

To Reviewer #1 [Dr. Jerry Tjiputra]

First, we greatly appreciate that you agreed to review our paper, and we thank you for your careful reading, positive comments, and many helpful suggestions. Following consideration of your insightful remarks, together with those of the other referee, we have revised our manuscript accordingly. Please find below (in bold) our detailed responses to your specific comments.

General comments

The manuscript by Hajima et al., describes the update in MIROC-ES2L (CMIP6) ESM relative to previous MIROC (CMIP5) ESMs, with emphasis on the land and ocean biogeochemistry components. In addition to the standard piControl and transient Historical simulations, the authors also performed additional sensitivity simulations with the updated model to analyze the impact of new parameterizations and new model improvements on the simulated biogeochemical metrics such as the land carbon content, ocean primary production, nutrient limitations, etc. They also use a set of C4MIP 1%CO₂ simulations to quantify the simulated carbon fluxes sensitivity to climate change and atmospheric CO₂ increase, and compare these quantities with that from previous MIROC ESM and other CMIP5 ESMs.

The paper is well structured and nicely written, providing a good overview of the new model with key information that would be of interest for GMD readers who need reference to the carbon cycle components in MIROC-ES2L model. Below I have listed several suggestions and comments that the author can consider to further improve the manuscript prior to publication in GMD. I also disclose that I am not an expert in land carbon cycle and therefore can only offer limited reviews on the land biogeochemical part of the paper. It would therefore be good to have additional referee(s) who can offer better perspectives on the land discussions of the paper.

Thank you for your positive comments regarding this research. The other reviewer of our paper is expert in the field of land biogeochemistry, and thus we believe the manuscript has been reviewed by peers with expertise in both the land and the ocean elements of the subject area.

The structure of the revised manuscript has been changed slightly from that of the first draft in accordance with the comments from Reviewer #2. In the first draft, the results on the physical climate were split into two subsections (i.e., “3.1.1. Global climate: net radiation balance and global temperature” and “3.1.4. Climate: atmosphere and ocean physical fields”), whereas these two subsections have been merged into a single unit (“3.1.1. Global climate: atmosphere and ocean physical fields”) in the revised version.

Specific comments

The title gives away an impression that the paper fully describes the MIROC-ES2L model. While it does briefly, most of the content is focused on the land and carbon cycle description and assessments of the performed (biogeochemical-focused sensitivity) simulations. I therefore suggest modifying the title to something like “Description and sensitivity analysis of the carbon cycle components of MIROC- ES2L Earth system model.”

Thank you for your suggestion regarding the article title. Yes, we agree that the sensitivity analysis and model evaluation performed in this study focused mainly on biogeochemical processes (and the feedbacks on climate via CO₂ exchange). To reflect this fully, we have therefore changed the title to “*Development of the MIROC-ES2L Earth system model and the evaluation of biogeochemical processes and feedbacks*”.

The performed sensitivity experiments are very useful to characterize the model’s response to (some are newly implemented) external forcing and future climate change. Many of the simulated changes in the key metrics, such as the ocean primary production and export production were quantified and discussed (e.g., Page 35). In addition to this useful discussion, I recommend the authors to expand (add additional columns) Tables 3 and 4 to include the same metrics but from the relevant sensitivity experiments

We thank you for this good idea to expand the tables to include other simulation results and we agree it would be informative for the readers. To keep the manuscript as concise as possible, we have included the results of the other nine experiments in Supplementary Tables 1 and 2.

Additionally, we found an inconsistency between land (Table 3) and ocean (Table 4) with regard to the averaging period for the CTL experiment. In the revised manuscript, this inconsistency has been resolved and thus the numbers for land in Table 3 have been updated. These minor modifications have not changed the fundamental conclusions of this study.

Some information on how stable (or any drift, if exist) the ocean biogeochemistry budgets in the preindustrial control run would be useful. Also, one of the uniqueness of the MIROC-ES2L among other CMIP6 models is the fact that it has a very long model spin up (i.e., >3500 years; albeit some are offline), which is thought to be crucial to reduce model bias (e.g., in the interior ocean biogeochemical tracers such as oxygen; Seferian et al., 2015; GMD). I think it would be of interest

to many readers to know whether in fact interior biases is improved through this computationally costly process.

We agree that information on bias would be useful to the readers. Following your suggestion, we have mentioned model bias in the main text (as below) and added a table in the Supplementary Material.

“Owing to the long spin-up, the drift in global averaged concentrations of biogeochemical tracers becomes close to zero. The linear drift of dissolved oxygen, NO₃, and Alk-DIC over the final 250 years of the spin-up is less than 3% kyr⁻¹ (Supplementary Table 3). This small bias is significant in providing results on ocean biogeochemistry and carbon cycle feedbacks that are quantitatively more correct (S  ferian et al., 2016).”

On Page 7, the authors wrote “a static biome distribution”. Please briefly clarify what you meant by this? Do the prescribed PFTs change annually or or static in the sense that it is constant from preindustrial states?

We meant the distribution of PFTs is fixed (constant) throughout the simulations because the terrestrial model is not a dynamic vegetation model. We have reworded this passage in the main text as follows:

“...the biogeochemical processes are simulated under a fixed biome distribution (Supplementary Fig. 2)...”

The Figures’ resolutions and qualities need some improvements. Namely, Fig. 2,3,4,10,12: x-labels and y-labels are difficult read in my printouts. Legends in Fig. 10 are also too small to read.

We apologize for this inconvenience. In the revised manuscript, we have increased the font size used in the figures mentioned.

On Page 17, there is a statement that the model might overestimate net carbon uptake by land and/or ocean, or underestimate LUC emissions. This was implied through comparing the diagnosed atmospheric CO₂ concentration with the observed values. I found this strange. Since the simulation was performed with prescribed CO₂ concentrations, the authors should instead compute the diagnosed anthropogenic emissions, and compared that with the observations (as in Jones et al. 2013), e.g., 403PgC. Based on this diagnosed emissions, the authors can then make a statement whether or not the land and/or ocean sinks are under/overestimated. Furthermore, if the authors have completed the prognostic CO₂ simulations, it would be interesting to compare the diagnosed atmospheric CO₂ concentrations and determine if the analysis on land/ocean carbon uptake strengths is consistent with the above approach.

Yes, we agree the comparison of anthropogenic (fossil fuel) emission, as in Jones et al. (2012) would be straightforward and informative for the readers. Following your suggestion, we have also compared the diagnosed fossil fuel emission with the GCP estimation in the revised manuscript.

We also agree it would be a good idea to mention the prognostic CO₂ concentration in the emission-driven historical run. As we had finished the emission-driven runs (esm-historical) during the reviewing process, we have mentioned the prognostic CO₂ concentration in the revised manuscript as follows:

“However, the model might overestimate net carbon uptake by the land and/or ocean or underestimate LUC emissions. This is because the cumulative fossil fuel emission, diagnosed from the simulated atmosphere–land/ocean CO₂ fluxes and prescribed CO₂ concentration change ($FF = CA + CL + CO$; Appendix D), was 447 PgC, i.e., larger than the estimate of 400 ± 20 PgC of Le Quéré et al. (2018). Additionally, this speculation is also supported by the diagnosed CO₂ concentration at the end of the HIST run (Appendix D); the diagnosed concentration is 376 ppmv, which is lower (by 22 ppmv) than that actually monitored. We note, however, the likely biases in land/ocean carbon uptake, suggested by the larger diagnosed emission/lower diagnosed CO₂ concentration, could be alleviated partially if the model were driven by anthropogenic CO₂ emissions. This is because in emission-driven mode, the relatively stronger land/ocean carbon uptake leads to lower atmospheric CO₂ concentration, which could weaken the land and ocean sink through negative CO₂–carbon feedback. Indeed, in emission-driven mode, the atmospheric CO₂ concentration in the historical run (“esm-historical”, Jones et al., 2016) is simulated to be 384 ppmv in 2014 (as an average of three ensemble experiments; data not shown but available via the Earth System Grid Federation servers), which is closer to the actual level monitored (but still lower by 14 ppmv).”

Ocean carbon uptakes. While there’s discussion on the cumulative carbon sinks over the historical period, there was no discussion on the simulated contemporary CO₂ sinks, i.e., annual mean and spatial distributions (only stated in in Table 4). Given the importance of carbon sinks and its application in ESM simulations, I recommend adding some air-sea CO₂ flux comparison between the model with e.g., spatial patterns from Landschutzer et al., 2014-<https://doi.org/10.1002/2014GB004853>; or Takahashi et al., 2009-<https://doi.org/10.1016/j.dsr2.2008.12.009>), and this discussion can be linked to the currently still limited surface DIC/alkalinity discussions, as shown in Fig. 11.

In addition to the contemporary spatial air-sea CO₂ flux patterns, several studies have shown the importance of simulating proper regional seasonal cycle for constraining long-term spread in ESM projections (Kessler and Tjiputra, 2016-ESD; Goris et al., 2018-J. Climate). If the authors agree, it would be great to see how the regional CO₂ fluxes in key world ocean regions (North Atlantic, Southern Ocean, etc.) are simulated in MIROC-ES2L and compare that with results from the previous model version.

We thank you for your useful suggestion. Accordingly, we have added a comparison between the spatial distribution of observed air–sea CO₂ flux and that simulated by MIROC-ES2L to the revised manuscript (Fig. 12a). We have also included comparison of the regional seasonal cycle of CO₂ fluxes between the model and observations (Fig. 12b and 12c).

Similarly for land, if seasonal cycle is an important criteria for constraining future projections (I am not fully aware of such studies on the terrestrial carbon side), then such presentation could be considered as well, e.g., similar to that shown in Tjiputra et al. (2013 - GMD) for GPP across different latitudinal bands.

This is an important suggestion and just such a multimodel comparison study on contemporary land GPP has been reported by Anav et al. (2015), although the relationship between the seasonal cycle and the long-term trend of global GPP remains unclear. Thus, following your suggestion, we have analyzed GPP seasonality and a relevant figure is included in the Supplementary Material. We have mentioned it in the revised manuscript as follows:

“The simulated GPP seasonality is also compared with that of Jung et al. (2011) (Supplementary Fig. 9). It reveals a reasonable summertime peak and the seasonality of GPP in the extratropical Northern/Southern Hemisphere, where vegetation phenology is controlled primarily by air temperature. However, the region around 40°N displays a longer growing season than that of Jung et al. (2011), and the tropics (20°S–20°N) show less seasonality, suggesting room for improvement of the phenology-related processes and surface climate fields in the corresponding region/biome types.”

