energy System (CERES; Wielicki
137 et al., 1996) Single Scanner FootPrint (SSF; Minnis et al., 2011) data set, and precipitation against the TRMM
138 Multisatellite Precipitation Analysis (TMPA; Huffman et al., 2007). Our third goal aims at understanding differences
139 in the LWP, IWP, precipitation, and cloud radiative effects as functions of horizontal resolution with GF and MSKF
140 using the capability of local mesh refinement developed for MPAS.

141 In Section 2, we summarize the characteristics of the GF and MSKF parameterizations of deep and shallow
142 convection. In Section 3, we provide a short description of MPAS, including physics parameterizations used with both
143 convective parameterizations, the design of our experiments with uniform- and variable-resolution meshes, and
144 description of the satellite data sets used to validate our results. In Section 4, we analyze our results in terms of
145 precipitation and varying contribution of the convective and grid-scale precipitation to the total precipitation as a
146 function of spatial resolution. In Section 5, we compare the LWP, IWP, and TOA long- and short-wave radiation
147 against satellite data. In Section 6, we summarize our results and propose areas of future research.

148 **2 Description of the convective parameterizations**

149 Mass flux-based convective parameterizations distinguish themselves through the use of different triggering functions
150 to initiate convection, the details of their entraining-detraining cloud models, and formulation of their closures that
151 control the intensity of convection and computation of the cloud base mass flux. For convective parameterizations that
152 include deep and shallow convection, criteria that characterize the two kinds of convection strongly vary. Furthermore,
153 how convective parameterizations account for the dependence of convection on the horizontal resolution differs in
154 complexity. In this section, we summarize the chief characteristics of GF and MSKF, including differences in their
155 treatment of deep and shallow convection, and spatial-scale dependence.

156 **2.1 The Grell-Freitas (GF) parameterization**

157 The version of GF used in our numerical experiments is that implemented in version 3.8.1 of the Advanced Research
158 Weather Research Forecast model (Skamarock et al., 2008), as described in Grell and Freitas (2014). Its properties

159 were first discussed in Grell (1993) and later expanded by Grell and Devenyi (2002) to include stochasticism. GF
160 treats deep and shallow convection separately by using different initial entrainment rates ($7 \times 10^{-5} \text{ m}^{-1}$ and $1 \times 10^{-2} \text{ m}^{-1}$
161 for deep and shallow convection, respectively) to control the depth of convective cloud layers and closures to calculate
162 the cloud base mass flux. GF includes an ensemble of closures from well-known convective parameterizations to
163 compute a mean cloud-base mass flux. For deep convection, these four closures are the *AS* closure (Arakawa and
164 Schubert, 1974) that assumes instantaneous equilibrium between the large-scale forcing and subgrid-scale convection;
165 the *W* closure (Brown, 1979; Frank and Cohen, 1987) that relates the cloud base mass flux to the grid-scale upward
166 vertical velocity; the *MC* closure (Krishnamurti et al., 1983) that calculates the cloud base mass flux as a function of
167 the vertically-integrated vertical moisture advection; and the *KF* closure (Kain and Fritsch, 1993) that reduces the
168 convective available potential energy over a prescribed convective time-scale. Qiao and Liang (2015) analyze the
169 separate and combined impacts of the four closures on the simulated summer precipitation over the United States
170 coastal oceans. On the one hand, they found that computing the cloud base mass flux using the *W* and *MC* closures
171 led to precipitation patterns and amounts that are in better agreement against TMPA data than those using the *AS* and
172 *KF* closures. On the other hand, they found that the *AS* and *KF* closures yield improved diurnal cycle of precipitation
173 relative to the other two closures. In our numerical experiments, GF gives an equal weight to each closure to calculate
174 the mean cloud base mass flux for deep convection. As for deep convection, GF includes different closures for shallow
175 convection. In our numerical experiments using GF, we choose the boundary layer quasi-equilibrium (*BLQE*) closure
176 of Raymond (1995) for shallow convection.

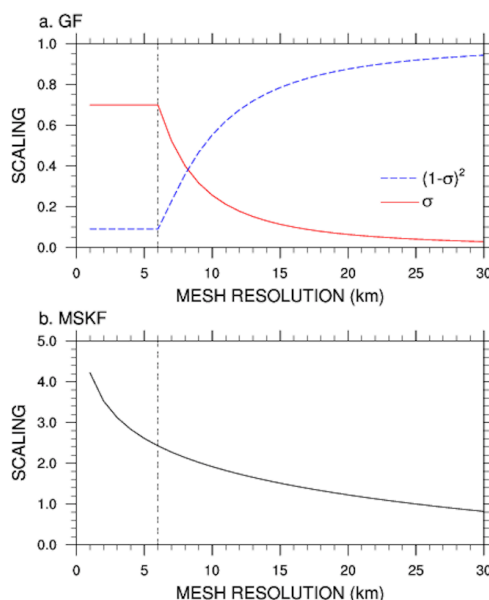

177 Both types of convection transport total water and moist static energy in a conservative manner but neglect to
178 include ice phase processes in updrafts and downdrafts. In this version of GF, the only feedback between shallow
179 convection and the large-scale environment is lateral and cloud-top detrainment of water vapor and corresponding
180 heating, as liquid water formed in shallow updrafts evaporates immediately. Deep convection returns potential
181 temperature, water vapor, and condensed water tendencies to the environment. Detrained condensed water acts as a
182 source of liquid water (ice) if the large-scale temperature is warmer (colder) than the prescribed 258 K threshold.
183 While GF assumes that shallow convective plumes are not deep enough to produce precipitation, the conversion of
184 liquid water to rain water in deep convective plumes depends on a simple Kessler-type (Kessler, 1969) conversion
185 threshold and precipitation reaches the surface instantaneously.

186 As discussed in Grell and Freitas (2014), deep convection includes a simplified representation of the unified
187 parameterization of deep convection described in Arakawa and Wu (2013). Arakawa and Wu (2013) demonstrate that
188 mass flux-based convective parameterizations can be modified to work at all resolutions spanning between hydrostatic
189 and non-hydrostatic scales through the reduction of the convective vertical eddy transport as a quadratic function of
190 the horizontal fraction of the grid box occupied by convective updrafts. In GF, the convective updraft fraction (σ) is
191 computed as a simple function of the initial entrainment rate ($\varepsilon = 7 \times 10^{-5} \text{ m}^{-1}$) and half-width radius (R) of convective
192 updrafts following Simpson and Wiggert (1969), or

$$193 \quad \sigma = \frac{\pi R^2}{A} \quad \text{and} \quad R = \frac{0.2}{\varepsilon} \quad (1)$$

194 where A is the area of the grid box. In Eq. (1), σ cannot exceed 0.7, as discussed in Fowler et al. (2016). Figure 1.a
195 highlights the rapid decrease in σ from 0.7 to 0.3 as spatial resolutions decrease from 6.1 to 9.2 km. σ further decreases
196 from 0.3 to 0.1 for resolutions between 9.2 and 16 km, and from 0.1 to 0.05 for resolutions spanning between 16 and
197 30 km. The $(1-\sigma)^2$ quadratic function used to scale the cloud-base mass flux starts to significantly impact the cloud-
198 base mass flux at resolutions greater than 20 km. Using a variable-resolution mesh varying between 50 km over the
199 coarse area of the mesh down to 3 km over the refined area of the mesh centered over South America, Fowler et al.
200 (2016) show that the impact of parameterized convection weakens and that of grid-scale vertical motion strengthens
201 as horizontal grid-spacing increases from hydrostatic to non-hydrostatic scales.

202
203 **Figure 1:** a) Convective updraft fraction as a function of the mesh resolution used to scale the cloud base mass flux in GF; and b)
204 Scaling factor as a function of the mesh resolution used to scale the convective time scale in MSKF.

205 2.2 The Multi-Scale Kain-Fritsch (MSKF) parameterization

206 MSKF is the scale-aware version of the Kain-Fritsch (KF) convective parameterization, first developed by Kain and
207 Fritsch (1990; 1993), and later updated by Kain (2004) to include, among other improvements, non-precipitating
208 shallow convection. The trigger function is that used in Fritsch and Chappell (1980), originally tested in Kain and
209 Fritsch (1992) and recently in Suhas and Zhang (2014). In MSKF, convection may be triggered if the temperature of
210 a *mixed layer* is greater than that of the environment. The pressure thickness of the mixed layer is the sum of adjacent
211 layer depths until it reaches at least 50 hPa starting at the layer next to the surface. The mixed layer temperature is a
212 pressure-weighted function of the temperatures in those adjacent layers after being lifted to the Lifting Condensation
213 Level (LCL) plus a perturbation temperature linked to the magnitude of the grid-scale vertical motion at the LCL.
214 Once the base of a potential updraft source layer is found, convection remains activated if the vertical velocity of an
215 air parcel lifted using the Lagrangian parcel method remains positive for a minimum cloud depth of 3 km, as a test
216 that the convective instability is strong enough for the air parcel to reach the Level of Free Convection (LFC). If not,

217 the procedure is repeated by moving up to the next model layer until a new updraft source layer is found or until the
218 search reaches above the lowest 300 hPa of the atmosphere. Further details on the equations used to compute the
219 perturbation temperature and parcel vertical velocity are found in Kain (2004).

220 In MSKF, the closure assumption assumes that the Convective Available Potential Energy in a cloud layer is
221 removed within a time adjustment period following Bechtold et al. (2001). The convective time scale is defined as the
222 advective time scale in the cloud layer with maximum values of 1 h and 0.5 h for deep and shallow convection,
223 respectively. In contrast to GF, the thermodynamics inside the cloud model includes the ice phase. The condensed
224 water formed in each cloudy layer is partitioned between liquid water and ice, assuming a linear transition of the cloud
225 temperature between 268 K and 248 K. A fraction of the condensed water converts to rain, following Ogura and Cho
226 (1973), and reaches the ground instantaneously. As discussed in Kain (2004), when an updraft source layer is
227 identified, the classification of a convective cloud layer as deep or shallow depends on the cloud depth. Shallow
228 convection is activated when all the criteria for deep convection are met, but the depth of the updraft is shallower than
229 the minimum cloud depth (3 km). This definition implies that shallow and deep convection are not allowed to coexist.
230 In the case of shallow convection, precipitation formed in updrafts is detrained to the environment as rain or snow,
231 providing an additional moisture source to the large-scale environment. As in GF, MSKF provides tendencies of
232 temperature, water vapor, cloud liquid water/ice to the environment, and tendencies of rain and snow from shallow
233 convection.

234 MSKF contains many improvements over KF, as summarized in the supplemental material of Glotfelty et al.
235 (2019). These improvements include subgrid-scale cloud feedbacks to radiation from both shallow and deep
236 convection leading to more realistic surface downward radiation, as described in Alapaty et al. (2012), and the scale
237 dependence of fundamental parameters so that MSKF can be used at spatial resolutions varying between hydrostatic
238 and nonhydrostatic scales. As detailed in Glotfelty et al. (2019) and Zheng et al. (2016), MSKF uses a scale dependent
239 formulation (β) to the adjustment time scale (τ) for deep and shallow convection based on Bechtold et al. (2008), or

$$240 \quad \tau = \frac{H}{w_{cl}} \beta \quad \text{and} \quad \beta = 1 + \ln\left(\frac{25}{\Delta x}\right) \quad (2)$$

241 where H and w_{cl} are the depth of the convective cloud and cloud-averaged vertical velocity scale, and Δx is the grid
242 spacing. Figure 1.b highlights the dependence of the β scaling parameter as a function of horizontal resolution. As
243 many MSKF parameters are optimized for a resolution around 25 km (Kain, 2004), β is equal to 1 at 25 km, ramping
244 up to values greater than 2.4 for resolutions higher than 6km. Because the adjustment time scale is proportional to
245 β (Zheng et al., 2016), it increases as horizontal resolution increases, leading to scale-aware stabilization of the
246 atmosphere by MSKF. In addition, MSKF includes a new scale-aware formulation of the minimum entrainment rate
247 using the LCL as a function of the scale-dependent *Tokioka* parameter (Tokioka et al., 1988), a scale-dependent
248 conversion rate for liquid water and ice condensates to precipitation, an increased grid-scale velocity expressed in
249 terms of the subgrid scale updraft mass flux, and elimination of double counting of precipitation in cloudy layers. The
250 separate and combined impacts of the development of MSKF on high resolution weather forecasts and regional climate
251 simulations are discussed in Herwehe et al. (2014), Mahoney (2016), He and Alapaty (2018), Zheng et al. (2016), and
252 Glotfelty et al. (2019).