In Section 3.1.4, MLD bias (too deep) is described as the partial reason for the SST cold bias. One could argue the other way around. On the other hand, in the Southern Ocean, there is a general warm bias, yet the MLD in the model also appears to be too deep. This should be elaborated. In this regard, I would also suggest adding Southern Hemisphere sea ice extent to Fig. 8.

Thank you for this important suggestion. We agree that we cannot conclude that only deep MLD bias causes the SST cold bias, and careful discussion should address the SST bias. In particular, we think the mechanisms responsible for producing the SST biases are potentially different between the Southern Ocean and western North Pacific Ocean. To clarify the possible mechanisms, we have revised the manuscript (Section 3.1.4) as follows:

(1) We have added a figure showing the sea ice extent in the Southern Hemisphere (Fig. 6), in accordance with your suggestion.

(2) The mechanism that possibly produces the warm (T2) bias in the Southern Ocean is discussed more carefully as follows:

“The warm bias in the Southern Ocean can be attributed mainly to poor representation of cloud radiative processes (Bodas-Salcedo et al., 2012; Williams et al., 2013; Hyder et al., 2018), but also to poor representations of the mixed-layer depth and deep convection in the open ocean attributable to the lack of modeled mesoscale processes in the Antarctic Circumpolar Current (Tatebe et al., 2019). A related warm bias in SST over the Southern Ocean is also confirmed, which is discussed later.”

(3) The mechanism that possibly produces the cold SST bias in the western North Pacific Ocean is also mentioned in the revised manuscript as follows:

“A cold bias is also evident over the western North Pacific Ocean, which is attributable to the lack of narrow and swift western boundary currents owing to the coarse horizontal resolution in the ocean parts of the present ESM.”

Figure 15 shows that in many regions, there are two (instead of one) nutrients limit the primary production. It is not clear to me how the authors arrive with two limiting nutrients. Shouldn't it be only one, which is the minimum of the three? Some clarification on how it is derived would be useful.

As you correctly commented, the estimation of the limiting (two) nutrients was not clear in the original manuscript. We have clarified it in the main part of the revised text as follows:

“Here, NO_3 , Fe, and PO_4 limitation is diagnosed using the equations $NO_3/(kN + NO_3)$, $Fe/(kFe + Fe)$, and $PO_4/(kP + PO_4)$, respectively, as simulated in MIROC-ES2L (see Equation (B17)); Fig.16 presents the strength of each limitation visualized by the intensity of each of the three primary colors (red, blue, and green).”

Figure 17 and Table 5 essentially show the same information and appear redundant. I suggest removing Fig. 17 and keep the table.

Following your suggestion, Fig. 17 (the figure for TCR, AF, and TCRE) has been removed from the revised manuscript and Table 5 has been retained.

Technical corrections

In addition to the above comments, please find below a list of minor comments that needs to be clarified as well as edits to improve the manuscript readability.

We appreciate your careful reading of our manuscript and the listing of identified technical corrections.

L25: Comparison ... the model could reproduce well the transient global climate change and carbon cycle as well as reproduce the observed large-scale spatial patterns of land carbon cycle and upper ocean biogeochemistry.

We have changed the manuscript accordingly.

L29: ... revealed that the simulated ocean biogeochemistry could be altered regionally (and substantially) by ...

We have changed the manuscript accordingly.

L35: Suggest removing “model performance in”

We have removed the corresponding words.

L36-7: The MIROC-ES2L could further improve our understanding of climate ...

We have changed the manuscript following your suggestion.

L48: future climate due to processes ...

Corrected.

L52: semicolon between Watanabe and Collins references.

Corrected.

L55-6: As ESMs explicitly simulate ..., they can simulate the temporal ...

Corrected.

L60: Furthermore, their simulations can be ...

Corrected.

L66: ... on climate manifests through ... OR ... on climate is manifested through ...

Corrected to "...climate is manifested through..."

L69: ... ocean, and eventually ...

Reworded as follows:

"...and the absorbed CO₂ is transported into the deeper ocean..."

L77: transport instead of transportation

Corrected.

L100: you can also cite Kessler and Tjiputra (2016; <https://doi.org/10.5194/esd-7-295-2016>)

Thank you for suggesting we include this useful reference; the work has been cited in the revised manuscript.

L111: remove 'nutrient'

Corrected.

L117: as well as the physical response

Corrected.

L162: with existing studies.

Corrected.

L170: used in the CMIP5

Corrected.

L182: ... ocean physical model ... land physical model ...

Corrected.

L183: river routing (?)

Replaced with “river submodel”.

L201: what is the ocean horizontal resolution?

In the revised manuscript, we have specified the ocean horizontal resolution as follows:

“...that is divided horizontally into 360 × 256 grids. (To the south of 63°N, the longitudinal grid spacing is 1° and the meridional spacing becomes fine near the Equator. In the central Arctic Ocean, the grid spacing is finer than 1° because of the tripolar system.)”

L236: prescribed in the forcing data

Corrected.

L236-7: The fluxes of nitrogen out of the land ecosystem are simulated through N₂ and N₂O production during nitrification ...

Corrected.

L277: is transported by rivers

Corrected.

L281: erosion and dissolution of organic carbon in the ocean, these processes are not activated to close the global mass conservation of carbon and nitrogen.

Corrected.

L283: replace ‘simply diagnosed’ with ‘only for diagnostic purpose’

Replaced as suggested, albeit as “...only for diagnostic purposes...”

L290: ... are simulated with 13 biogeochemical tracers.

Replaced by the suggested words.

L294: .. the Redfield ratio of C:N:P:O= ...

Corrected.

L295: remove ‘types of’

Corrected.

L298: The nitrogen cycle in OECO2 is similar ..

Corrected.

L301: denitrification is also ...

Corrected.

L330: assumed to be

Corrected.

L334: remove 'oxygen' (it is not remineralized, it is consumed)

Removed.

L347: this is only true when the model simulations is configured to be fully interactive, right? i.e., prognostic (not prescribed) atmospheric CO₂.

Yes, you are correct. The sentence has been modified in the revised manuscript:

"...this is the only pathway via which ocean biogeochemistry affects climate if the model is driven by prescribed CO₂ concentration."

L376: carbon cycle variation relative to the preindustrial control (CTL). climate-carbon feedback (Arora et al. 2013; Schwinger et al., 2014-<https://doi.org/10.1175/JCLI-D-13-00452.1>)

The two references are now cited in the corresponding section of text.

L386: these experiments

Corrected.

L387: I don't understand 'which would be noise in the analysis'. Maybe clarify or remove it.

To avoid confusion, this text has been removed.

Table 1 caption: Summary of experimental details.

Corrected.

Table 1, row NO-NRD: replace combination with combining; replace ' doesn't get impact from' with ' is not impacted by'

Corrected.

Table 1, row NO-FD: replace ' doesn't get impact from de' with ' is not impacted by Fe'

Corrected.

L414: replace status with states

Corrected.

L415: ... is calculated independently of ocean biogeochemical states.

Corrected.

L427: The first term on the right

Corrected.

L432: replace 'which is because' with 'since'

Corrected.

L437: second term

Corrected.

L438: This sentence is a bit confusing. TCRE quantifies only the global temperature change in response to emissions, and not the 'entire climate-carbon cycle response', right?

Yes, your understanding is correct. For clarity, we have reworded the sentence as follows:

"As shown in Matthews et al. (2009), AF summarizes the carbon cycle response to anthropogenic CE; the second term in Eq. 5 (TCR/CA) captures the global temperature response to CO₂ increase in the models; and TCRE thus summarizes the two, i.e., the global temperature response to anthropogenic CO₂ emission in the model."

L441: ... response to atmospheric CO₂ increase ...

Corrected.

Eqs (8) and (9) are wrong.

Thank you for drawing our attention to this error; the equations have been corrected by replacing CA with T.

L456: ... (TOA), and anomalies of new-surface ...

Corrected.

Corrected.

L606: Shouldn't 4.5 be 4.2? (Table 3: 13.7-9.5)

The incorrect number has been replaced with 4.3 TgN yr⁻¹.

L615: ... shows a net ...

Because of the rewording applied in response to the following point, these words have been removed.

L616: "... stimulates ecosystem nitrogen demand." Is this implied from the increasing atmospheric N₂ fixation in the model?

This is implied from the net increase of land N uptake in 1PPY-BGC.

In 1PPY-BGC, N inputs (deposition, fertilizer, and BNF) are almost unchanged from the CTL; thus, atmospheric CO₂ increase is the main driver of change in land N cycles. However, the 1PPY-BGC run indicated land N uptake, suggesting that atmospheric CO₂ increase alters the C:N ratio in land organic materials and that a higher C:N ratio in the organic materials promotes N uptake. We have clarified this in the revised manuscript as follows:

"In addition to the increasing N input, the net positive N uptake by land is likely accelerated by the increased nitrogen demand by plants and soils that have higher C:N ratios under elevated CO₂ concentrations. This is because the net increase of land N uptake is also found in 1PPY-BGC (Supplementary Table 1), even though the N inputs such as BNF, fertilizer, deposition, and climate condition in the 1PPY-BGC simulation are almost unchanged from the CTL run. It suggests atmospheric CO₂

increase in HIST has changed the C:N ratios in plants and soil and hence stimulated ecosystem nitrogen demand.”

L623: suggests that the historical ...

Corrected.

Fig. 4 caption: Rate of change of global nitrogen budget in (a) land and in (b) ocean ...

Corrected.

L660: ... attributed to the model bias in simulating cloud cover

The corresponding sentence has been changed as follows to clarify the mechanism that produces the warm bias:

“The warm bias in the Southern Ocean can be attributed mainly to poor representation of cloud radiative processes (Bodas-Salcedo et al., 2012; Williams et al., 2013; Hyder et al., 2018)...”

Fig 6: Why not show the difference between HIST and GPCP as Figs. 5 and 7?

Following your suggestion, the map of GPCP precipitation has been replaced with a map of the bias (HIST – GPCP). The map of raw GPCP precipitation has been moved to the Supplementary Material because it remains useful regarding the discussion of the problems in land biogeochemistry.

L684-5: suggest revising it to something like:

When projecting future climate change, it is important for an ESM to reproduce the observed climatological patterns of key physical and biogeochemical tracers (Ohgaito

Following your suggestion, we have included this text with some modifications:

“When projecting future climate change, it is important for a model to reproduce the observed climatological patterns of key physical variables, as suggested in Ohgaito and Abe-Ouchi 2009. The biogeochemical tracers are also affected by the representation of the physical fields.”