253 3 Methodology

254 3.1 Numerical experiments

255 We discuss differences in our MPAS results between GF and MSKF configurations on precipitation, cloud properties,
256 and TOA radiation using 30-day long numerical experiments in MPAS (Skamarock et al., 2012). MPAS is a global
257 nonhydrostatic atmospheric model developed for NWP and climate studies. The horizontal discretization uses an
258 unstructured spherical centroidal Voronoi tessellation with a C-grid staggering, as described in Ju et al. (2011), while
259 the vertical discretization is the height-based hybrid terrain-following coordinate of Klemp (2011). The dynamical
260 solver integrates the prognostic equations (cast in flux form) for the horizontal momentum, vertical velocity, potential
261 temperature, dry air density, and scalars using the split-explicit technique of Klemp et al. (2007). The temporal
262 discretization uses a third-order Runge-Kutta scheme and the explicit time-splitting technique described in Wicker
263 and Skamarock (2002). We use the monotonic option of the scalar transport scheme of Skamarock and Gassmann
264 (2011) for horizontal and vertical advection of all moist scalars on the unstructured Voronoi mesh. Finally, horizontal
265 filtering of the state variables is based on Smagorinsky (1963) in which the horizontal length scale is defined as the
266 minimum distance between cell centers.

267 In MPAS, the computational flow includes three distinct steps. The first step calls the physics parameterizations
268 that update the surface energy budget and calculate the tendencies of potential temperature, moist species, and zonal
269 and meridional wind due to long- and short-wave radiation, sub-grid scale convection, condensation and mixing in
270 the PBL and free troposphere, and gravity wave drag due to orography. The physics parameterizations use the same
271 input surface boundary conditions and soundings to compute their respective tendencies. Besides GF and MSKF, these
272 parameterizations are,

- 273 • the Noah land surface parameterization described by Chen and Dudhia (2001),
- 274 • the long- and short-wave Rapid Radiative Transfer Model for GCMs (RRTMG) described by Mlawer et al. (1997)
275 and Iacono et al. (2000),
- 276 • the semi-empirical parameterization of the cloud fraction of grid-scale clouds from Xu and Randall (1996) and
277 convective clouds from Xu and Krueger (1991) for use in the long- and short-wave RRTMG schemes. Following
278 Xu and Randall (1996), the fractional amount of grid-scale clouds is a function of the relative humidity and grid-
279 averaged condensate mixing ratio of cloud liquid water, ice, and snow. In MSKF, the fractional amount of shallow
280 and deep convective clouds depends on the convective mass flux.
- 281 • the Mellor–Yamada–Nakanishi–Niino (MYNN) Planetary Boundary Layer (PBL) and surface layer scheme
282 described by Nakanishi and Niino (2009) with many updates described in Olson et al. (2019), and
- 283 • the gravity wave-drag parameterization of Hong et al. (2008).

284 The second step calls the dynamical solver which updates the state variables with their respective diabatic tendencies
285 in conjunction to applying horizontal and vertical advection. Finally, the third step calls the grid-scale cloud
286 microphysics parameterization so that at the end of the model time step, supersaturation has been entirely removed or
287 the relative humidity does not exceed 100%. Unlike the physics parameterizations listed for step one, the grid-scale
288 cloud microphysics scheme updates the potential temperature and moist species for the next time step instead of

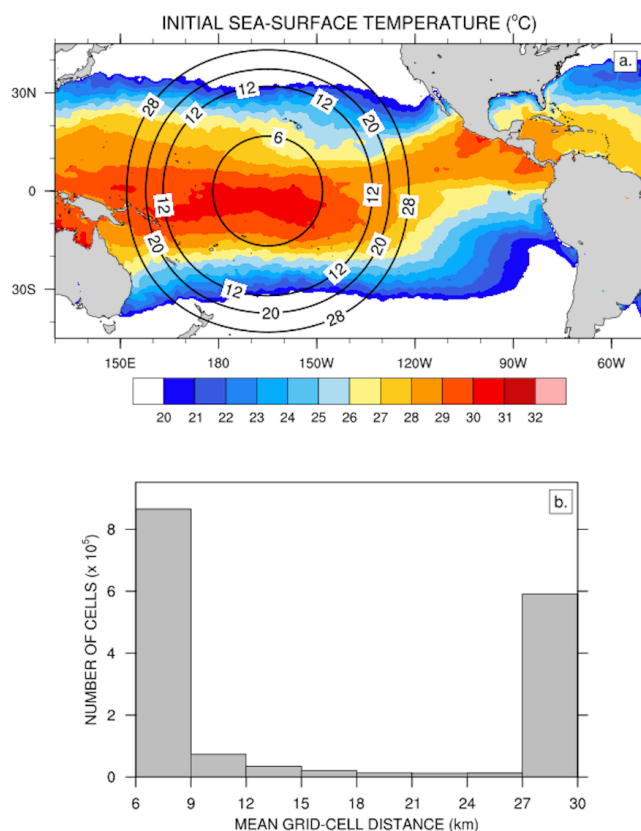

289 providing individual tendencies. The bulk cloud microphysics parameterization of Thompson et al. (THOM; 2004,
290 2008) is used in all our numerical experiments. THOM includes prognostic equations for temperature, mass mixing
291 ratio of water vapor, cloud liquid water, rain, cloud ice, snow, and graupel, and number concentration of cloud ice and
292 rain. We set the number concentration of cloud droplets to $300 \times 10^6 \text{ m}^{-3}$ over land and $100 \times 10^6 \text{ m}^{-3}$ over oceans. In
293 RRTMG, we diagnose the radiative effective radii of cloud liquid water, cloud ice, and snow as functions of the
294 THOM cloud particle assumptions to add coupling between the cloud microphysics and cloud optical properties, as
295 discussed in Thompson et al. (2016).

296 To compare the two convective parameterizations against satellite-derived data at hydrostatic scales, we use a
297 quasi-uniform resolution mesh for which the mean distance between cell centers is 30 km, corresponding to 655,362
298 cells. The vertical scale includes 55 layers with monotonically increasing thicknesses varying from 50 meters next to
299 the surface to 700 meters below 10 km to 1000 meters below the model top over ocean cells. The model top is set at
300 30 km. The dynamics and physics time steps are both set to 150 s, and the horizontal diffusion length scale is set to
301 30 km. Long- and short-wave radiation is called every 15 mins and THOM is cycled twice so that the cloud
302 microphysics time-step is less than 90 s to ensure computational stability (Thompson, private communication). With
303 each convection scheme, we have performed a one-month long experiment preceded by a two-day spin-up to simulate
304 Northern Hemisphere early winter, initializing our experiments with ERA-Interim (Dee et al., 2011) reanalyses for
305 0000 UTC 29 November 2015. ERA-Interim sea surface temperatures and sea ice fractions are used to update ocean
306 cells daily. We refer to our quasi-uniform resolution experiments run with GF and MSKF as GFu and MSKFu,
307 respectively.

308 3.2 Sensitivity experiments

309 Using a variable-resolution mesh spanning between 50 km and 3 km in MPAS, Fowler et al. (2016) demonstrate that
310 subgrid-scale convection parameterized with GF weakens and grid-scale cloud microphysics parameterized with
311 WSM6 (Hong and Lim, 2006) strengthens as resolution increases from the coarse to most refined area of the mesh.
312 Over the most refined area, grid-scale precipitation contributes a major part to total precipitation, and vertical profiles
313 of subgrid -scale convective heating and drying resemble those obtained with a precipitating shallow convection
314 scheme. Fowler et al. (2016) later suggest investigating the effect of variable resolution on cloud macrophysical
315 properties and TOA radiation, as condensation and precipitation shift from being parameterized rather simply in the
316 GF convective cloud model to being described in detail in WSM6. With the aim to quantify changes in cloud properties
317 and radiation across scales using GF and MSKF, we repeat the early winter experiments but with a variable-resolution
318 mesh that spans between 30 km and 6 km and includes 1,622,018 cells. As shown in Fig. 2.a, we centered the refined
319 area of the mesh over the Pacific warm pool which we defined as the area in the Western Pacific Ocean where sea-
320 surface temperatures (SSTs) exceed 28.5°C , or between 170°E and 140°W . East of 140°W , the north-south width of
321 warmest SSTs across the transition zone between the refined and coarse mesh narrows to delineate the location of the
322 ITCZ in the Tropical Eastern Pacific. West of 170°E , the end of mesh refinement borders the eastern tip of Papua New
323 Guinea. Along the Equator, the transition zone between nonhydrostatic and hydrostatic scales spans 20° in the
324 meridional direction on either side of the most refined area of the mesh. Figure 2.b displays a histogram of the mean

325
326 **Figure 2:** a) Initial sea-surface temperature and refined variable-resolution mesh depicted using isolines of the mean distance
327 between grid-cell centers (km) over the Tropical Pacific Ocean; and b) histogram of the number of cells as a function of the mean
328 distance between grid-cell centers.

329 distance between cell centers. Differences between the initialization of the variable- versus quasi uniform-resolution
330 experiments include a reduced time-step from 150 s to 30 s and a reduced horizontal diffusion length scale from 30
331 km to 6 km. Also, THOM is called only once per time-step. We refer to our variable-resolution experiments run with
332 GF and MSKF as GFv and MSKFv, respectively. Differences between GFu, GFv, MSKFu, and MSKFv are listed in
333 Table 1.

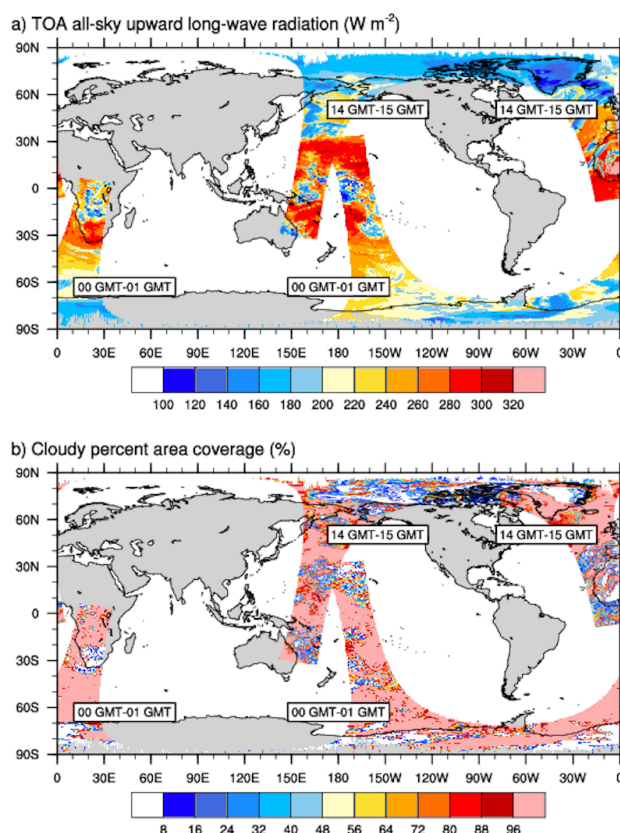

334

	GFu	MSKFu	GFv	MSKFv
No. of cells	655,362	655,362	1,622,018	1,622,018
Min. cell distance (km)	22.8	22.8	4.4	4.4
Max. cell distance (km)	31.8	31.8	37.8	37.8
Time step (s)	150	150	30	30
Diffusion length scale (km)	30	30	6	6
CP	GF	MSKF	GF	MSKF

335 **Table 1:** Horizontal mesh resolution, minimum and maximum distance between grid-cell centers, time-step, horizontal diffusion
 336 length scale, and convective parameterization (CP) for numerical experiments with the quasi uniform- and variable-resolution
 337 meshes.

338 3.3 Satellite data sets

339 We compare the cloud liquid water path (LWP) and ice water path (IWP), cloud area fraction (CF), and the top-of-
 340 the-atmosphere longwave upward (TOALW) and shortwave net (TOASW) radiation simulated in our numerical
 341 experiments against the Edition-4 Single Scanner Footprint (SSF) products from the Clouds and the Earth’s Radiant
 342 Energy System (CERES; Wielicki et al., 1996). Minnis et al. (2011) describe in great details the retrieval of
 343 simultaneous and collocated radiation fluxes and cloud properties from the CERES radiometers and the Moderate-
 344 resolution Imaging Spectroradiometer (MODIS) using consistent algorithms and calibration across satellite platforms,
 345 and shared auxiliary input (temperature and humidity profiles). SSF data are available in two different formats. The
 346 first data file format contains one hour of radiation fluxes and cloud properties at the instantaneous CERES 20 km
 347 footprint level from the sun-synchronous afternoon (morning) equatorial crossing time Aqua (Terra) satellites. As
 348 illustrated in Minnis et al. (2011; their Fig. 15), the CF in each SSF is given in terms of a clear fraction, a fraction for
 349 an upper and lower cloud layer separately, and a fraction for an upper layer over a lower layer, although the overlap
 350 CF is not available and set to zero in the Edition 4 release version that we are using. The LWP, IWP, and all other
 351 cloud fields are provided for the lower and upper layers, separately. Figure 3 illustrates two orbits of the Aqua satellite,
 352 one between 00 GMT and 01 GMT, and one between 14 GMT and 15 GMT, showing the TOALW (top panel) and
 353 CF (bottom panel), after gridding the hourly orbital data to a $0.2^\circ \times 0.2^\circ$ latitude-longitude grid. Gridded radiation fluxes
 354 and cloud data are means over all SSF data contained inside each rectangular grid, after applying a linear interpolation
 355 to reduce the number of missing values. Missing values, highlighted in gray in all figures, depict rectangular grids that
 356 did not contain radiation and cloud data in any of the SSF inside the $0.2^\circ \times 0.2^\circ$ grid. As seen in Fig. 3, our gridding of
 357 the orbital data removes most of the missing data along each orbit, providing a clear depiction of the relationship
 358 between the TOALW and CF for cloudy and cloud-free grid cells. Areas of high (low) TOALW coincide with areas
 359 of small (large) cloudy areas, but it is also interesting to note that areas of each orbit are characterized as overcast in
 360 conjunction with areas that are not as spatially uniform in TOALW as in CF.

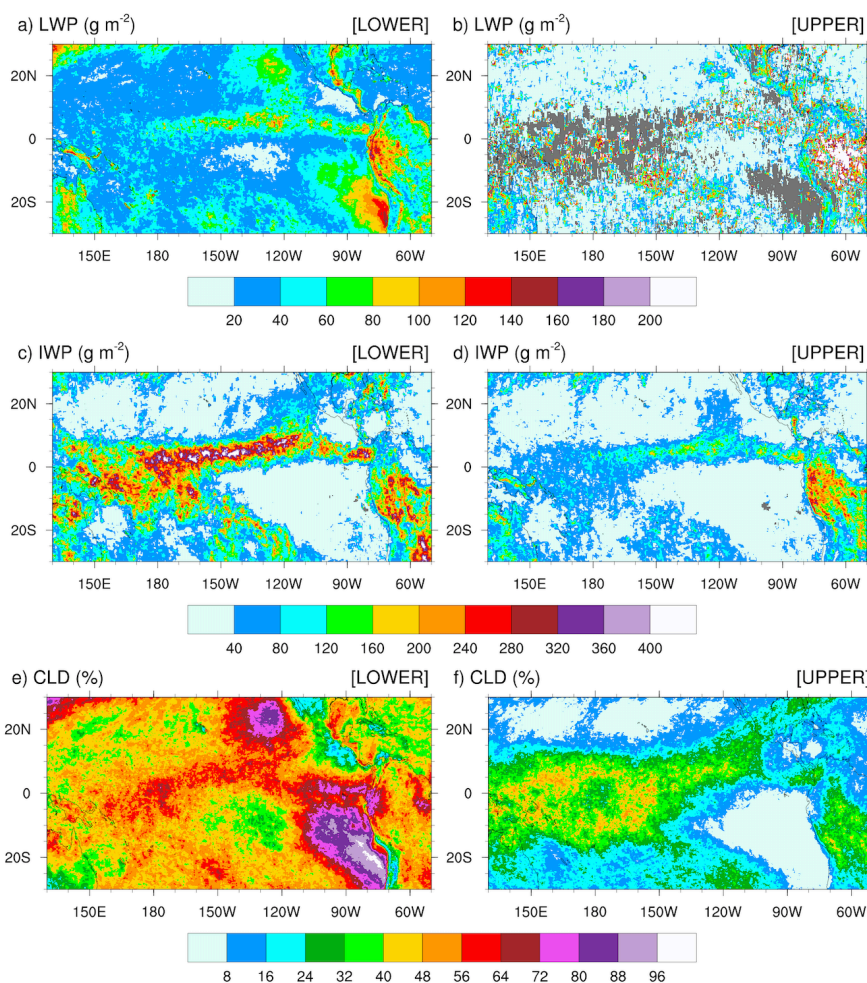

361
362 **Figure 3:** Orbital paths of the Aqua satellite between 00 GMT-01 GMT and 14 GMT-15 GMT after binning the SSF data onto a
363 $0.2^\circ \times 0.2^\circ$ rectangular grid for a) the TOA all-sky upward long-wave radiation, and b) the cloudy percent area coverage for 1st
364 December 2015.

365 The second data file format (SSF1deg) includes daily and monthly averages of the original SSF orbital data but
366 interpolated on a $1^\circ \times 1^\circ$ latitude-longitude grid. The difficulty in using hourly higher-resolution orbital data instead of
367 monthly mean lower-resolution $1^\circ \times 1^\circ$ latitude-longitude gridded product is that the former are available in two distinct
368 *dynamic* layers while the latter is provided at fixed pressure levels and for the atmospheric column. The lower and
369 upper layers are referred to as *dynamic* layers because the cloud-top (base) pressure of each layer varies between SSFs
370 along each orbit. The advantage of using orbital hourly data is that they can be gridded and interpolated to a spatial
371 resolution close to that of our uniform and variable-resolution numerical experiments prior to computing monthly
372 mean radiation and cloud fields. We choose the $0.2^\circ \times 0.2^\circ$ latitude-longitude gridded hourly data derived from the first
373 data file format through the entire manuscript.

374 In order to best compare the simulated against satellite-derived LWP and IWP, we need to understand the
375 partitioning of the SSF LWP and IWP between the two cloud layers. In brief, a lower and an upper cloud layer can be
376 detected simultaneously if they lie adjacent to each other inside an SSF. In that case, the cloud properties for each
377 layer are reported separately. In the case when an opaque upper cloud layer is detected to be above a lower cloud
378 layer, it is impossible to identify the two layers separately. Then, only one cloud layer is reported and always classified

379 as the lower cloud layer, regardless of its cloud-base (top) pressure (Loeb, private communication). Further details on
380 the cloud classification, including determination of the cloud phase, are found in Geier et al. (2003) and Minnis et al.
381 (2011). Figure 4 shows the monthly-mean LWP, IWP, and CF for the lower (left panels) and upper (right panels) layer
382 measured by Aqua for December 2015 over the Tropical Pacific Ocean. Figure S1 is as Fig. 4, but for the Terra satellite
383 (see supplemental figures). LWP and IWP are *in-cloud* values meaning that they have not been weighted by CF. The
384 lower cloud layer includes stratiform clouds that form over colder sea-surface temperatures along the coast of Peru
385 and off the Baja Peninsula. Over these areas of CF greater than 72% for the lower cloudy layer, CF for the upper cloud
386 layer is less than 8%, highlighting that a single layer of low-level clouds fills a major fraction of the SSF. Increased
387 values of CF are seen in conjunction with increased (decreased) values for the LWP (IWP) in the lower cloud layer
388 indicative of warm-phase clouds, as well seen as off the coast of Peru. High values for the CF and IWP juxtaposed
389 with lower values for the LWP in the lower cloud layer depict clearly deep convection over the Eastern Pacific Ocean,
390 ITCZ, and warm pool region. Over areas of deep convection, upper cloud layers are often detected in conjunction with
391 lower cloud layers within the same SSF but are defined by decreased values for the CF and IWP. For the LWP, the
392 coexistence of a lower and upper cloud layer is quite infrequent, as seen by the number of missing grid-points in Fig.
393 4.b (S1.b). Where detected, the LWP in the upper layer exceeds that in the lower layer, indicative of warm-phase
394 mature thicker cumulus clouds coexisting with developing thinner cumulus clouds in the lower layer. Finally, outside
395 of the typical stratus cloud regions and either sides of the ITCZ and warm pool region, SSF data reveal extended
396 regions of warm-phase thinner clouds characteristic of widespread shallow convection over tropical oceans.

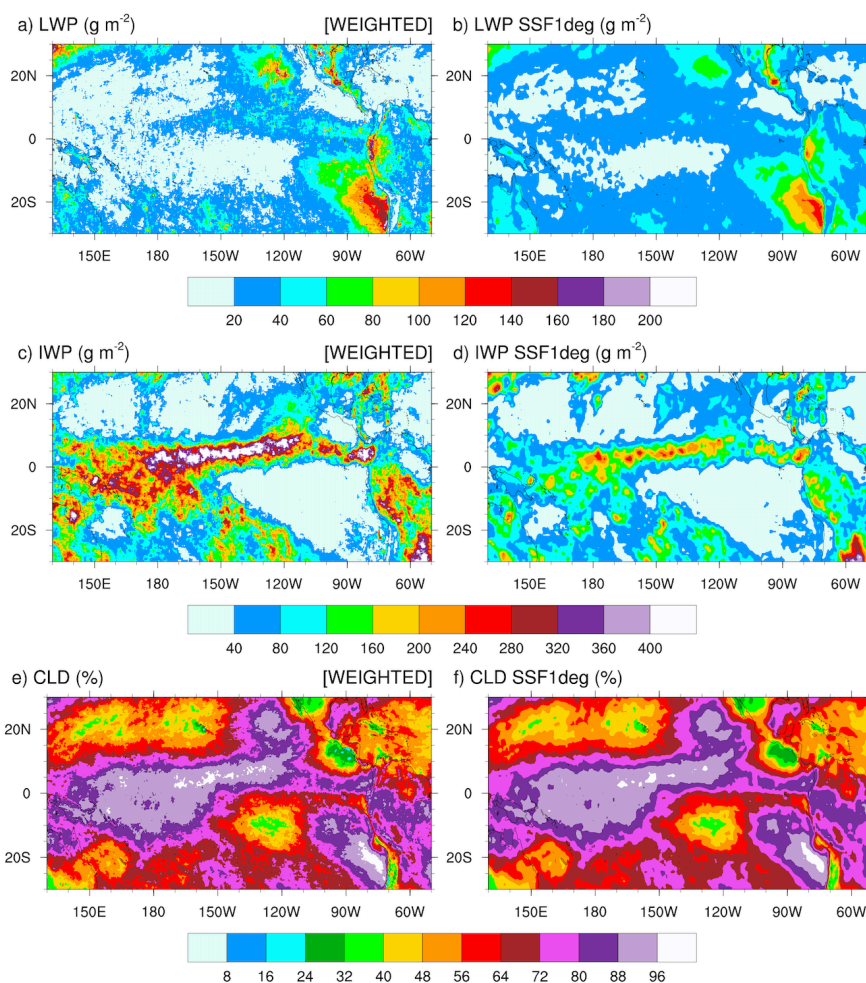

397
398 **Figure 4:** Monthly-mean cloud liquid water path (LWP, top panels), cloud ice water path (IWP, middle panels), and cloud fraction
399 (CLD, bottom panels) over the Tropical Pacific Ocean for December 2015 from the Aqua satellite. Panels a), c), and e) are for the
400 lower cloud layer; panels b), d), and f) are for the upper cloud layer.

401 Calculating the satellite-retrieved LWP and IWP in an atmospheric column for validation of those from our
402 numerical simulations is a two-step process. Because simulated LWPs and IWPs are *gridcell mean* values and not
403 *local* values, we first multiply the SSF LWP and IWP by CF to get their mean values in the lower and upper cloud
404 layers separately, prior to gridding the hourly orbital data. Second, because the lower and upper layers are defined as
405 adjacent to each other and never overlap in a SSF, we simply add the gridcell mean LWP and IWP in the lower layer
406 to that in the upper layer to compute the total LWP and IWP. Our processing method is simpler than the processing
407 steps taken by the CERES Science Team to spatially grid and temporally average SSF hourly orbital data to SSF1deg
408 gridded monthly mean data. Figure 5 compares the monthly-mean 0.2°x0.2° latitude-longitude CF-weighted LWP
409 and IWP and CF (left panels) against the SSF1deg products (right panels) for December 2015 over the Tropical Pacific
410 Ocean. The top panels of Fig. 5 show that our method reproduces successfully the geographical patterns and magnitude

411 of the LWP over the Tropical Pacific when compared against the SSF1deg data for both months. In contrast, because
 412 our method does not weigh the IWP as a function of height, it systematically overestimates the SSF IWP when
 413 compared against the SSF1deg data, as seen over the ITCZ and South Pacific Convergence Zone (SPCZ) in both
 414 months.