L701: cover. Sea ice ...

Corrected.

L701: ... summertime minimum concentration is slightly ...

Corrected.

L718: Briefly describe how the MLD is computed in the model.

We have clarified this in Section 3.1.1 as follows:

“The mixed-layer depth is defined as the depth where the potential density becomes larger than that of the sea surface by 0.125 kg m^{-3} .”

L738: replace higher with high

Corrected.

L740: is generally still underestimated

Corrected.

L749: Suggest replacing the reference Anav et al. with Jung et al., 2011.

Replaced as suggested.

L756: vegetation carbon content including ...

Corrected (we supposed you intended L758).

L761: define NCSCDv2

The abbreviation has now been expanded.

L780: replace panels with rows

Corrected.

L784: add units to the bottom row figures, presumably (g C m^{-2})

The unit for SOC has now been specified in the caption.

L797: replace nitrate with nutrient

Corrected.

L799: consistent with the observed

Corrected.

L800: because of the implementation

The relevant sentence was changed as follows:

“This increase of macronutrients in HNLC regions is reasonable because the

implementation of the iron cycle and the iron limitation on phytoplankton growth can reduce macronutrient utilization in these regions.”

L801: Ocean circulation also ...

Corrected.

L803: ... over estimation of nutrients entrainment to the surface and thus ...

Corrected.

L804: The simulated global mean vertical profile of nitrate concentration ...

Corrected.

L804-6: I am not convince this is the main or only reason of the well fitted model nitrate with observations. Model can simulate correct sources and sinks but still compare poorly with observations if the circulation fields is correct. There are several ways to get analyze whether the circulation fields is reasonable or not, e.g., using apparent oxygen utilization tracer. Nevertheless, you can get correct distribution for the wrong reason (Duteil et al., 2012 - Biogeosciences)

We agree with your suggestion. We have mentioned the significance of the ocean circulation with regard to the simulated tracer distributions in the revised manuscript (as below) and we have added a model–data comparison of the AOU in Supplementary Fig. 10.

“To check the influence of ocean circulation on the tracer distributions, we compared the AOU between the model and observations (Supplementary Fig. 10). Although the model captures the observed AOU distributions, the strong and deep AMOC causes underestimation of AOU values in the Atlantic Ocean deep water. The largest bias is underestimation in the North Pacific Ocean, which is caused by the strong Pacific Ocean deep circulation. It should be noted that the difficulty of simulating the Pacific Ocean deep circulation appears to be a general problem in present coarse-resolution models (Hasumi et al., 2010).”

L825: ... the equatorial Pacific Ocean, and the Southern Ocean ... L826: ... the equatorial Pacific ... than the observed ...

Corrected.

L828: ... much of the low-latitude surface ocean ...

Corrected.

L846: ... (Fig. 9), which also transports ...

Corrected.

L848: replace parameters with tracers

Replaced as suggested.

L847-50: You mention alkalinity bias leads to DIC bias. Can you elaborate what cause the alkalinity bias in the first place?

We have added the reason for the alkalinity bias to the revised manuscript in accordance with your comment:

“Salinity bias as well as parameterization of calcium carbonate production in the model can contribute to the alkalinity bias.”

L882: replace Northwest with ‘path of north’

Corrected.

Corrected.

L995: remove ‘produce a resultant’

Corrected.

L1002: .. the model is capable ...

Corrected.

Fig. 16b shows that for the Neva, Yukon, and Churchill rivers, the DIN flux is larger in HIST-NOLUC than in HIST. This is in contrast to other rivers. Can the authors clarify the mechanism behind these patterns?

One of the possible reasons for the larger DIN in HIST-NOLUC than in HIST is the difference in leaf area index (LAI). In HIST-NOLUC, land use maintains the preindustrial condition, while in the HIST simulation LAI is affected by forcing

associate with land use change (LUC). Consequently, LAI in the HIST-NOLUC experiment should be different from that of HIST (the left-hand panel in the figure below), producing a slightly different spatial pattern of temperature (the right-hand panel). In particular, we can confirm the temperature anomaly in each of the three river basins is positive, which suggests the decomposition rate of soil organic matter is likely accelerated in HIST-NOLUC compared with HIST. This could lead to more inorganic soil N and allow the rivers to transport more DIN to the coastal region. Given that the three river basins are affected little by agriculture (e.g., see Fig. 13), the difference in DIN between HIST-NOLUC and HIST is likely attributable to the indirect LUC impact via temperature change. In addition, the averaging period for the analysis might affect the result, particularly for a region with little LUC.

Although this is an interesting point to analyze in detail, we believe this issue is beyond the scope of this paper. Thus, rather than specifically explaining the possible mechanism, we briefly acknowledge it in the revised manuscript:

“We note that the DIN discharge in each river is not always smaller in HIST-NOLUC than in HIST. This is because LAI in HIST-NOLUC is different to that in HIST, which sometimes is accompanied by slight change in the surface climate via biophysical feedback. If soil temperature is slightly warmer in HIST-NOLUC than in HIST, the soil mineralization rate in HIST-NOLUC should be accelerated and thus the DIN loadings of rivers could be increased.”

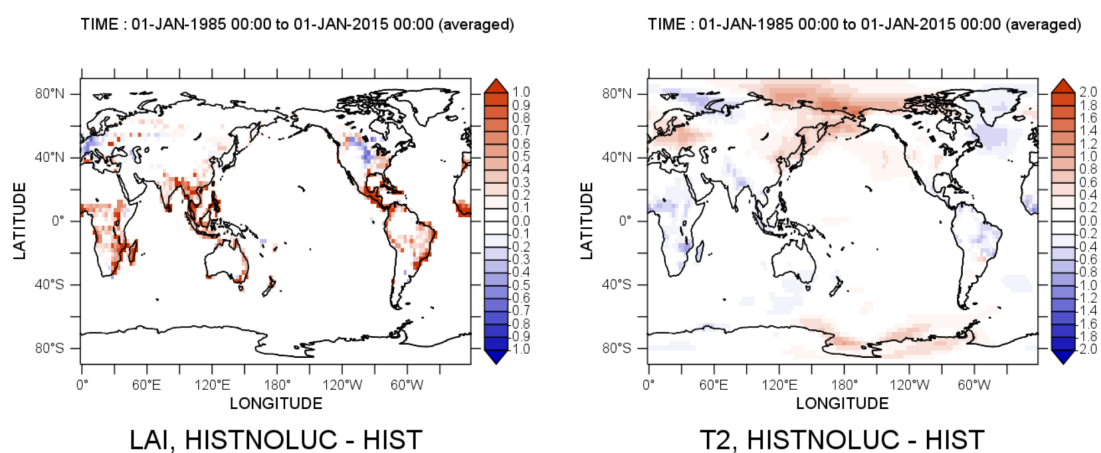

Figure for Reviewer: the difference in leaf area index (left) and air temperature (right) between HIST-NOLUC and HIST (HIST-NOLUC – HIST). Averages over 30 years (1985–2014) in each experiment were used for the calculation.

L1126: Actually, there is no comparison of global biogeochemical (nitrate, phosphate, oxygen, etc.) budget trends, except for carbon. Suggest revising it to: ... capture the observations-based estimates of contemporary air-sea and air-land carbon fluxes.

Thank you for your suggestion. We have changed the sentence as you recommended. In addition, as we also discuss the global nitrogen budget (section 3.1.3), we have also mentioned this in the revised manuscript:

“It was confirmed that the model could successfully capture the observation-based estimates of contemporary air–sea and air–land carbon fluxes in terms of cumulative values. We also confirmed that the component fluxes of global nitrogen between land, atmosphere, and ocean are reproduced reasonably by the model.”

L1127: ... assessed through comparison ...

Corrected.

L1228: the model produced reasonable ...

Corrected. (at L1128 in the first draft)

L1133: compared with those of the CMIP5 ESMs.

Corrected.

L1138: ... This is reduced from the value seen in the model ...

Corrected.

L1141-4: Suggest rephrasing the sentence to: A multimodal comparison on feedback strengths using CMIP6 ESMs is necessary to potentially determine whether the climate and carbon cycle sensitivities in MIROC-ES2L are realistic, and furthermore to establish constraints on each feedback process based on observations (e.g., Wenzel et al., 2016; Goris et al., 2018 - J. Climate).

Thank you for this useful suggestion. We have rephrased the sentence and added the reference to the work of Goris et al. (2018) in the revised version.

L1148: model alters the land carbon cycle. ... carbon content during 1850-2014 is 44

Corrected, as you suggested.

L1154: nitrogen cycle alters the carbon cycle ... did not quantify to what extent the soil nutrient

Corrected.

L1159: remove ‘inputs’. ‘external sources’ already implies ‘inputs’

Corrected.

L1164: replace GPP with primary production. You have used NPP in section 3.1.6 and 3.2.2.

Generally, in ESMs, we refer it to simply ‘primary production’

This correction has been made, i.e., it has been replaced with “primary production.”

L1173: ... should also be ...

Corrected.

L1177: here you said strongly impact, but on L1160, you states minor contributions. Please clarify.

We meant to emphasize that river input is minor on the global scale (L1160 in the previous manuscript), but significant on the regional scale (L1177 in the previous manuscript). In the revised manuscript, this has been clarified as follows:

“Our sensitivity analyses under the preindustrial condition suggested minor contributions of these two external sources to primary productivity on the global scale” and

“This conclusion is supported by the sensitivity analysis that showed relatively strong regional-scale impact of riverine nitrogen on marine primary productivity, although the global-scale impact was demonstrated to be minor.”

L1179-80: ... radiative balance in the atmosphere. Nitrous gases with a long

Corrected.

L1191: ... a similar set of sensitivity simulations should be ...

Corrected.

L1192: remove ‘with which’

Corrected.

L1193: replace explorations with quantifications

Corrected.

L1196-7: ... ESMs can reproduce some of the dominant long-term environmental changes on Earth ...

Corrected.

L1198: ocean acidification ...

Corrected.

L1201: replace evolve with improve

Corrected.

L1447-9: Shouldn't GCaCO_3 be PrCaCO_3 instead (based on Table B2)?

The S terms in Eqs. (B12)–(B14) represent the “source minus sink” and thus the Eqs. (B12)–(B14) are correct as presented.

L1467: see eq. (14) of

Corrected.

L1498: (CE^{D}) should be (CE^{P})

Corrected.

L1596: ... Cycles, 26, GB2009, doi ...

Corrected.

L2022-4: this citation needs to be updated.

This reference has been updated in the revised text.