415 **Figure 5:** Monthly-mean cloudy area-weighted cloud liquid water path (LWP, top panels), cloudy-area weighted cloud ice water
 416 path (IWP, middle panels), and cloud fraction (CLD, bottom panels) over the Tropical Pacific Ocean for December 2015. Panels
 417 a), c), and e) are SSF data; panels b), d), and f) are SSF1deg climatological data.
 418

419 Using ice water content data from the ascending (daytime) and descending (nighttime) portion of CloudSat orbits,
 420 Waliser et al. (2009; Fig. 7) estimate that day-night fluctuations in the ice water content at 215 hPa account for as
 421 much as 13% (20 %) of the annual mean ice water content over the warm pool (Tropical Eastern Pacific), in response
 422 to the diurnal cycle of deep convection over the tropical oceans. Therefore, when computing the monthly-mean CF,
 423 LWP, IWP, TOALW, and TOASW produced with GFu, GFv, MSKFu and MSKFv, we first sample the hourly model
 424 diagnostics in accordance with the Aqua and Terra satellite orbits in order to reduce biases from different diurnal

425 sampling between our experiments and SSF data. Because the MODIS-based retrieval of the LWP and IWP is
426 insensitive to precipitation, and the rain, snow, and graupel mixing ratios are prognostic variables in THOM and fall
427 through the atmosphere at finite velocities, we infer that the LWP and IWP must include all precipitating and non-
428 precipitating condensates.

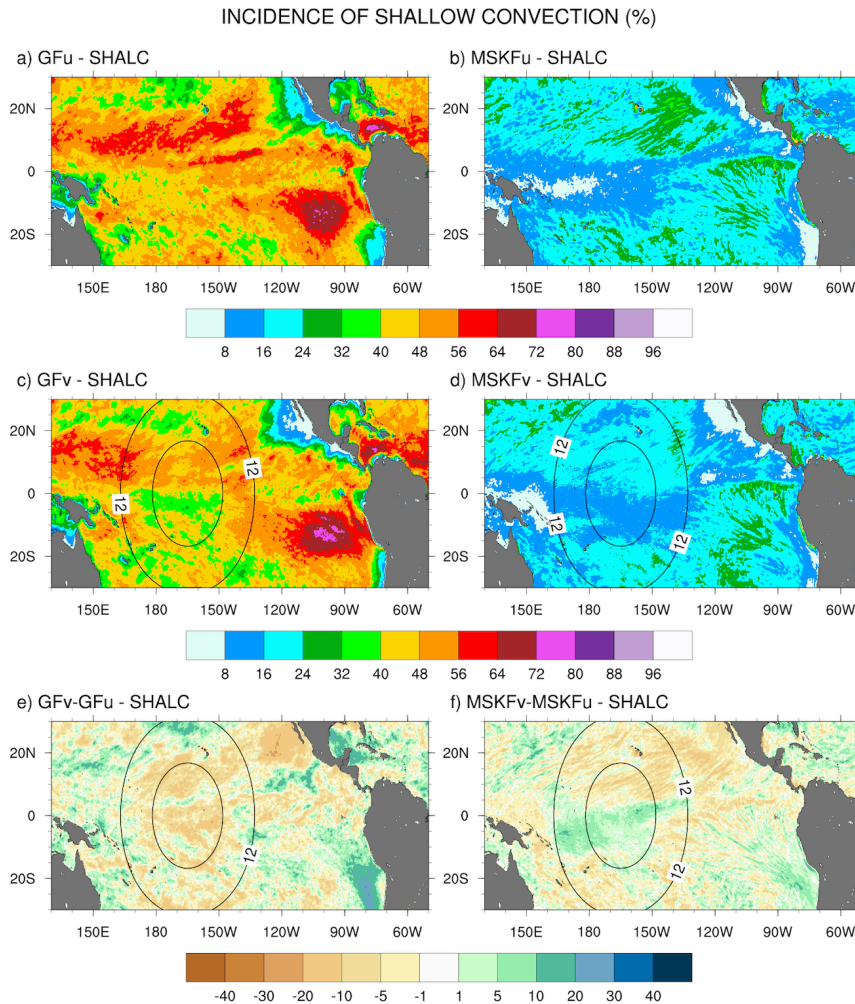

429 In addition to CERES SSF data, we use the monthly-mean precipitation rates from the TRMM Multisatellite
430 Precipitation Analysis (TMPA Version 7; Huffman et al., 2007) to compare simulated versus observed precipitation
431 rates, and monthly mean ERA-Interim reanalyses (Dee et al., 2011) to compare simulated versus observed precipitable
432 water in the lower troposphere.

433 **4 Simulated versus satellite-retrieved precipitation**

434 **4.1 Incidence of subgrid-scale shallow and deep convection**

435 Differences in the treatment of interactions between shallow and deep convection in GF and MSKF, as described in
436 Section 2, are bound to modify the partitioning between shallow and deep convection as spatial resolution increases
437 over the refined area of the mesh. A useful diagnostic to analyze the response of shallow and deep convection to local
438 mesh refinement is the incidence of convection. Because shallow convection in both GF and MSKF is non-
439 precipitating, we set the incidence of shallow convection to 100 % when cloud-tops of shallow convective updrafts
440 are detected, and 0 % otherwise. We set the incidence of deep convection to 100 % when convective precipitation
441 occurs and 0 % otherwise. Figures 6 and 7 highlight the impact of the horizontal scale dependence of convection on
442 the monthly-mean incidence of subgrid-scale shallow and deep convection in our uniform- and variable-resolution
443 experiments for December 2015.

444 Figure 6 shows that simulated shallow convection occurs over the entire Tropical Pacific, and that its incidence
445 is about twice as large in GFu and GFv as in MSKFu and MSKFv. In GFu and GFv, incidence in excess of 48 %
446 covers most of the Tropical Pacific, including the ITCZ and warm pool where GF allows shallow and deep convection
447 to occur simultaneously. GFu and GFv exhibit highest incidence of shallow convection off the coast of Peru where
448 persistent low-level stratiform clouds are formed. In contrast, the incidence of shallow convection in MSKFu and
449 MSKFv never exceeds 32 % over the entire domain and is less than 16 % over the ITCZ and warm pool where shallow
450 and deep convection are not allowed to coexist in MSKF. The bottom panels highlight differences in the incidence of
451 shallow convection between GFv and GFu, and MSKFv and MSKFu. Despite the fact that GF does not include a
452 spatial scale dependence in its formulation of shallow convection, GFv produces reduced shallow convection relative
453 to GFu over most of the Tropical Pacific, except most notably immediately off the coast of Peru. In contrast to GFv,
454 MSKFv yields increased incidence of shallow convection over most of the warm pool region. In MSKF, the height of
455 deep convective clouds decreases as horizontal resolution increases. As the classification between deep and shallow
456 convection is a function of cloud depth, convective clouds originally defined as deep are reclassified as shallow,
457 leading to increased incidence of shallow convection in the refined area of the mesh.

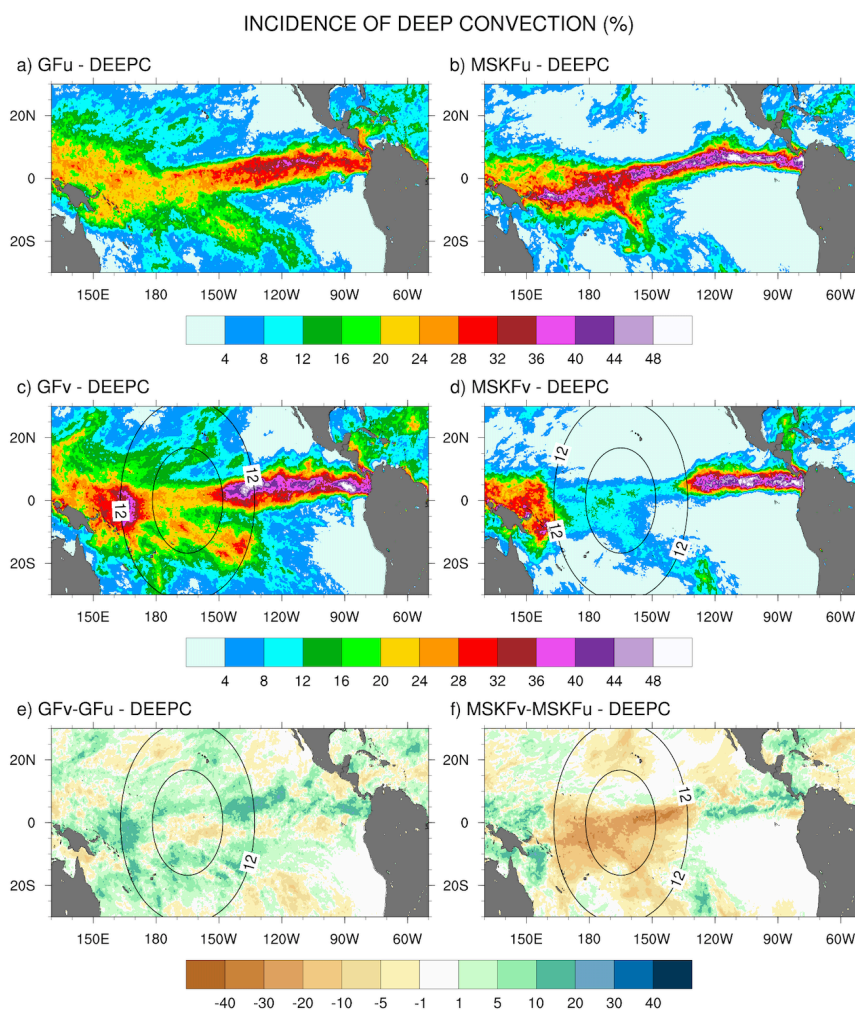

458
 459 **Figure 6:** Monthly-mean incidence of shallow convection (SHALC) over the Tropical Pacific Ocean simulated in GFu and MSKFu
 460 (top panels) and GFv and MSKFv (middle panels), and difference in the incidence of shallow convection between GFv and GFu
 461 (bottom left panel) and MSKFv and MSKFu (bottom right panel) for December 2015.

462 In Fig. 7, the top and middle panels show that, in contrast to shallow convection, the incidence of deep convection
 463 has the same order of magnitude in GFu and MSKFu, and GFv and MSKFv. The top panels reveal that the incidence
 464 of deep convection is higher in MSKFu than GFu over the ITCZ and warm pool. In MSKFu, a sharp transition between
 465 areas of high and low incidence of deep convection causes areas outside of the ITCZ and warm pool to be mostly void
 466 of deep convection, as seen between 10°N and 30°N. In GFu, the incidence of deep convection is decreased over the
 467 warm pool relative to the ITCZ west of 160°W. Outside of the ITCZ and warm pool, GFu and GFv lead to higher
 468 incidence of deep convection than MSKFu and MSKFv because, in contrast to MSKF, GF allows deep and shallow
 469 convection to coexist in the same grid-cell. Middle panels highlight decreased incidence of subgrid-scale deep
 470 convection inside the refined area of the mesh over the warm pool in both GFv and MSKFv, as we expect clouds to

471 be resolved on the higher resolution grid, in conjunction with increased incidence east and west of the refined area.
 472 The decreased incidence in the refined area is more pronounced between MSKFu and MSKFv than between GFu and
 473 GFv whereas the upscaling impact of spatial refinement outside the refined area is greater in GFv than MSKFv. The
 474 scale-aware formulation in GF does not produce the same contrast between the refined and coarse mesh in GFv and
 475 GFu as that in MSKF in MSKFv and MSKFu. Fig. 7.f reveals a reduced incidence in excess of 25 % between MSKFu
 476 and MSKFv starting at resolutions higher than 12 km flanked by increased incidence of deep convection east and west
 477 of the refined area. In contrast, Fig. 7.e displays a longitudinal band of decreased incidence of deep convection between
 478 90°W and the dateline, bordered by increased deep convection north of the equator and south of 10°S. Table 2 lists
 479 the area-averaged incidence of deep and shallow convection over an area located inside the refined mesh (REFINED:
 480 0.1°N to 5.1°N; 150°W to 180°W) and over the Tropical Eastern Pacific (EAST: 3.1°N to 8.1°N; 90°W to 120°W).

481
 482

Figure 7: As Fig. 6, but for the monthly-mean incidence of deep convection (DEEPC).

483 Table 2 summarizes our results displayed in Figs. 6 and 7. The REFINED and EAST areas display little variation in
484 the incidence of shallow convection in any of the experiments. The incidence of shallow convection in GFu and GFv
485 is much higher than in MSKFu and MSKFv. The incidence of subgrid-scale deep convection is increased in the EAST
486 area relative to the REFINED area. Over the refined area, the incidence of subgrid-scale deep convection remains
487 about the same between GFu and GFv while strongly decreases between MSKFu and MSKFv.
488

	DEEP CONVECTION		SHALLOW CONVECTION	
	REFINED	EAST	REFINED	EAST
GFu	20	30	52	52
GFv	23	36	47	48
MSKFu	27	33	14	17
MSKFv	10	36	17	15

489 **Table 2:** Area-averaged incidence of deep and shallow convection. Units are %.

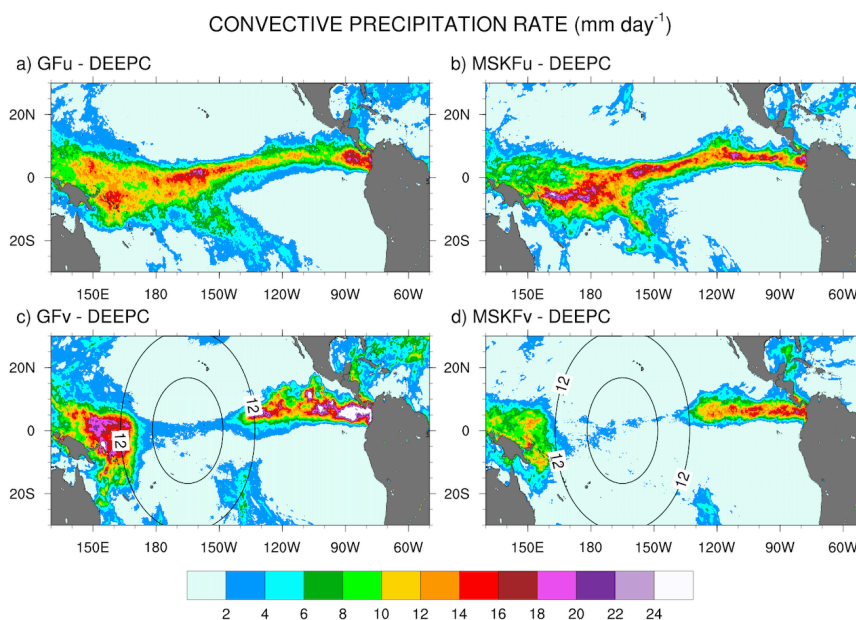

490 As described in Section 2, MSKF differentiates shallow from deep convection as a function of the convective
491 cloud depth. As spatial resolution increases, the scale aware formulation leads to a reduction in the intensity of
492 convection and depth of convective clouds, mostly deep convection, over the refined area as seen in Fig. 7.f. As the
493 depth of convective clouds originally classified as precipitating deep convective clouds become shallower, MSKF
494 reclassifies those same clouds as nonprecipitating shallow clouds, leading to near-equal compensation between the
495 decreased and increased incidence of deep and shallow convection over the warm pool. In contrast to MSKF, GF
496 causes precipitating deep convection to become precipitating shallow convection at increased spatial resolution. As
497 this process occurs in the deep convection scheme and both cloud types precipitate, variations in the incidence of deep
498 convection between GFu and GFv are small. Further analysis of the response of shallow convection between GFu and
499 GFv over the refined area is beyond the objectives of this research.

500 4.2 Precipitation rates

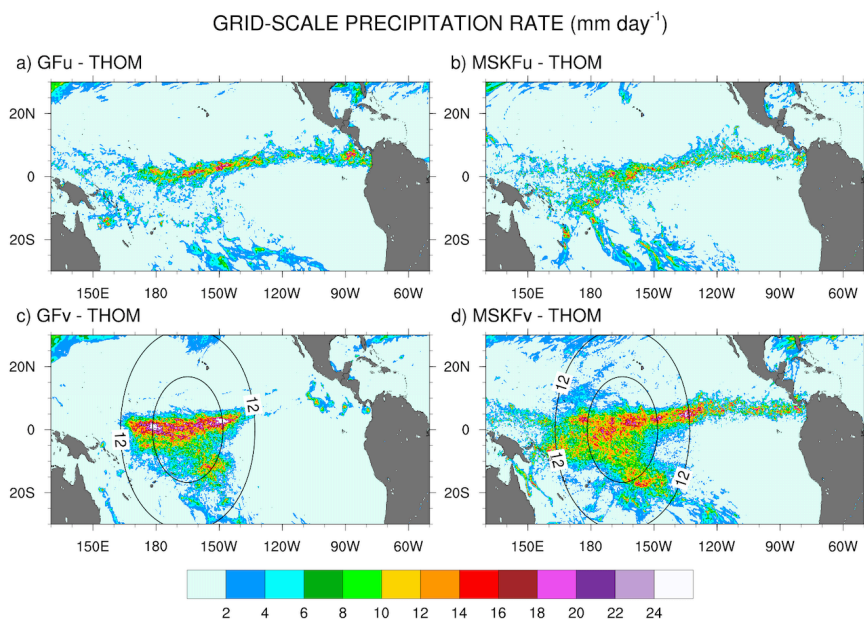

501 Figures 8 and 9 show the monthly-mean convective and grid-scale precipitation rates simulated in GFu and MSKFu
502 (top panels) and GFv and MSKFv (bottom panels). The top panels highlight similar geographical patterns of
503 convective and grid-scale precipitation rates in GFu and MSKFu. Between 80°W and 160°W, increased convective
504 and grid-scale precipitation rates are located over the ITCZ, in conjunction with increased incidence of deep
505 convection seen in Fig. 7.a,b. West of 160°W, GFu leads to decreased but more widespread convective precipitation
506 relative to MSKFu over the warm pool, in conjunction with decreased but more widespread incidence of convection.
507 In contrast to convective precipitation, there are few differences in grid-scale precipitation between GFu and MSKFu
508 (Figs. 9.a,b). This result infers that while deep convection is not triggered as often over the warm pool as over the
509 ITCZ, the amount of convective precipitation produced in one time-step is higher over the warm pool than over the
510 ITCZ, so that convective precipitation rates remain about the same in both regions. This result may also explain the

511 decrease in grid-scale precipitation over the warm pool compared to the ITCZ, as increased convective drying inhibits
512 grid-scale cloud microphysics processes and precipitation in the lower troposphere. In Fig. 8, and in agreement with
513 the middle panels of Fig. 7, bottom panels show that the scale-aware formulation in MSKF reduces convective
514 precipitation more efficiently than GF, leading to precipitation rates that are systematically smaller in MSKFv than
515 GFv in the refined area. The upscaling effect of spatial refinement produces different convective precipitation patterns
516 between MSKFv and GFv over the coarse area of the mesh. In GFv, increased incidence of deep convection on each
517 side of the refined area leads to increased convective precipitation and strongly decreased grid-scale precipitation in
518 the warm pool and Tropical Eastern Pacific, as seen in Figs. 8.c and 9.c. In contrast to GFv, MSKFv yields similar
519 convective (grid-scale) precipitation as MSKFu over those two areas, when comparing Fig. 8.b to Fig 8.d (Fig. 9.b to
520 Fig. 9.d). Over the refined area, grid-scale precipitation increases to compensate for the decrease in convective
521 precipitation in GFv and MSKFv so that total precipitation remains about the same between GFu (MSKFu) and GFv
522 (MSKFv). Comparing Fig. 9.c (Fig. 9.d) against Fig. 9.a (Fig. 9.b) reveals that grid-scale precipitation increases the
523 most along the ITCZ in conjunction with the greatest decrease in convective precipitation. GFv and MSKFv also lead
524 to an increase in grid-scale precipitation over the SPCZ, more so in MSKFv than GFv. MSKFv does not produce as
525 drastic a reduction in grid-scale precipitation as GFv over the coarse area of the mesh, indicating a smaller upscaling
526 impact of the refined mesh in MSKFv than GFv.

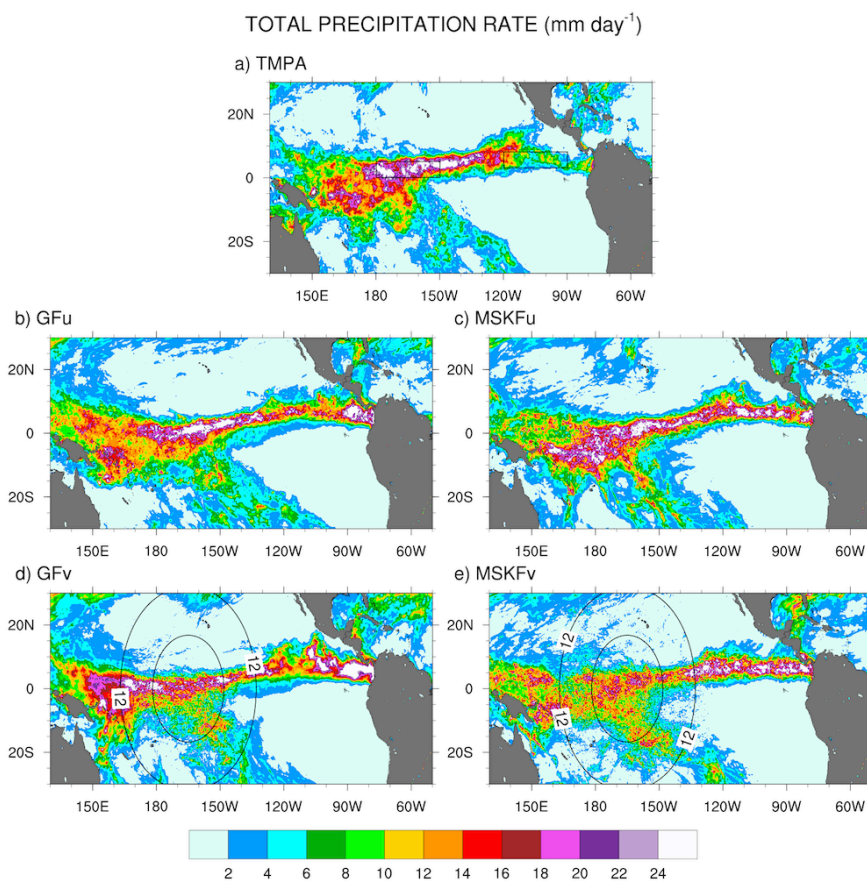

527
528 **Figure 8:** Monthly-mean convective (DEEPC) precipitation rate over the Tropical Pacific Ocean simulated in GFu and MSKFu
529 (top panels) and GFv and MSKFv (bottom panels) for December 2015.

530
531

Figure 9: As Fig. 8, but the monthly mean grid-scale (THOM) precipitation rate.

532 The simulated total precipitation rate can be evaluated to observed TMPA precipitation using Figs. 10 and 11
533 which show the precipitation rates and differences between simulated and observed precipitation rates, respectively.
534 Areas of maximum satellite-retrieved precipitation are found over the ITCZ between 130°W and the dateline (Fig.
535 10.a). Observed precipitation decreases over the warm pool west of the dateline and decreases strongly along the
536 Tropical Eastern Pacific (between 80°W and 120°W) and the SPCZ. The four simulations overestimate precipitation
537 in the Tropical Eastern Pacific between 80°W and 120°W (Figs. 10.b,e) with biases in excess of 11 mm day^{-1} (Figs.
538 11.a,d). The four simulations also overestimate precipitation between 130°E and 160°E , or west of the refined area,
539 with biases about as large as those seen east of the refined area, except for MSKFu. The uniform-grid MPAS results
540 (Figs. 10.b,c) display the highest precipitation rates over the area of warmest SSTs where we expect deepest
541 convection to occur and are in reasonable agreement with TMPA data. However, GFu and MSKFu locate the ITCZ
542 south of its observed location (Fig. 11.a,b), producing a positive bias straddling the Equator and a negative bias north
543 of the Equator. The scale-aware dependence of deep convection in GF leads to decreased total precipitation in GFv
544 compared to GFu over the entire refined area (Fig. 11.e). In contrast, Fig. 11.f shows that while the scale-aware
545 dependence in MSKF leads to decreased precipitation in MSKFv over a major fraction of the refined area, it also leads
546 to an improved location of the simulated ITCZ, as evidenced by increased precipitation north of the Equator.