Supp Fig 3: If I understood correctly, the ‘N₂ fixation’ box should be labeled ‘Diazotroph’.

There should also be arrows from PHY and ZOO to CaCO_3 ?

Arrows from PHY to nutrients should only be labeled (Fast) remineralization, and the arrows from PHY to “DNO₃, DFe, (and DPO₄)” should then be labelled ‘mortality’

What is the purpose of the green label ‘Definition of Alkalinity’? I suggest removing it. Should the ‘Nitrification’ arrow be reversed?

Your suggested points are correct. In the new figure:

- **“N₂ fixation” has been replaced by “Diazotroph”**
- **Arrows from PHY/ZOO to CaCO_3 have been added**
- **The label from PHY to detritus has been changed to “mortality” only**
- **The label “Definition of Alkalinity” has been removed**
- **The “Nitrification” arrow has been removed**

Finally, if any of my comments are unclear, please feel free to contact me.

Thank you very much again for your careful reading and many suggestions. All your suggestions and comments were very helpful to us in improving our manuscript. We believe we have fully reflected all of your comments properly in the revised manuscript.

To Reviewer #2

This article presents the CMIP6 version of the MIROC Earth system model. I appreciate this work, because a detailed description and evaluation of the CMIP6 models helps to interpret their results and raises the scientific value of this major community effort. The article is written clearly and is quite extended (73 pages), but I guess that just a complete description of the complex model would require several hundred pages. Therefore, the authors concentrate on those aspects in the biogeochemical part of the model that are new in comparison to the CMIP5 version of the model. I completely agree with this approach

First, we greatly appreciate that you agreed to review our paper and we thank you for your positive comments on this work. Following consideration of your comments, together with those of the other referee, which we found very helpful, we have revised the manuscript accordingly. Please find below (in bold) our detailed responses to your specific comments.

it should be followed more consequently. I suggest two steps in this direction. First, the results of the physical model should be evaluated at one place (i.e. merge subsections 3.1.1 and 3.1.4). This can go along with a comment that these results are presented first as a basis for the assessment of the biogeochemical results and the climate-carbon cycle feedbacks. Second, I see some potential to shorten the subsection 3.1.4, e.g. fig. 7 (SST) can be skipped as fig. 5 (2m temperature) is very similar. Also the title may be adapted towards the biogeochemical focus.

Thank you for this observation on the structure of the paper. Following your suggestion, subsections 3.1.1 and 3.1.4 have been merged into one, titled “Global climate: atmosphere and ocean physical fields”.

As you pointed out, we agree that the two maps (2 m temperature and SST) look similar in some part. However, the detailed discussion on ocean biogeochemical fields relies on the SST map, as discussed between Reviewer #1 and the authors. We believe its inclusion would be informative for the readers and thus we have decided to retain the SST figure in the revised manuscript.

Scientific questions

- section 3.1.1: For a more complete view on the simulated climate, please specify the strength of the AMOC and the amplitude of ENSO as these two features of the physical system also affect the simulated carbon cycle quite profoundly. Just mention the numbers.

Following your suggestion, we briefly mentioned the amplitude of both AMOC and

ENSO in the revised manuscript without any additional figures as follows:

“In addition to the radiation/temperature responses against historical external forcing, we briefly describe here the El Niño–Southern Oscillation (ENSO) and Atlantic meridional overturning circulation (AMOC) strength in MIROC-ES2L, both of which can affect interannual–multidecadal carbon cycle processes (Zickfeld et al., 2008; Pérez et al., 2013; Friedlingstein 2015). In HIST experiment, the standard deviation of monthly SST anomaly in the Niño-3 region (5°S–5°N; 90°–150°W) was 1.57 K in 1950–2009, which is larger than that of HadSST (0.94 K). This unrealistically large ENSO amplitude tends to influence the simulated interannual global temperature variability (Fig. 2b), which is suggestive of further effect on the interannual variability in biogeochemical fields (e.g., CO₂ flux in the tropics). The AMOC intensity, quantified by the North Atlantic Deep Water transport across 26.5°N, was approximately 13 Sv (1 Sv = 106 m³ s⁻¹) as the 1850–2014 average, which is smaller than the observational estimates of 17.2 Sv (McCarthy et al., 2015). In the HIST run, the AMOC strength was weakened at a rate of 0.01 Sv yr⁻¹ (i.e., reduction of 1.7 Sv during the 165 years of HIST), which seems slightly smaller than the recent estimates of AMOC weakening of 3 ± 1 Sv from the mid-twentieth century (Caesar et al., 2018).”

- line 527-530: Uncertainty in land carbon uptake (estimated from data) is smaller if calculated from the global carbon budgets (following $CL = CE - CA - CO$, s. line 435) than if it is calculated from the uncertainties in LUC emissions and the natural land sink. The uncertainty in CO is 20 PgC (s. line 550). The uncertainties in CE (derived directly from inventory data) and CA (derived from precise and representative measurements) are even smaller. Thus, the uncertainty in CL is much smaller than 90 PgC.

Thank you for the important suggestion regarding the range of uncertainty for CL. As you pointed out, if we calculate the possible CL range from the combination of CE (fossil fuel), CA, and CO, the CL range is changed to 15 ± 29 PgC, where the uncertainty range (±29 PgC) is much smaller than that of the bottom-up approach (i.e., the sum of the natural land sink + land use change, i.e., ±90 PgC). Thus, in the revised manuscript, we have mentioned both estimation ranges as follows:

“The possible range for CL can be changed if we estimate it as the residual of other global carbon budgets (i.e., $CL = FF - CA - CO$, where FF is the cumulative fossil fuel carbon emission). Using the estimated ranges of FF, CA, and CO reported by Le Quéré et al. (2018) (i.e., 400 ± 20, 235 ± 5, and 150 ± 20 PgC, respectively; the budget imbalance of 25 PgC is ignored here), the CL range is suggested to be 15 ± 29 PgC. In this case, the result of MIROC-ES2L (44 PgC) is still within the estimation boundaries

although it is at the upper end of the suggested range.”

- line 531-542: I'm not an expert in ocean biogeochemistry, but as far as I understand, a buildup of the ocean sediment reduces alkalinity in the ocean water, so that the ocean on the long term will outgas CO₂ to the atmosphere and ocean water + ocean sediment loses carbon after the sedimentation process has been switched on (and the loss in alkalinity is not compensated by riverine input). By contrast, in the manuscript it is mentioned, that the ocean carbon uptake in the control run is partly explained by the sediment extracting carbon from the ocean bottom.

Thank you for your inquiry regarding the effect of the sedimentation process on the carbon cycle. As you indicated, CaCO₃ burial reduces alkalinity, leading to ocean carbon release. However, organic matter burial decreases DIC, resulting in the ocean carbon uptake. In our model, the ocean absorbed CO₂ during the spin-up period because the latter process is dominant.

- line 766-769: I don't understand, why the different treatment of the vertical SOC profile in the model and WISE30sec explains the large difference in the amount of SOC in the boreal range. I think, that has to do with permafrost. It should be mentioned here, if the model includes freezing in the soil and how this affects SOC.

We apologize for this confusion. Yes, as you correctly pointed out, the direct reason for the difference between WISE30sec and the model is the frozen carbon within the permafrost region; it is considered in WISE30sec but not in the model. We have clarified this point in the revised text as follows:

“This is likely attributable to different treatment of frozen carbon in deeper soils in permafrost regions, i.e., WISE30sec covers the total SOC down to 2 m depth including frozen carbon, while the model does not consider the frozen carbon and instead simulates only upper SOC as litter form and lower SOC as humus.”

- section 3.2.2: The simulations NO-NR, NO-NRD, and NO-FD are only 100 years long. Do you've analyzed, if the signals that are based on these simulations and discussed in section 3.2.2 are already stable after 100 years? Or are they still very transient?

Thank you for your suggestion. In our model, NPP changes in response to the changes in nutrient input within several decades, consistent with Somes et al. (2016). We have added this information to the revised manuscript as follows.

“In the simulations, because changes in NPP and surface nutrient concentrations continued to change over several decades after the abrupt switching-off

manipulation, the average over the final 10 years is used for the following analysis. The rapid response of NPP to changes in nutrient input is consistent with that found in previous research (Somes et al., 2016)."

Minor corrections

- line 18: "article describes" instead of "study developed"

We have made this change as you suggest.

- line 176: Figure 1 is not helpful. Please specify for each model component whether it represents atmosphere, ocean, or land. You can also add for each model component the elements that are handled prognostically (C,N for VISIT-e, C,N,P,Fe,Ca,O for OECO-v2?, Fe,S for SPRINTARS?) and indicating by labeled arrows which elements are passed from each component to others (e.g. N,P from VISIT-e to OECO-v2). I think, this would result in a nice overview schematic, how the components are coupled concerning biogeochemistry.

Thank you for this very good suggestion. The schematic has been modified accordingly and we agree that the revised figure is much more powerful and more informative for the readers.

- line 201: Please indicate the horizontal resolution of the ocean model (e.g. average size of a grid box in km or the number of grid boxes of the global field).

This has been documented in the revised manuscript as follows:

"The horizontal coordination for the ocean is changed from the bipolar system employed in MIROC5 to a tripolar system in MIROC5.2 that is divided horizontally into 360 × 256 grids. (To the south of 63°N, the longitudinal grid spacing is 1° and the meridional spacing becomes fine near the Equator. In the central Arctic Ocean, the grid spacing is finer than 1° because of the tripolar system.)"

- line 210: What is a "snow-derived wetland"?

In the revised manuscript, this has been clarified as follows:

"...wetland formed temporarily in the snowmelt season is newly considered to reduce..."

- line 257: "of vegetation (each represented on a separate tile) in each land grid box" instead of "of tile in each land grid"

Thank you for suggesting this correction. We have changed it as follows in the revised manuscript:

“The model assumes five types of land cover (each represented on a separate tile) in each land grid box (i.e., primary vegetation, secondary vegetation, urban, cropland, and pasture)...”

- line 277: “transported by rivers” instead of “transported rivers”

Corrected.

- line 305: The phosphorous cycle has also no analog to denitrification.

Following your comment, we have rephrased it as follows:

“The structure of the phosphorus cycle is generally similar to that of nitrogen except in two respects: 1) the riverine input of phosphate is the only process that introduces phosphorus into the ocean, and 2) there is no process of outgassing from the ocean, unlike the denitrification process in the nitrogen cycle.”

- line 346: It would be nice to mention how the DMS affects the climate (I guess as sulfate aerosol in MATSIRO that affects radiation).