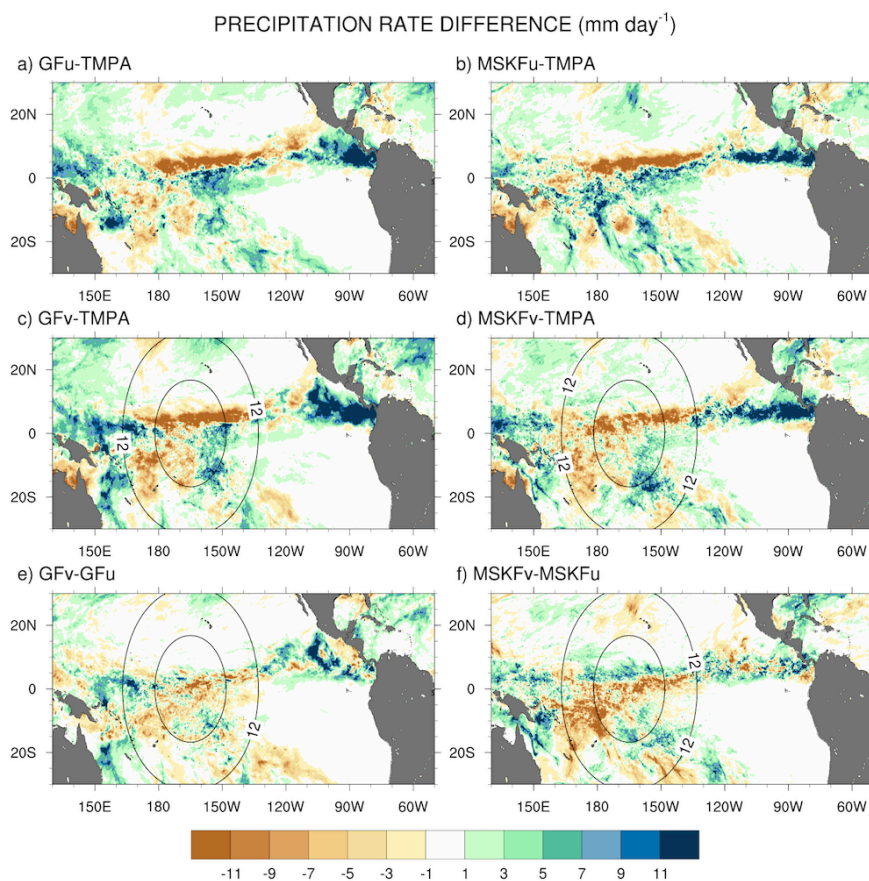

547
 548
 549

Figure 10: Monthly-mean total precipitation rate over the Tropical Pacific Ocean from TPA data (top panel) and simulated with GFu and MSKFu (middle panels) and GFv and MSKFv (bottom panels) for December 2015.

 557
 558
 559
 560

Table 3 summarizes the area-mean monthly-mean convective, grid-scale, and total simulated and observed TPA precipitation rates over the REFINED and EAST areas. Over the REFINED area, the total precipitation is about the same in all four experiments, but less than that from TPA data. This bias results because the simulated ITCZ is located south of that actually observed (see Fig. 11). Total precipitation is reduced by 2.1 (2.3) mm day^{-1} between GFu (MSKFu) and GFv (MSKFv), highlighting a near-equal compensation between decreased convective and increased grid-scale precipitation rates as horizontal resolution increases. GFu and MSKFu, and GFv and MSKFv, have similar partitioning between convective and grid-scale precipitation rates. Table 3 quantifies the increased (decreased) convective (grid-scale) precipitation between GFu and GFv observed outside of the refined mesh in Fig. 6. For the EAST area, Table 3 shows that total precipitation increases by 2.7 (1.2) mm day^{-1} in conjunction with a 5.3 (0.5) mm day^{-1} increase in convective precipitation between GFu and GFv (MSKFu and MSKFv), highlighting the impact of the refined area on the coarse area of the mesh in GFv and MSKFv.

561
 562 **Figure 11:** Monthly-mean precipitation rate difference over the Tropical Pacific Ocean between GFu (MSKFu) and TMPA data
 563 (top panels), GFv (MSKFv) and TMPA data (middle panels), and between GFv (MSKFv) and GFu (MSKFu) (bottom panels) for
 564 December 2015.

565 In summary, the scale dependence of convection in GF and MSKF produces the same partitioning between
 566 convective and grid-scale precipitation inside the refined area or decreased convective and compensating increased
 567 grid-scale precipitation as horizontal resolution increases. The upscaling impact on convective and grid-scale
 568 precipitation varies between GF and MSKF. As seen in Fig. 8 and Table 3, convective precipitation increases strongly
 569 over the warm pool and Eastern Pacific starting across the transition zones east and west of the refined area in GFv.
 570 In contrast, while the parameterization of the scale dependence of deep convection in MSKF produces a stronger
 571 decrease in convective precipitation in MSKFv than GFv, it produces a smoother transition in convective precipitation
 572 and decreased upscaling effect as spatial resolution reaches 30 km

573

	CONVECTIVE		GRID-SCALE		TOTAL	
	REFINED	EAST	REFINED	EAST	REFINED	EAST
GFu	10.0	8.7	6.1	3.7	16.1	12.4
GFv	1.9	14.0	12.1	1.1	14.0	15.1
MSKFu	10.9	10.6	4.9	4.76	15.8	15.3

574 **Table 3:** Area-averaged convective, grid-scale, and total precipitation rates over the same areas as those described for Table 2.
 575 Units are mm day⁻¹.

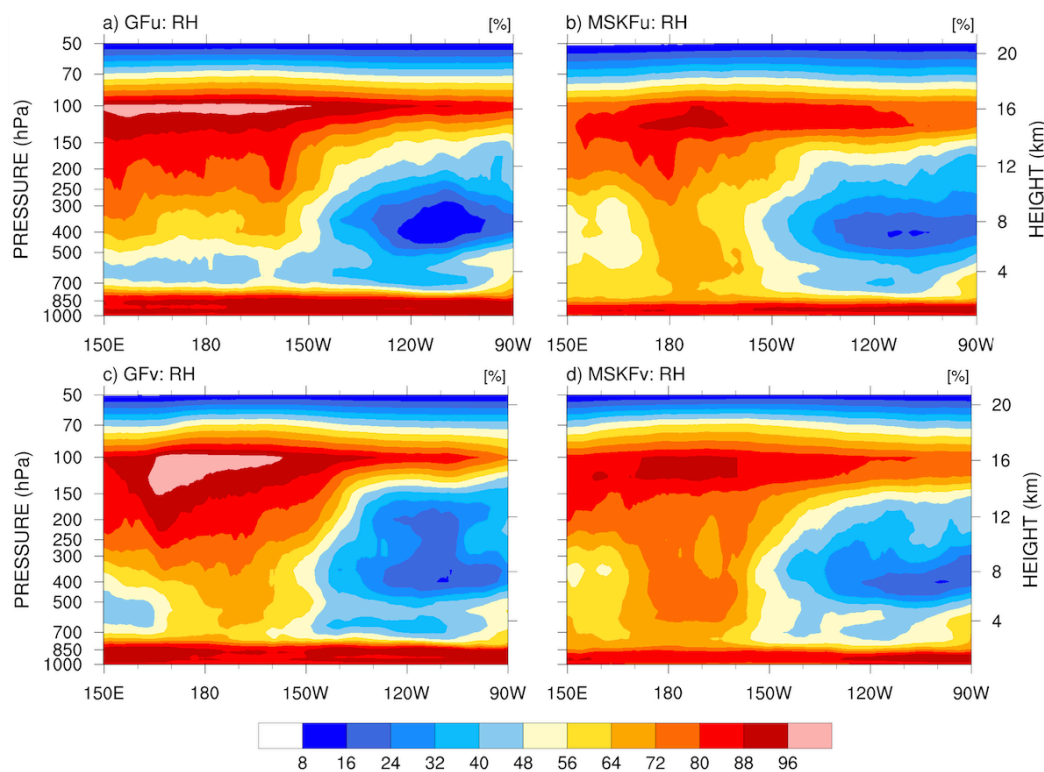

576 **5 Simulated relative humidity and simulated versus satellite-retrieved LWP and IWP**

577 **5.1 Relative humidity**

578 One effect of local mesh refinement is the decreased contribution of parameterized convection compensated by
 579 increased contribution of grid-scale cloud microphysics to condensation processes and cloud formation with
 580 increasing spatial resolution. Therefore, prior to comparing the simulated LWP and IWP against SSF data, we first
 581 investigate differences in relative humidity (RH) between our uniform- and variable-resolution experiments. Figure
 582 12 displays the monthly-mean longitude-pressure cross sections of RH latitudinally-averaged between 5°S and 5°N.
 583 East of 150°W over the Tropical Eastern Pacific, the four experiments display similar vertical distributions of RH,
 584 with relatively lower RH between 700 hPa and 150 hPa and higher RH in the PBL below 700 hPa and in the upper-
 585 troposphere above 150 hPa. All four experiments show significant increase in RH west of 150°W across the entire
 586 troposphere, over the warm pool where the warmest SSTs are seen (Fig. 2.a) and deepest convective updrafts are
 587 formed. Comparing GFu against MSKFu over the warm pool shows that GF has stronger drying than MSKF in the
 588 lower troposphere, leading to a lower RH between 850 hPa and 300 hPa in GFu than MSKFu. In addition, GF produces
 589 stronger moistening than MSKF in the upper troposphere leading to a higher RH between 300 hPa and 100 hPa in
 590 GFu than MSKFu. As seen in the bottom panels of Fig. 12, reducing parameterized deep convection while enhancing
 591 grid-scale cloud microphysics produces a higher RH over the refined area in GFv and MSKFv, but without
 592 significantly modifying RH over the coarse area of the mesh. Variations in the vertical distribution of RH at pressures
 593 less than 400 hPa are more pronounced between GFu and GFv than between MSKFv and MSKFu. Because the cloud
 594 fraction (CF) is a function of RH, as described in Xu and Randall (1996; Eq. 1), there is a strong relationship between
 595 the longitude-pressure cross sections of RH and CF, as seen in Fig. S2 (see supplemental figures). The highest CF
 596 coincide with the highest RH at about 100 hPa over the warm pool in all four experiments. As for RH, GFu and GFv
 597 display higher and lower values of CF than MSKFu and MSKFv in the upper and lower troposphere. The top and
 598 bottom panels of Fig. S3 show differences in RH and CF between GFv and GFu, and between MSKFv and MSKFu.

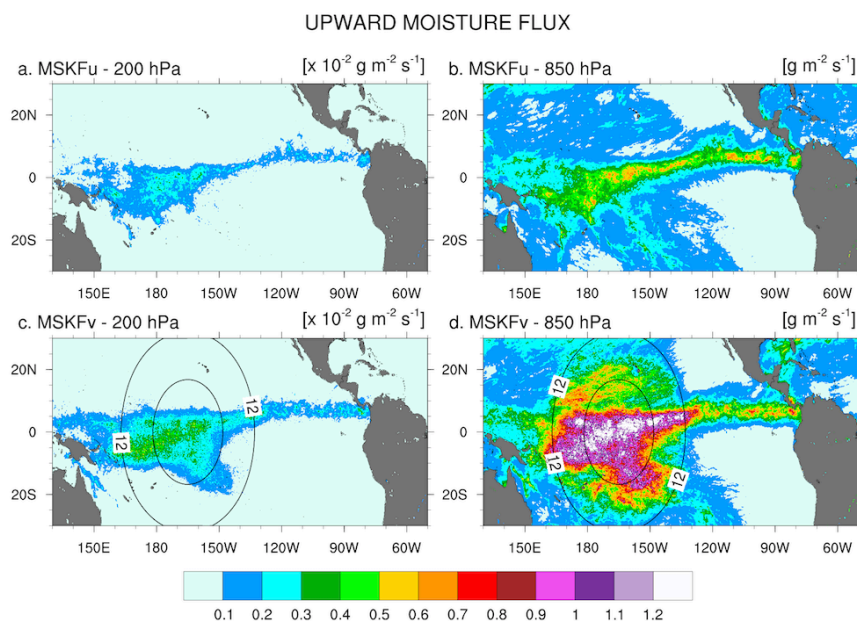

599 One notable difference is a stronger increase in upper-tropospheric clouds between MSKFu and MSKFv than between
600 GFv and GFu, particularly over the refined area of the mesh. While increased grid-scale condensation over the refined
601 area impacts the entire troposphere in GFv, it more strongly affects the upper-troposphere in MSKFv.

602
603 **Figure 12:** Longitude versus pressure cross-section of latitudinally-averaged relative humidity (RH) across the Tropical Pacific
604 Ocean simulated in GFu and MSKFu (top panels) and GFu and GFv (bottom panels) for December 2015.

605 To explain the change in RH over the refined area between the uniform- and variable-resolution experiments, we
606 compare the monthly-mean upward moisture flux at 850 hPa and 200 hPa between MSKFu and MSKFv over the
607 Tropical Eastern Pacific (Fig. 13). There is a significant decrease in the upward moisture flux between 850 hPa and
608 200 hPa in conjunction with decreased specific humidity with height in MSKFu and MSKFv (Fig. 12). As seen in the
609 top panels of Fig. 13, MSKFu yields highest values of the upward moisture flux along the ITCZ and over the warm
610 pool in association with parameterized deep convection. Outside the ITCZ and warm pool, lower values of the upward
611 moisture flux at 850 hPa result because of reduced deep convection in conjunction with shallow convection, as seen
612 over the SPCZ. At increased spatial resolution, convective processes transition from being parameterized to resolved,
613 producing larger grid-scale vertical velocities, stronger upward moisture flux, and increased grid-scale condensation
614 through the entire troposphere over the refined area of the mesh. Comparing the bottom versus top panels of Fig. 13
615 outlines the intensification of vertical moisture transport at both pressure levels over the refined area, leading to the
616 increased relative humidity with increased spatial resolutions shown in Fig. 12.

617

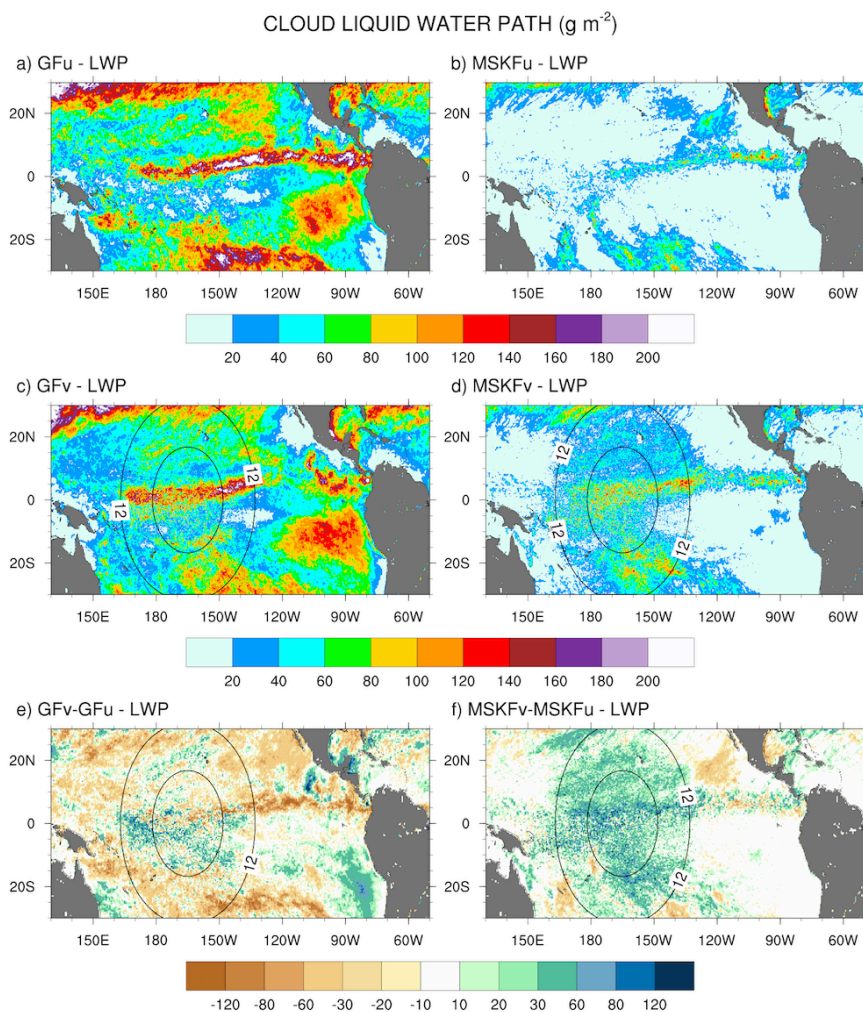

618 **Figure 13:** 200 hPa (left panels) and 850 hPa (right panels) monthly-mean upward moisture flux simulated with MSKF over the
619 Tropical Pacific Ocean for December 2015. Top panels are for MSKFu and bottom panels are for MSKFv. Note the 1×10^{-2} scaling
620 between 200 hPa and 850 hPa.

621 5.2 Liquid Water Path (LWP)

622 The LWP from the four simulations (Fig. 14) is evaluated with satellite-derived LWP (shown in Fig. 5) as well as
623 compared among the simulations. In Fig. 14, the LWP is calculated using only the grid-scale cloud liquid water mixing
624 ratio from THOM. Separate analyses would show that adding the prognostic grid-scale rain mixing ratio to the
625 simulated LWP further increases biases when compared against the SSF LWP (not shown for brevity). We also did
626 not include the contribution of the convective cloud liquid water mixing ratio to the LWP which is small compared to
627 that from grid-scale cloud microphysics. Comparing Fig. 14.a with Fig. 5.a highlights that GFu strongly overestimates
628 the LWP over the ITCZ, and between 20°N (20°S) and the northern (southern) limits of our analysis. As seen in Fig.
629 6, GFu attempts to form low-level boundary layer clouds off the coast of Peru but these clouds form too far west from
630 the coast when compared against observations. This same bias is depicted in Fig 14.a since these low-level boundary
631 layer clouds are characterized by high LWP. Fig. 14.b shows that the LWP is strongly decreased in MSKFu compared
632 to GFu. If we set aside that MSKFu is unable to simulate low-level clouds off the Baja Peninsula and coast of Peru,
633 the magnitude and regional patterns of the LWP simulated in MSKFu is in relatively good agreement with the SSF
634 LWP. Because MSKF does not allow deep and shallow convection to coexist within the same grid-cell and deep
635 convection dominates shallow convection over the ITCZ and warm pool, we suggest that detrained convective cloud
636 water from deep convection as a source to grid-scale microphysics contributes a major part to the LWP produced by
637 MSKFu (Fig. 14.b). The bottom panels of Fig. 14 reveal that the mesh refinement impacts the LWP simulated with
638 MSKF more effectively than that simulated with GF inside and outside the refined area. This result is in agreement

639 with the stronger increase in RH between MSKFu and MSKFv than between GFu and GFv at lower levels. MSKFv
640 yields an increased LWP relative to MSKFu over the entire refined area (Fig. 14.f). MSKFv also has increased LWP
641 compared to MSKFu over the coarse area, but not as large as that seen over the refined area of the mesh. The LWP
642 predicted by GFu and GFv does not have a strong positive or negative trend, due to the fact that GF allows deep and
643 shallow convection to coexist within the same grid-cell of deepest convective activity, mainly over the ITCZ and
644 warm pool, and shallow convection does not account for variations in horizontal grid-spacing. While GFv mostly
645 leads to a decrease in the LWP between GFu and GFv over the coarse area, some grid cells inside the refined area
646 show a decrease in the LWP while other neighboring grid-cells show an increase in the LWP between GFu and GFv.
647 Over the coarse area, an obvious decrease in the LWP between GFv and GFu is seen over the ITCZ along the Tropical
648 Eastern Pacific as well as along the southern boundary of our analysis.

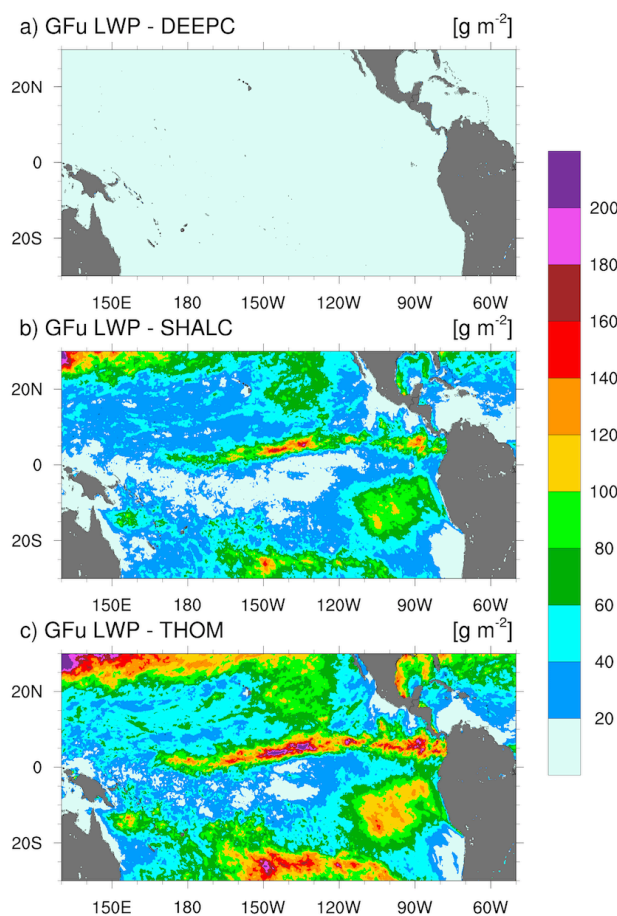

649

650 **Figure 14:** Monthly-mean cloud liquid water path (LWP) over the Tropical Pacific Ocean simulated with GFu and MSKFu (top
 651 panels) and GFv and MSKFv (middle panels), and monthly-mean LWP difference between GFv and GFu, and MSKFv and MSKFu
 652 (bottom panels) for December 2015.

653 In order to investigate the reasons why the LWP simulated in GFu strongly exceeds that from the SSF products
 654 and MSKFu, we calculate the monthly-mean LWP produced in grid-cells with incidence of deep convection, shallow
 655 convection, and without any kind of convection, using hourly outputs of the LWP from GFu. Comparing Fig. 15.a
 656 against Figs. 15.b and 15.c shows that a major fraction of the LWP over convectively active regions such as the ITCZ
 657 is actually produced at times when no convection is active or when only shallow convection is triggered. In contrast,
 658 the LWP produced in grid-cells with deep convection does not exceed 20 g m^{-2} at the scale used in Fig. 15. In GF, and
 659 in contrast to deep convection, shallow convection detrains total water as a source to grid-scale water vapor instead
 660 of water vapor, and cloud liquid and ice water separately. Because the detrained total water is treated as a source of
 661 water vapor, supersaturation conditions are more likely to persist and later removed by grid-scale condensation. In

662 contrast, detrainment from deep convective updrafts acts as a source of liquid water if temperatures are warmer than
663 258 K. Deep convection in conjunction with grid-scale condensation contributes the least to the LWP because updrafts
664 are taller than those formed from shallow convection, leading to condensation and deposition to occur at levels where
665 temperatures are colder than 258 K, and ice phase processes dominate.

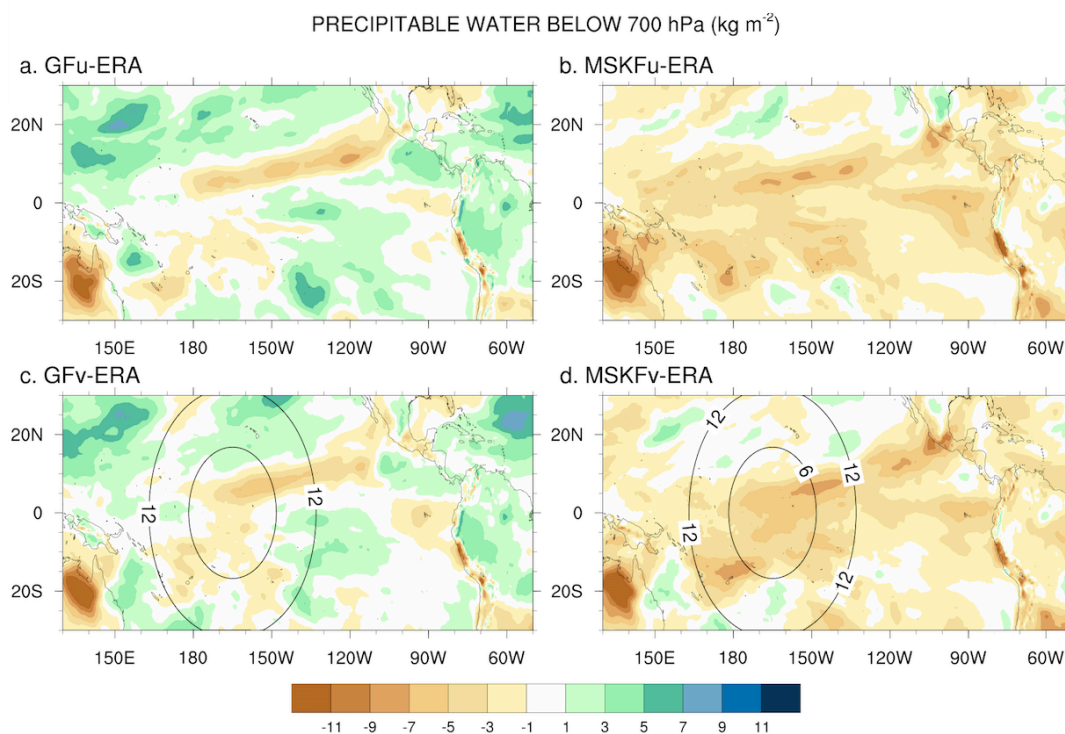

666 **Figure 15:** Monthly-mean of cloud liquid water path of corresponding to a) deep convection only (DEEPC); b) shallow convection
667 only (SHALC); and c) no convection (THOM) simulated with GFu over the Tropical Pacific Ocean for December 2015.
668

669 The impact of more active shallow convection in GFu and GFv relative to MSKFu and MSKFv is best seen in
670 Fig. 16 which shows differences between the monthly-mean precipitable water below 700 hPa from our experiments
671 and ERA-Interim (Dee et al., 2011) reanalyses. First, because varying horizontal resolution does not affect shallow
672 convection, the GFv and MSKFv results (Figs. 16.c, d) display similar biases as the GFu and MSKFu results (Figs.
673 16.a, b) over our entire analysis domain. Second, differences in the parameterization of shallow convection between
674 GF and MSKF lead GFu and GFv to produce significantly different biases than MSKFu and MSKFv against ERA-
675 Interim analyses. Over areas of deep convection, GFu and MSKFu exhibit a dry bias, implying that parameterized
676 deep convective updrafts are too strong and tend to overdry the lower atmospheric layers, as seen over the ITCZ, the
677 SPCZ, and warm pool. Over areas of shallow convection, GFu and MSKFu lead to increased and decreased

678 precipitable water below 700 hPa, in concordance with our earlier findings that GF and MSKF tend to overestimate
679 and underestimate the intensity of shallow convection respectively. Over the refined area, GFv and MSKFv produce
680 a negative bias, suggesting that reduced parameterized deep convection plus resolved grid-scale dynamics are as strong
681 in drying the lower troposphere as parameterized convection alone.