In response to your comment, we have added the following sentences at the end of this paragraph:

“This modification of the DMS emission scheme increases the sulfate aerosol amount, particularly over high-latitude oceans during winter and in regions where strong surface wind speed occurs. Solar irradiance of the surface decreases in such regions; however, this effect is not sufficiently significant to change the mean physical climate states.”

- line 364, 372, 373: I would not use the word “detect” in that way. Please substitute it by e.g. “except that the prescribed CO₂ increase affects only the carbon cycle processes”.

Corrected.

- line 403: last 4 lines of table 1, NO-NRD Configurations “N depositions” instead of “Fe depositions”, NO-FD Configurations “Fe depositions” instead of “de depositions”.

Corrected.

- line 438: “coupled” instead of “entire”

The corresponding sentence has been reworded following the comment from Reviewer #1.

- line 448,449: The denominator should be T. The common unit of Gamma is PgC/K (s. also table 6).

Thank you for identifying this error. The equation was originally presented incorrectly and in the revised manuscript, “CA^{1PPY}” has been replaced with “T^{1PPY-RAD}”.

-line 471: “deviations of the model results from HadCRUT4” instead of “discrepancies between the model result and HadCRUT4”

Corrected.

- line 555: “in the HIST run” instead of “at the end of the HIST run”

We are sorry but we cannot find the corresponding text in the first manuscript. We suppose you meant <“at the end of the HIST run” instead of “in the HIST run”>. Based on this idea, we have rephrased L555 as follows:

“...this speculation is also supported by the diagnosed CO₂ concentration at the end of the HIST run...”

- line 606: “4.2 TgN yr⁻¹” instead of “4.5 TgN yr⁻¹” - compare with line 11 of table 3

This has been replaced with the correct number (4.3 TgN yr⁻¹) in the revised manuscript.

- line 644: “decay of biomass in the LUC-product pools” instead of “decay of LUC-product pools”

Corrected.

- line 701: “concentration minimum” instead of “concentration peak”

Corrected.

- line 721: Please mention that the model (obviously) simulates no deep water formation in the Labrador Sea.

Thank you for your suggestion. The problem in relation to the Labrador Sea has been mentioned in the revised manuscript.

- line 738: “high” instead of “higher”

Corrected.

- line 755: “GPP in these regions is captured reasonably well by the model (Fig. 10a and

10b). Thus, the overestimation” instead of “Considering the GPP in these regions is captured reasonably well by the model (Fig. 10a and 10b), the overestimation”

Corrected.

- line 760: “products” instead of “product”

Corrected.

- line 784: unit of SOC is missing

The unit for SOC has been added (gC m⁻²).

- line 875: I see also some regions north of the equator, where GPP is reduced by climate change (e.g. South Asia). Please remove “of the Southern Hemisphere”.

Corrected.

- line 879-890: Please comment on the strong reduction of GPP by LUC in the tropics.

Following your comment, we have mentioned the GPP reduction in the tropics as follows:

“In the tropics, LUC reduces the non-crop GPP but weakly increases crop GPP, which results in net negative reduction of GPP as grid averages (Fig. 13j). Meanwhile, regions with intensive agriculture with nitrogen fertilizer input (e.g., Western Europe, East Asia, and parts of North America) show net positive change of GPP as grid averages, where increases in the crop contribution overcome reductions in the non-crop contribution (Fig. 13k and 12l).”

- line 917: I think, it would be good to mention that the NPP increase in the open ocean by N input from rivers mainly occurs in the Atlantic.

We agree with your comment. Significant NPP increase due to riverine N input in the Atlantic has been mentioned in the revised manuscript.

- line 973: “CO₂-induced ocean acidification and warming-induced deoxygenation” instead of “warming-induced ocean acidification and deoxygenation”

The suggested change has been made.

- line 1002,1003: This sentence is better placed at the end of the para-graph.

The suggested change has been made.

- line 1022,1023: This sentence is just repetition. You can remove it to shorten the article.

The sentence has been removed from the revised manuscript.

- line 1026: “climate, carbon cycle, and coupled climate-carbon cycle system” instead of “climate, carbon cycle, and climate-carbon cycle system”

The suggested change has been made.

- line 1130: “confirmed to be captured well” instead of “confirmed captured well”

The suggested change has been made.

Development of the MIROC-ES2L Earth system model and the evaluation of biogeochemical processes and feedbacks

Abstract

This article describes a new Earth system model (ESM), the Model for Interdisciplinary Research on Climate, Earth System version2 for Long-term simulations (MIROC-ES2L), using a state-of-the-art climate model as the physical core. This model embeds a terrestrial biogeochemical component with explicit carbon–nitrogen interaction to account for soil nutrient control on plant growth and the land carbon sink. The model’s ocean biogeochemical component is largely updated to simulate biogeochemical cycles of carbon, nitrogen, phosphorus, iron, and oxygen such that oceanic primary productivity can be controlled by multiple nutrient limitations. The ocean nitrogen cycle is coupled with the land component via river discharge processes, and external inputs of iron from pyrogenic and lithogenic sources are considered. Comparison of a historical simulation with observation studies showed the model could well reproduce the transient global climate, change and carbon cycle, as well as the observed large-scale spatial patterns of the land carbon cycle and upper-ocean biogeochemistry. The model demonstrated historical human perturbation of the nitrogen cycle through land use and agriculture, and simulated the resultant impact on the terrestrial carbon cycle. Sensitivity analyses under preindustrial conditions revealed that the simulated ocean biogeochemistry could be altered regionally (and substantially) by nutrient input from the atmosphere and rivers. Based on an idealized experiment in which CO₂ was prescribed to increase at a rate of 1% per year, the transient climate response (TCR) is estimated to be 1.5 K, i.e., approximately 70% that of our previous ESM used in the Coupled Model Intercomparison Project Phase 5 (CMIP5). The cumulative airborne fraction (AF) is also reduced by 15% because of the intensified land carbon sink, which results in an airborne fraction close to the multimodel mean of the CMIP5 ESMs. The transient climate response to cumulative carbon emission (TCRE)

is 1.3 K EgC⁻¹, i.e., slightly smaller than the average of the CMIP5 ESMs, which suggests that “optimistic” future climate projections will be made by the model. This model and the simulation results contribute to CMIP6. The MIROC-ES2L could further improve our understanding of climate–biogeochemical interaction mechanisms, projections of future environmental changes, and exploration of our future options regarding sustainable development by evolving the processes of climate, biogeochemistry, and human activities in a holistic and interactive manner.

1. Introduction

Originally, global climate projections using climate models were based on simulations using atmosphere-only physical models (Manabe et al., 1965). Numerical climate models had evolved through the integration or improvement of component models on ocean circulation (Manabe and Bryan, 1969), land hydrological processes (Sellers et al., 1986), sea ice dynamics (e.g., Meehl and Washington, 1995), and aerosols (e.g., Takemura et al., 2000), most of which focus on physical aspects that affect how climate is formed. Cox et al. (2000) attempted to couple a carbon cycle model and a climate model to investigate the roles of biophysical and biogeochemical (carbon cycle) feedbacks on climate. Their results showed that such interactions are significant in projecting future climate, due to processes and feedbacks beyond those incorporated in traditional climate models. Models that incorporate biogeochemical processes, such as what by Cox et al. (2000), are often called Earth system models (ESMs). Currently, the most comprehensive state-of-the-art ESMs include component models of the land and ocean carbon cycle, atmospheric chemistry, dynamic vegetation, and other biogeochemical cycles (e.g., Watanabe et al., 2011; Collins et al., 2011).

- 削除: ,

Among many processes and possible interactions in the Earth system, the carbon cycle and its feedback on climate remain the focus of simulation studies using ESMs because of the importance of anthropogenic CO₂ as the primary driver for climate change and the complexity of the natural carbon cycle that determines its fate. As ESMs simulate explicit climate–carbon interactions, they can simulate the temporal evolution of atmospheric CO₂ concentration and the resultant climate change using anthropogenic CO₂ emissions as an input (Friedlingstein et al., 2006, 2014). It is also possible to make climate projections using prescribed CO₂ concentrations, and the diagnosed CO₂ fluxes in the simulations can be used to calculate the level of anthropogenic CO₂ emissions compatible with prescribed CO₂ pathways (Jones et al., 2013). Furthermore, ESM simulations can be diagnosed in terms of the relationship between anthropogenic CO₂ emissions and global temperature rise, i.e., the so-called transient climate response to cumulative carbon emissions (TCRE) (Allen et al., 2009; Matthews et al., 2009). The ESMs of the Coupled Model Intercomparison Project Phase 5 (CMIP5) revealed that the relationship is approximately linear (Gillett et al., 2013), which facilitates estimation of the total amount of anthropogenic CO₂ emissions to restrict global warming to below a specific mitigation target.

- 削除: ESMs
- 削除: for calculating
- 削除: simulation results

The feedback of the carbon cycle on climate is manifested through regulation of the atmospheric CO₂ concentration, which can be decomposed into two feedback processes. The first process is the carbon cycle response to CO₂ increase. Elevated CO₂ concentration accelerates vegetation growth that intensifies the land carbon sink. Additionally, increased levels of atmospheric CO₂ accelerate CO₂ dissolution into the surface water of the ocean, and the absorbed CO₂ is transported into the deeper ocean via ocean circulation and biological processes. Consequently, an increase of atmospheric CO₂ triggered by external forcing (e.g., anthropogenic emissions) can be mitigated partly by natural CO₂ uptake, forming a negative feedback loop between atmospheric CO₂ concentration and natural carbon uptake, i.e., the so-called CO₂–carbon feedback (Gregory et al., 2009) or carbon–concentration feedback (Boer and Arora et al., 2009). The second feedback process is the carbon cycle response to global warming. Global warming induces loss of carbon from the land to

- 削除: manifest
- 削除: In addition
- 削除: which eventually propagates

the atmosphere by accelerating ecosystem respiration (Arora et al., 2013; Todd-Brown et al., 2014; Friedlingstein et al., 2014), while ocean surface warming reduces the solubility of CO₂ in seawater. Intensification of upper-ocean stratification and weakening of the biological pump by global warming also prevent effective transport of dissolved carbon into the deeper ocean (Frölicher et al., 2015; Yamamoto et al., 2018). Global warming might lead to localized intensification of the natural carbon sink (e.g., lengthening of the growing season and exposure of the ocean surface through melting of sea ice). However, state-of-the-art ESMs have projected global natural carbon loss due to warming, which suggests a positive feedback loop between climate change and natural carbon uptake, i.e., the so-called climate-carbon feedback (Friedlingstein et al., 2006; Arora et al., 2013).

刪除: transportation

刪除: suggesting

Quantification of the strength of the carbon cycle feedbacks and their comparison among ESMs were first made by Friedlingstein et al. (2006), who showed that all ESMs agreed with the positive sign of the climate-carbon feedbacks for both land and ocean. The latest comparison using CMIP5 ESMs was made by Arora et al. (2013). They found that the widest spread between the models was in the land carbon response to CO₂ increase, while the second greatest spread was in the land carbon response to warming. Two of the ESMs in their analysis employed explicit carbon-nitrogen (C-N) interactions in the land component for considering the limitation of soil N on land CO₂ uptake, and these two models showed the smallest land carbon response to CO₂ increase. Although it was pointed out later that the lowest response of the two C-N models was not necessarily induced by N limitation (Hajima et al., 2014b), the comparison study by Arora et al. (2013) aroused interest in terrestrial biogeochemical feedbacks other than the carbon cycle. The importance of N limitation on the land carbon sink has also been suggested following simulation studies using offline land models (e.g., Thornton et al., 2007; Sokolov et al., 2008; Zaehle and Friend, 2010) and diagnostic analyses using the simulation output of ESMs (e.g., Wieder et al., 2015).

刪除: .

Compared with land, the oceans showed better agreement among the CMIP5 ESMs (Arora et al., 2013) in terms of the strength of both CO₂-carbon and climate-carbon feedbacks. However, the ESMs showed substantial discrepancies in the spatiotemporal patterns of ocean CO₂ uptake, even in historical simulations. In particular, in the Southern Ocean, although the models indicated dominance of the region in relation to anthropogenic carbon uptake (Frölicher et al., 2015), the seasonality of the atmosphere-ocean CO₂ flux and the cumulative values in that region showed divergent patterns among the models (Anav et al., 2013; Frölicher et al., 2015; Kessler and Tjiputra, 2016).

刪除:).

The ecological response of the ocean in ESMs remains far from certain. A benchmark study by Anav et al. (2013) revealed that all CMIP5 ESMs underestimate net primary productivity (NPP) in the high latitudes of the Northern Hemisphere, where seawater temperature and N availability likely limit primary production (e.g., Moore et al., 2013). They also found that most models overestimate NPP in the Southern Hemisphere high latitudes, where nutrient supply is sufficient because of strong upwelling but iron supply is limited (Moore et al., 2013). Globally, the CMIP5 ESMs simulate NPP with different magnitudes, even in the preindustrial condition, and the global NPP response among the models to past and future climate change is largely divergent (Laufkötter et al., 2015), as is the sinking particle flux (Fu et al., 2016). Although such problems regarding oceanic NPP might be attributable partly to inaccurate reproduction of oceanic physical fields by the models (Frölicher et al., 2015; Laufkötter et al., 2015), it is critical in simulations to accurately reproduce the relative abundances of nutrients in the euphotic zone and their availability to microorganisms. In particular, nutrients in the upper ocean are sustained by upwelling from the deeper ocean and inputs from external sources. Some studies suggest that nutrient availability to marine ecosystems could decline in the future through reduction of nutrient upwelling because of intensified stratification (e.g., Ono et al., 2008; Whitney et al., 2013; Yasunaka et al., 2016). Conversely, other studies suggest that nutrient supply through atmospheric deposition and river discharge processes could be amplified in the future

刪除: nutrient

because of human activities (Gruber and Galloway, 2008; Mahowald et al., 2009) unless robust mitigation policies are adopted. Thus, to project the effects of biogeochemical feedback on climate, it is necessary to consider the response of ecological processes to changing nutrient inputs as well as the physical response.

削除: to climate change

170 On the basis of the above, we previously reviewed the CMIP5 exercises and we discussed the perspective for new ESM development (Hajima et al., 2014a). In our ESM development, we prioritized the incorporation of explicit C–N interaction in the land biogeochemical component. The terrestrial nitrogen cycle regulates the carbon cycle by modulating soil nutrient availability to plants, regulating leaf N concentration and photosynthetic capacity, and changing the C:N ratio in plants and soils. In particular, CO₂ stimulation of plant growth (the so-called CO₂ fertilization effect) is the main driver of terrestrial CO₂–carbon feedback, while N limitation on plant growth might regulate the feedback strength (Arora et al., 2013; Hajima et al., 2014a; Hajima et al., 2014b). Thus, consideration of C–N coupling in the terrestrial ecosystem in an ESM will enable change in the land carbon sink capacity following a change of N dynamics induced by human perturbation (e.g., fertilizers) and/or atmospheric N deposition.

削除: capacity of the

削除:

180 For the ocean, the biogeochemical component in our previous model (the MIROC-ESM; Watanabe et al., 2011) was unchanged from that used for the first stage of the Coupled Climate Carbon Cycle Model Intercomparison Project (C4MIP: Friedlingstein et al., 2006; Yoshikawa et al., 2008). The ocean component simulated C and N cycles only, using simple parameterizations of ocean ecosystem dynamics with four types of N tracer and five C tracers (Watanabe et al., 2011) with fixed C:N ratios of the organic components. Furthermore, the ocean N cycle in the model was isolated from other subsystems, i.e., there was no N input into the ocean (e.g., biological N fixation, atmospheric N deposition, and riverine N input) or flux out of the system (e.g., outgassing and sedimentation). To account for changing inputs of N nutrients into the ocean in the simulations, we gave second priority to the coupling of the ocean N cycle to other subsystems by incorporating N exchange processes between the ocean and other components in the new ESM. The ocean N fixer (i.e., diazotrophs) can be regulated strongly by P availability (Shinozaki et al., 2018); therefore, inclusion of the ocean P cycle should be adopted together with improvement of the N cycle. Additionally, as the denitrification process is strongly regulated by the level of oxygen in seawater, it was also decided to include the oxygen cycle in the new model. Inclusion of the oxygen cycle provides potential to project future oceanic deoxygenation that is likely to threaten the habitable zone of marine ecosystems, driven by changes in oxygen solubility, mixing, circulation, and respiration due to global warming (Oschlies et al., 2018; Yamamoto et al., 2015).

削除: strongly

削除:

195 The third priority in developing a new ESM was incorporation of Fe cycle processes. Fe is an essential micronutrient for phytoplankton. Thus, any model lacking consideration of the Fe cycle potentially overestimates primary productivity, especially in regions in which subsurface macronutrient supply is enhanced but Fe availability is limited, e.g., the main oceanic upwelling “high-nutrient, low-chlorophyll” (HNLC) regions (Martin and Gordon, 1988; Moore et al., 2013). Similar to the N cycle, the ocean Fe cycle is also an open system. One of its main external sources is dissolved Fe from continental margins and from hydrothermal vents along mid-ocean ridges (Tagliabue et al., 2017). Thus, continental and hydrothermal Fe supply is important in terms of determining the background Fe concentration in seawater. Additionally, the ocean Fe cycle is also connected to the land through the atmosphere (Jickells et al., 2005; Mahowald et al., 2009; Ito et al., 2019). Fe-containing aerosols are emitted from dry land surfaces, open biomass burning, and fossil fuel combustion, and they are delivered to marine ecosystems via dry and wet deposition processes. These processes have been perturbed by climate change, land use change (LUC), and air pollution (Jickells et al., 2005; Mahowald et al., 2009; Ito et al., 2019). Thus, consideration of atmospheric Fe deposition in particular is necessary to reflect the anthropogenic impact on future marine ecosystem dynamics via Fe cycle processes.

Here, we present a description of a new ESM, the Model for Interdisciplinary Research on Climate, Earth System version2 for Long-term simulations (MIROC-ESL2), which considers explicit carbon and nitrogen cycles for land, and carbon, nitrogen, iron, phosphate, and oxygen cycles for the ocean. In the model, the biogeochemical components are coupled interactively with physical climate components, enabling consideration of climate–biogeochemical feedbacks. The model description and experimental settings are presented in Sect. 2. The basic performance of the model, evaluated by executing a historical simulation and comparison of the results with observation-based studies, is presented in Sect. 3.1. To evaluate the sensitivity of the biogeochemical processes, experiments for sensitivity analysis were performed and the results compared with existing studies. In particular, global temperature response to cumulative anthropogenic CO₂ emissions in the new model was quantified and compared with that of the CMIP5 ESMs to characterize the general features of the new model in relation to existing ESMs. The results of the sensitivity analyses are presented in Sect. 3.2. Finally, a summary and perspectives obtained from this study are offered in Sect. 4.

2. Methods

2.1. Model configurations

To comprehensively describe the MIROC-ESL2 structure (Fig. 1), we first present the physical core of MIROC5.2, which is an updated version of MIROC5 used in CMIP5. Only a brief summary is presented here because a detailed description on the modeling of MIROC5 can be found in Watanabe et al. (2010) and an account of a simulation study performed by MIROC5.2 can be found in Tatebe et al. (2018). Additionally, a description of MIROC6, which shares almost the same structure and many of the characteristics of MIROC5.2, except for the atmospheric spatial resolution and cumulus treatments, can be found in Tatebe et al. (2019). In this paper, description of the land and ocean biogeochemistry is presented in detail because those two components represent the main modifications from the previous version of the ESM (i.e., the MIROC-ESM; Watanabe et al., 2011).

265 **2.1.1. Physical core,**

The MIROC5.2 physical core comprises component models of the atmosphere, ocean, and land. The atmospheric model is based on a spectral dynamical core, originally named the Center for Climate System Research–National Institute for Environmental Studies atmospheric general circulation model (CCSR-NIES AGCM; [Numaguti et al., 1997](#)), which is coupled interactively with an aerosol component model called the Spectral Radiation-Transport Model for Aerosol

Species (SPRINTARS; Takemura et al., 2000, 2005). For the ocean, the CCSR Ocean Component (COCO) model (Hasumi, 2006) is used in conjunction with a sea ice component model. For land, the Minimal Advanced Treatments of Surface Interaction and Runoff (MATSIRO) model (Takata et al., 2003) is coupled to simulate the atmosphere–land boundary conditions and freshwater input into the ocean. Considering the application possibility of the ESM to long-term climate simulations of more than hundreds of years, e.g., paleoclimate studies (Ohgaito et al., 2013; Yamamoto et al., 2019), the horizontal resolution of the atmosphere is set to have T42 spectral truncation, which is approximately 2.8° intervals for latitude and longitude. The vertical resolution is 40 layers up to 3 hPa with a hybrid σ -p coordinate, as in MIROC5. The horizontal coordination for the ocean is changed from the bipolar system employed in MIROC5 to a tripolar system in MIROC5.2, that is divided horizontally into 360×256 grids. (To the south of 63°N, the longitudinal grid spacing is 1° and the meridional spacing becomes fine near the Equator. In the central Arctic Ocean, the grid spacing is finer than 1° because of the tripolar system.) The vertical levels increase from 44 to 62 with a hybrid σ -z coordinate system. For land, the same horizontal resolution as used for the atmosphere is employed; the vertical soil structure of the model has six layers down to the depth of 14 m. Subgrid fractions for two land use types (agriculture plus managed pasture and others) are considered for the physical processes.

For the AGCM, the schemes used for the dynamical core, radiation, cumulus convection, and cloud microphysics are mostly the same as in MIROC5; the major update of processes mainly concerns the aerosol module. The version used here treats atmospheric organic matter (OM) as one of the prognostic variables, and emission of primary OM and precursors for secondary OM are diagnosed in the component. For land, the scheme for subgrid snow distribution is replaced by one incorporating a physically based approach (Nitta et al., 2014; Tatebe et al., 2019), and wetland formed temporarily in the snowmelt season is newly considered to reduce the warm bias in temperature in the European region during spring–summer (Nitta et al., 2017; Tatebe et al., 2019). The ocean and sea ice components are mostly the same as in MIROC5.

2.1.2. Land biogeochemical processes

The model of the land ecosystem/biogeochemistry component in MIROC-ES2L is the Vegetation Integrative Simulator for Trace gases model (VISIT; Ito and Inatomi, 2012a). This model simulates carbon and nitrogen dynamics on land (schematics can be found in Ito and Oikawa 2002 for the carbon cycle and Supplementary Fig. 1 for the nitrogen cycle). It has been used for ecological studies of site–global scale (e.g., Ito and Inatomi, 2012b), impact assessments of climate change (e.g., Warszawski et al., 2013; Ito et al., 2016), prior to CO₂ flux inversion studies (e.g., Maksyutov et al., 2013; Niwa et al., 2017), and in contemporary assessments of CO₂, CH₄, and N₂O emissions in the Global Carbon Projects (Le Quéré et al., 2016; Saunois et al., 2016; Tian et al., 2018). The early version of the model (Sim-CYCLE; Ito and Oikawa, 2002) was actually used as the land carbon cycle component in the first stage of the C4MIP project (Friedlingstein et al., 2006; Yoshikawa et al., 2008). The model covers major processes relevant to the global carbon cycle. Photosynthesis or gross primary productivity (GPP) is simulated based on the Monsi–Saeki theory (Monsi and Saeki, 1953), which provides a conventional scheme to simulate leaf-level photosynthesis in a semiempirical manner and for upscaling to canopy-level primary productivity. The allocation of photosynthate between carbon pools in vegetation (e.g., leaf, stem, and root) is regulated dynamically following phenological stages. Transfer of vegetation carbon into litter/soil pools is simulated using constant turnover rates and, in deciduous forests, seasonal leaf shedding occurs at the end of the growing period. The model focuses on biogeochemical processes and it does not explicitly simulate dynamic change in vegetation composition; therefore, the biogeochemical processes are simulated under a fixed biome distribution (Supplementary Fig. 2). The carbon stored in litter (i.e., foliage, stem, and root litter) and humus (i.e., active, slow, and passive) pools is decomposed

and released as CO₂ into the atmosphere, under the influence of soil water and temperature. Further details on the carbon cycle processes in the model can be found in Ito and Oikawa (2002).

删除: to
删除: ,

For the nitrogen cycle, the model considers two major nitrogen influxes into the ecosystem: biological nitrogen fixation (BNF) simulated based on the scheme of Cleveland et al. (1999) and external nitrogen sources such as fertilizer and atmospheric nitrogen deposition, which are prescribed in the forcing data. The fluxes of nitrogen out of the land ecosystem are simulated through N₂ and N₂O production during nitrification and denitrification in soils, based on the scheme of Parton et al. (1996), leaching of inorganic nitrogen from soils, which is affected by the amount of soil nitrate and runoff rate, and NH₃ volatilization from soils (Lin et al., 2000; Thornley, 1998). Within the vegetation–soil system, organic nitrogen in the soil is supplied from litter fall, whereas inorganic nitrogen is released through soil decomposition processes (soil mineralization) and stored as two chemical forms (NO₃⁻ and NH₄⁺). Inorganic nitrogen is taken up by plants, allocated to two vegetation pools (canopy and structural pools), and immobilized into a microbe pool. Finally, mineral nitrogen is lost via biotic/abiotic processes as mentioned above.

删除: processed by

Although the original land component model covers most major carbon/nitrogen processes, for the purposes of inclusion in the new ESM and making fully coupled climate–carbon/nitrogen projections, the land model was modified for this study (hereafter, the modified version is called VISIT-e). First, the modified model represents the close interaction between carbon and nitrogen in plants. This is because the original model has only loose interaction between these two cycles and thus it cannot predict precisely the nitrogen limitation on primary productivity. To achieve this, the photosynthetic capacity in VISIT-e is modified to be controlled by the amount of nitrogen in leaves (leaf nitrogen concentration), which is determined by the balance between the nitrogen demand of plants and potential supply from the soil. Thus, if sufficient inorganic nitrogen is not available for plants, leaf nitrogen concentration is gradually lowered, which reduces photosynthetic capacity and the plant production rate. This process is required to simulate the observed down-regulation in elevated CO₂ experiments (e.g., Norby et al., 2010; Zaehle et al., 2014). Other modifications regarding the nitrogen cycle are described in Appendix A.

删除: Thus
删除: tight

Second, although the original VISIT incorporates LUC and associated CO₂ emission processes, to take full advantage of the latest LUC forcing dataset (Land-use harmonization 2; Ma et al., 2019), additional LUC-related processes have been newly introduced in VISIT-e. The model assumes five types of land cover (each represented on a separate tile) in each land grid box (i.e., primary vegetation, secondary vegetation, urban, cropland, and pasture) with the same structure of carbon/nitrogen pools. All processes are calculated separately for each tile (i.e., no lateral interaction) and then the variables in the tile are summed after weighting by the areal fraction of each land use type. The LUC impact is modeled assuming two types of land use impact on the biogeochemistry. The first impact considers status-driven LUC processes, which affect land biogeochemistry even when the areal fractions of the tiles are fixed. For example, even when a simulation is conducted with fixed areal fractions (e.g., a spin-up run under 1850 conditions), crop harvesting, nitrogen fixation by N-fixing crops, and the decay of OM in product pools occur. The second type of land use impact includes transition-driven processes that happen only when areal changes occur among the tiles. For example, when an areal fraction is changed within a year (e.g., conversion of forest to urban land use), carbon and nitrogen in the harvested biomass are translocated between product pools. When cropland is abandoned and the area is reclassified as secondary forest, the apparent mean mass density of secondary forest is first diluted because of the increase in the less-vegetated area, and then secondary forest starts regrowth toward a new stabilization state. Further detailed description on LUC modeling is given in Appendix A.

380 The land ecosystem component runs with a daily time step in the ESM. It has fixed spatial distribution patterns of 12
 vegetation categories (see Supplementary Fig. 2), and the land biogeochemistry is affected by daily averaged atmospheric
 conditions (CO₂ concentration, downward shortwave radiation, air temperature, and air pressure) and land abiotic
 conditions (soil water, soil temperature, and runoff rate as the base flow) simulated by the physical core of the ESM. In
 turn, daily averaged land variables simulated by VISIT-e are used by other components of the ESM (Fig. 1). For example,
 the simulated leaf area index (LAI) is referenced in the physical core of the model to simulate physical dynamics on the
 land surface (e.g., evapotranspiration, albedo, and surface roughness). Furthermore, the rate of net atmosphere–land CO₂
 flux is used in the calculation of the atmospheric CO₂ concentration, and inorganic N leached from the soil is transported
 by rivers and subsequently used as an input of N nutrients to the ocean ecosystem. The chemical state of N in rivers is
 assumed conserved during transportation, and biogeochemical processes such as outgassing or sedimentation in freshwater
 systems are neglected in the present model. Additionally, although the model can simulate terrestrial carbon loss by
 erosion and dissolution of organic carbon, these processes are not activated to close the global mass conservation of
 carbon and nitrogen. Finally, although N₂O and NH₃ emissions are simulated, the emission fluxes are considered only for
 diagnostic purposes and they do not produce any change in the atmospheric radiation balance or air quality.

2.1.3. Ocean biogeochemical processes

395 The new ocean biogeochemical component model OECO2 (see Supplementary Fig. 3 for a schematic), is a nutrient–
 phytoplankton–zooplankton–detritus-type model that is an extension of the previous model (Watanabe et al., 2011).
 Although only an overview of OECO2 is presented here, a detailed description can be found in Appendix B.

In OECO2, ocean biogeochemical dynamics are simulated with 13 biogeochemical tracers. Three of them are
 associated with cycles of macronutrients (nitrate and phosphate) and a micronutrient (dissolved Fe). The model has four
 organic tracers of “ordinary” nondiazotrophic phytoplankton, diazotrophic phytoplankton (nitrogen fixer), zooplankton,
 and particulate detritus. All OM in these four tracers is assumed to have identical nutrient, oxygen, and micronutrient iron
 composition following the Redfield ratio of C:N:P:O = 106:16:1:138 (Takahashi et al., 1985) and C:Fe = 150:10⁻³ (Gregg
 et al., 2003). Four other tracers are associated with carbon and/or calcium, i.e., dissolved inorganic carbon (DIC), total
 alkalinity, calcium, and calcium carbonate. The two other tracers are oxygen and nitrous oxide.

405 The nitrogen cycle in OECO2 is similar to that in the previous version (Yoshikawa et al., 2008; Watanabe et al., 2011),
 except the new model accounts for nitrogen influxes such as nitrogen deposition from the atmosphere (as external forcing),
 input of inorganic nitrogen from land via rivers, and BNF by diazotrophic phytoplankton (Fig. 1). Additionally,
 denitrification is also modeled as the dominant process of oceanic nitrogen loss, with explicit distinction between the
 gaseous forms of N₂O and N₂ (see below for nitrogen fixation and denitrification processes). Loss of nitrogen through the
 sedimentation process is also considered. The phosphorus cycle is newly embedded in the model to represent strong
 phosphorous limitation on the growth of diazotrophic phytoplankton. The structure of the phosphorus cycle is generally
 similar to that of nitrogen, except in two respects: 1) the riverine input of phosphate is the only process that introduces
 phosphorus into the ocean and 2) there is no process of outgassing from the ocean, unlike the denitrification process in the
 nitrogen cycle. As the land ecosystem model cannot simulate the phosphorus cycle, the flux of phosphorous from rivers is
 diagnosed from the nitrogen flux, assuming that the phosphate brought to the river mouth satisfies the N:P ratio of 16:1,
 similar to the Redfield ratio.

削除: ,

445 The structure of the ocean iron cycle is also similar to that of nitrogen, except the following processes are modeled as iron input into the ocean. Two major sources of iron deposition from the atmosphere are included in the new model: lithogenic and pyrogenic sources. Mineral dust emission is diagnosed by the aerosol component module, depending on the near-surface wind speed, soil dryness, and bare ground cover, while iron emitted from biomass burning and the consumption of fossil fuel and biofuel follows external forcing. The latter emission dataset used in this study is shown in Supplementary Fig. 4. The iron emissions from pyrogenic sources are estimated based on the iron content and emissions of particulate matter (Ito et al., 2018). A shift from coal to oil combustion is considered in relation to shipping (Fletcher, 1997; Endresen et al., 2007). The iron content of mineral dust is prescribed at 3.5% (Duce and Tindale, 1991). The iron deposition from biomass burning is calculated from black carbon (BC) deposition and a ratio of 0.04 gFe gBC⁻¹ in fine particles at emission (Ito 2011). The emission, transportation, and deposition processes are simulated explicitly by the atmospheric aerosol component. The iron from different sources has different solubility in seawater and thus different amounts of iron are available for phytoplankton. The solubility of iron is prescribed at 79% for oil combustion, 11% for coal combustion, and 18% for biomass burning (Ito, 2013). The solubility of iron for mineral dust is prescribed at 2% (Jickells et al., 2005).

削除:

In addition to the Fe input from the atmosphere, recent studies suggest contributions of Fe supply from sediment and hydrothermal vents to ecosystem activities (Tagliabue et al., 2017). The contributions of these two natural Fe sources to the determination of atmospheric CO₂ concentration and export production are similar to or greater than that of dust (Tagliabue et al., 2014). Therefore, these three Fe sources are also considered in the new ESM (Appendix B).

削除:

460 Ocean ecosystem dynamics are simulated based on the nutrient cycles of nitrate, phosphorous, and iron. Nutrient concentration, in conjunction with the controls of seawater temperature and availability of light, regulates the primary productivity of the two types of phytoplankton. The model assumes that diazotrophic phytoplankton can prosper in regions in which phosphate is available but nitrate concentration is small (<0.05 μmol L⁻¹). In the model, zooplankton is assumed to be independent of abiotic conditions (e.g., seawater temperature) and dependent on biotic conditions (phytoplankton and zooplankton concentrations), as in the previous model. The denitrification process is modeled to occur only in suboxic waters (<5 μmol L⁻¹) (Schmittner et al., 2008) and it is suppressed in water with low nitrate concentration (<1 μmol L⁻¹). Detritus contains nitrate, phosphorus, iron, and carbon, most of which is remineralized while sinking downward. The detritus that reaches the ocean floor is removed from the system; however, a fraction of OM in the sediment is assumed to return to the bottom layer of the water column at a constant rate in each location (Kobayashi and Oka, 2018).

削除: where

削除: , oxygen

470 The ocean carbon cycle is formed by atmosphere–ocean CO₂ exchange, inorganic carbon chemistry, OM dynamics driven by marine ecosystem activities, and transportation and reallocation processes of ocean carbon within the interior. The formulations of atmosphere–ocean gas exchange, carbon chemistry, and related parameters follow protocols from the Ocean Model Intercomparison Project (OMIP; Orr et al., 2017). Production of DIC and total alkalinity is controlled by changes in inorganic nutrients and CaCO₃, following Keller et al. (2012).

削除:

475 Finally, the flux of dimethyl sulfide (DMS) from the ocean, which is produced by plankton and is a precursor of atmospheric sulfate aerosols, is diagnosed in the original aerosol module from the surface downward shortwave radiation flux. In MIROC-ES2L, this emission scheme is modified and the flux is calculated from the sea surface DMS concentration that is diagnosed from the simulated surface water chlorophyll concentrations and the corresponding mixed-layer depth (Appendix B). In the present model, this is the only pathway via which ocean biogeochemistry affects climate, if the model is driven by prescribed CO₂ concentration (Fig. 1). This modification of the DMS emission scheme increases the sulfate aerosol amount, particularly over high-latitude oceans during winter and in regions in which strong surface

削除: , except for atmosphere–ocean CO₂ exchange

wind speed occurs. Solar irradiance of the surface decreases in such regions; however, this effect is not sufficiently significant to change the mean physical climate states.

2.2. Experiments, forcing, and metrics

2.2.1. Experiments and forcing

To evaluate the performance and sensitivities of MIROC-ES2L, we conducted 4 groups of experiments comprising 11 experiments in total (Tables 1 and 2). The first group was a control run that comprised two types of experiment: a normal control run (CTL) in which the external forcing was set to preindustrial conditions and an alternative control run (CTL-D) used for sensitivity analysis of the ocean biogeochemistry, which is described later.

495

削除: four

削除: eleven

削除: consisted of

削除:

The second group, used for historical simulations, comprised three types of experiment during the period 1850–2014. All three experiments were driven by the Coupled Model Intercomparison Project Phase 6 (Eyring et al., 2016) official forcing datasets (version 6.2.1; details on forcing datasets used in the simulations are summarized in Appendix C), and the CO₂ concentration was prescribed in the simulations (i.e., so-called concentration-driven experiments). The first comprised a conventional historical simulation (HIST), and the simulation result is used for direct comparison with observation-based studies to evaluate model performance. The second was a special experiment named HIST-NOLUC, which was designed to evaluate the impact of LUC on the climate and biogeochemistry. In this experiment, land use and agricultural management (fertilizer application) were fixed at preindustrial levels. This experimental configuration is the same as the LUMIP experiment in CMIP6 named land-noLu (Lawrence et al., 2016). The third experiment (HIST-BGC) was the same as HIST, except that the CO₂ increase only affects the carbon cycle processes (named in C4MIP of CMIP6 as hist-bgc; Jones et al., 2016). Thus, there was no CO₂-induced global warming in the experiment.

500

削除: consisted of

505

削除: for evaluation of

削除: detect the CO₂ increase

The third experimental group was used to evaluate the climate and carbon cycle feedbacks. This group comprised three types of idealized experiment, following experimental designs proposed by Eyring et al. (2016) and Jones et al. (2016). In the three experiments, CO₂ concentration was prescribed to increase at the rate of 1.0% per year from the preindustrial state throughout the 140-year period (i.e., the concentration finally reached a value of approximately 1140 ppmv), while other external forcing was maintained at the preindustrial condition. The three experiments were configured as follows: (1) 1PPY: a normal experiment in which both climate and biogeochemical processes respond to the CO₂ increase; (2) 1PPY-BGC: the same as 1PPY but the prescribed CO₂ increase affects only the carbon cycle processes; and (3) 1PPY-RAD: the same as 1PPY but the CO₂ increase affects only atmospheric radiation processes. In 1PPY-BGC, carbon cycle processes respond to the CO₂ increase without CO₂-induced global warming; thus, the result of this simulation is used to quantify CO₂-carbon feedback. In 1PPY-RAD, as there is no direct CO₂ stimulation on the carbon cycle, climate change is the only cause of carbon cycle variation relative to the preindustrial control (CTL). Thus, this simulation result is used to evaluate climate-carbon feedback (Arora et al., 2013; Schwinger et al., 2014).

510

515

削除: detect the CO₂ increase

削除: detect the CO₂ increase

The final group comprised a set of experiments to evaluate ocean biogeochemistry, focusing mainly on the processes newly introduced in MIROC-ES2L. This group comprised three types of experiment. The first experiment (NO-NR) was configured similarly to the CTL run, except the ocean component did not receive any riverine N input. Through this experiment, the impact of riverine N on ocean biogeochemistry could be evaluated. The second experiment (NO-NRD) was the same as NO-NR, except atmospheric N deposition additionally had no effect on ocean biogeochemistry. By evaluating the difference between NO-NR and NO-NRD, the impact of nitrogen deposition on ocean biogeochemistry could be evaluated. The final experiment (NO-FD) was configured with atmospheric Fe deposition onto the ocean surface

switched off. To detect slight signals of ocean biogeochemistry arising from switching off the three processes (i.e., riverine N, N deposition, and Fe deposition), it was necessary to maintain consistency in the ocean physical fields between these experiments because a slight difference of the ocean physical fields produces perturbation on ocean biogeochemistry. In MIROC-ES2L, ocean DMS emission is the feedback process of ocean biogeochemistry on the atmospheric physical processes; thus, biogeochemical change induced by the switching-off manipulations must change the DMS emission, which leads to inconsistency in the physical fields between the experiments. To avoid this occurrence, the DMS emission scheme in all three experiments was reverted to that used in the original aerosol component model, which is independent of the ocean ecosystem state (Appendix B). Similarly, the special control run (CTL-D), which was based on CTL, also had the DMS emission scheme changed to the same as NO-NR, NO-NRD, and NO-FD.

To conduct the experiments described above, preindustrial spin-up was performed in advance. Land and ocean biogeochemical components were decoupled from the ESM, and the spin-up run was conducted for 3000 years for the ocean component and 30,000 years for land, by prescribing model-derived physical fields and other external forcing for the component models. In the final phase of the spin-up procedure, continuous spin-up, forced by the 1850-year condition of CMIP6 forcing, was performed for the entire system for 2483 years (Supplementary Fig. 5). All the experiments listed in Table 1 were initiated from the final condition of this spin-up procedure.

Table 1

Summary of experimental details.

Experimental Group	Experiment	Purpose	Configurations	Duration [yrs]
Control	CTL	Control run	CO ₂ conc. and other forcings are fixed at pre-industrial level	165
	CTL-D	Control run for NO-NR, NO-NRD, and NO-FD	Same as CTL, but DMS emission follows the scheme of original aerosol module	100
Historical	HIST	Evaluation of model performance	Following CMIP6-DECK historical run	165 (1850-2014)
	HIST-NOLUC	Evaluation of land-use change impact on carbon cycle	LUC and fertilizer are fixed at pre-industrial level	165 (1850-2014)
	HIST-BGC	Evaluation of response of carbon cycle to CO ₂ increase	Same as HIST but only biogeochemical processes "see" the CO ₂ increase	165 (1850-2014)
1%CO ₂	IPPY	