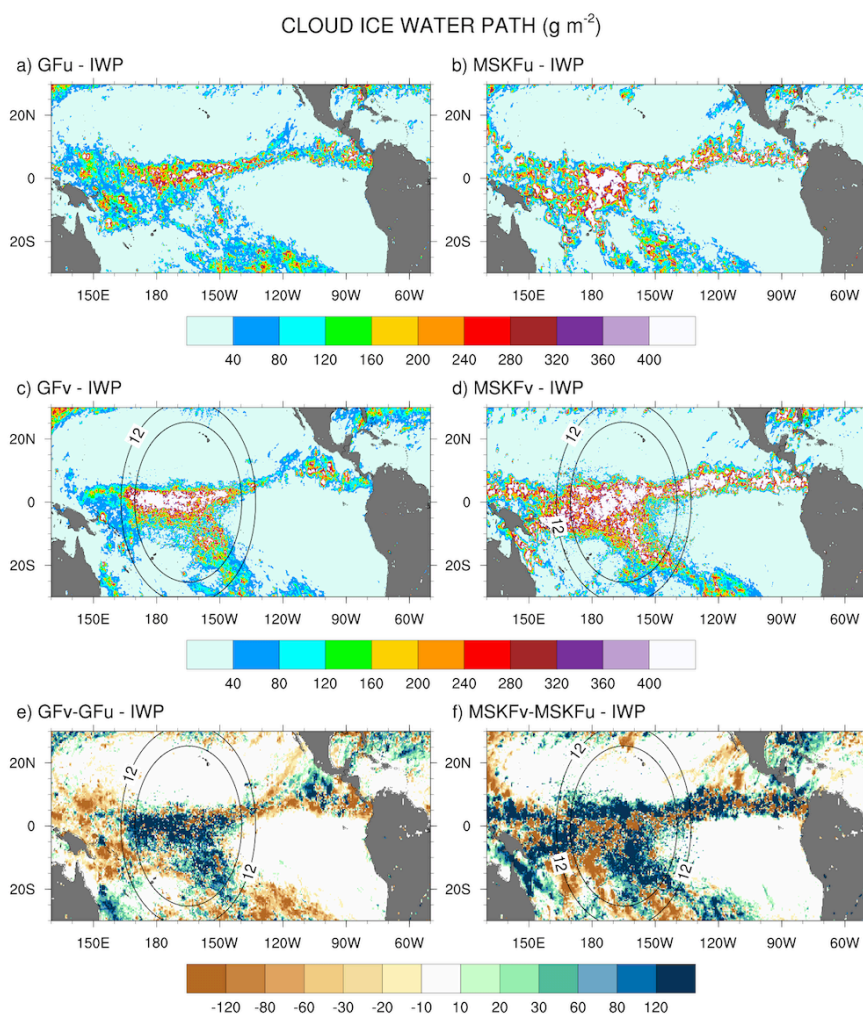

682
683 **Figure 16:** Monthly-mean difference between the simulated and ERA-Interim precipitable water below 700 hPa over the Tropical
684 Pacific Ocean for December 2015.

685 5.3 Ice Water Path (IWP)

686 Because MODIS is relatively insensitive to precipitation, the simulated IWP should comprise cloud ice, snow, and
687 graupel. Because graupel contributes a minor part to the IWP relative to cloud ice and snow and our results highlight
688 strong biases against SSF data, we do not include graupel in our computation of the simulated IWP. It is also important
689 to note that because THOM has the propensity to rapidly convert cloud ice to snow (Thompson et al. 2016), most of
690 the IWP is in the form of snow which falls at higher speeds than cloud ice, enhancing the depth of ice clouds. Lastly,
691 the middle panels of Fig. 5 show that our gridding and simple weighting of the IWP orbital data produce higher
692 monthly mean IWP than that from the official SSF1deg product. This result implies that biases between simulated and
693 satellite-derived IWP will be underestimated when using our SSF $0.2^\circ \times 0.2^\circ$ IWP data. Comparing GFu (MSKFu)
694 shown in Fig. 17 against the SSF IWP (Fig. 5.c) reveals that GFu (MSKFu) tends to underestimate (overestimate) the
695 IWP over the ITCZ and warm pool, and that GFu and MSKFu both overestimate the IWP along the west coast of
696 Central America. Comparing the top and middle panels of Fig. 17 highlights that MSKFu and MSKFv yield higher

697 IWP than GFu and GFv over the ITCZ and warm pool. Increased convective detrainment of cloud ice as a source of
 698 grid-scale cloud ice to THOM in MSKFu than in GFv, due to the fact that partitioning between cloud liquid and ice
 699 water starts at warmer temperatures in MSKFu than GFu, may be responsible to the increased IWP. The bottom panels
 700 of Fig. 17 reveal that increasing spatial resolution worsens the simulated IWP compared to the SSF IWP over the
 701 refined area in GFv and MSKFv. As shown in Fig. 12, mesh refinement over the warm pool produces higher upper-
 702 tropospheric relative humidity leading to increased ice cloud microphysics. In contrast to GFv, MSKFv displays an
 703 increase in the IWP over the coarse area of the mesh, showing a stronger upscaling effect of the refined area on the
 704 coarse area of the mesh in MSKFv than GFv in the upper-troposphere.

705
 706 **Figure 17:** As Fig. 14, but for the cloud ice water path (IWP).

707 **5.4 TOA radiation budget**

708 Biases in the LWP and IWP introduce biases in the cloud fraction and cloud optical properties which in turn lead to
709 biases in the simulated TOALW and TOASW compared to CERES-SSF data. Figures S4, S5, and S6 display the
710 monthly-mean CF, TOALW, and TOASW from SSF data for December 2015 and the differences between the model
711 results and observations. Focusing on areas of deep convection over the ITCZ and warm pool, all four simulations
712 overestimate CF with larger biases seen in the GF than the MSKF experiments, and larger biases seen in the variable-
713 resolution than the uniform-resolution experiments. All four simulations also overpredict CF along the west coast of
714 Central America while underpredicting CF over areas of stratiform clouds along the west coast of South America and
715 Baja Peninsula. The impact of CF biases is that all four experiments underestimate the size of the warm pool and
716 width of the ITCZ, leading the TOALW (TOASW) to be too high (low) over areas of deep convection. These
717 differences are clearly linked to the differences noted in the LWP and IWP between MPAS and SSF data.

718 **6 Discussion and future research**

719 Uniform- and variable-resolution experiments with two scale-aware parameterizations of deep and shallow convection
720 (GF and MSKF) in MPAS yield significant biases between simulated and satellite-derived monthly-mean precipitation
721 rates, LWP, IWP, and CF over the Tropical Pacific Ocean at horizontal resolutions of 30 km down to 6 km. Because
722 these biases affect cloud fraction and cloud optical properties, the four experiments present significant differences in
723 the TOALW and TOASW compared to CERES-SSF data for December 2015.

724 Precipitation simulated with the uniform-resolution experiments is overestimated compared to TMPA data. Biases
725 using GF are as large as those using MSKF, but part of the biases result because the simulated ITCZ is located south
726 of its observed location depicted as an area of maximum precipitation. Variable-resolution experiments do not yield
727 significant improvement in simulating precipitation. Inside the refined area, decreased convective precipitation plus
728 compensating increased grid-scale precipitation have the simulated total precipitation to exhibit similar biases between
729 our uniform- and variable-resolution experiments with both GF and MSKF. One major difference in using GF instead
730 of MSKF is the strong upscaling effect of the refined grid mesh on the coarse grid mesh, producing a strong increase
731 in convective precipitation east and west of the refined area of the mesh which did not exist in the MSKF. We plan to
732 further understand how the scale-aware formulation of deep convection in GF affect large-scale moist processes,
733 leading to increased triggering of convection over the coarse area of the mesh.

734 Differences in the simulated LWP between the uniform- and variable-resolution experiments using GF and MSKF
735 and against the CERES-SSF LWP highlight the need to revise the treatment of shallow convection in both convection
736 schemes and of its interactions with deep convection and cloud microphysics. While experiments using MSKF yield
737 the simulated LWP to be in reasonable agreement against that from the CERES-SSF product, those using GF yield
738 the simulated LWP to be strongly overestimated. Analyses show that the treatment of shallow convection in
739 conjunction with cloud microphysics processes explains most of the increased LWP in GFu and GFv compared to
740 MSKFu and MSKFv, and satellite-derived data. We propose to update our version of the GF shallow convection
741 scheme to that implemented in version 4.1 of the Advanced Research Weather Forecast (WRF) model. Because the

742 updated GF parameterization of shallow convection includes a revised cloud model that allows water vapor and cloud
743 liquid water to detrain separately and a fraction of the condensed water to precipitate, we propose to focus future
744 research on the impact of explicit detrainment of cloud liquid water and precipitation from shallow convective updrafts
745 on the simulated LWP in GF. Results show that MSKF underestimates shallow convection, leading the troposphere
746 below 700 hPa to be drier than actually observed. These results imply that the shallow convection parameterization in
747 MSKF needs to be updated or that a separate parameterization of shallow convection needs to be used in addition to
748 that in MSKF, which can be a part of our future study. The uniform- and variable-resolution experiments performed
749 here all overestimated the IWP compared to CERES-SSF data over the tropical Pacific region. This overprediction of
750 the IWP led to strong biases in the TOA long- and short-wave radiation budget compared to observations.

751 The scale-aware dependence of parameterized convection allows variable-resolution meshes spanning between
752 hydrostatic and nonhydrostatic scales to be used within a global framework. As horizontal resolution increases from
753 the coarse to refined area of the mesh, convection transitions from parameterized to resolved and grid-scale cloud
754 microphysics contribute a major part to moist processes over the refined grid mesh. Stronger grid-scale vertical
755 velocities associated with smaller grid-spacing over the refined area produce increased upward moisture flux and grid-
756 scale condensation, further increasing biases between the simulated and satellite-retrieved LWP, IWP, and clouds.
757 Our results show that mesh refinement over the Tropical Pacific Ocean does not systematically improve precipitation
758 and clouds, due to complicated interactions between convection, cloud microphysics, and radiation. As cloud
759 microphysics processes drive the moisture budget over the refined area of the mesh, we propose to expand this
760 diagnostic study to a process study by further understanding the cloud microphysics tendencies that need to be
761 improved with the aim to reduce discrepancies between model and observations. In that vein, the recently developed
762 MSKF that includes a double moment microphysics (Glofkel et al., 2019) would be useful in a future process study.

763
764

765 *Code and data availability:* The source code used to initialize and run our experiments is based on MPAS-v5.2 which
766 is freely available from <https://github.com/MPAS-Dev/MPAS-Model/releases/tag/v5.2>. Modifications to the original
767 source code and scripts to run the experiments are available from <https://doi.org/10.5281/zenodo.3515440> (Fowler,
768 2019) while initialization files, and outputs from the experiments are located on the NCAR Campaign Storage System.
769 These files can be made available by contacting the corresponding author. Examples of CERES SSF Aqua and Terra
770 orbital and gridded data, daily-mean and monthly-mean simulated diagnostics, and post-processing scripts are also
771 available from <https://doi.org/10.5281/zenodo.3515440> (Fowler, 2019).

772
773

774 *Author contributions:* LF developed all the modifications that were made to the MPAS-v5.2 released version and were
775 necessary to run the different experiments. KA made all the updates to the MultiScale Kain-Fritsch parameterization
776 of convection. LF and MB designed the experiments, and LF conducted and analyzed the simulations. LF prepared
777 the manuscript with contributions from all co-authors.
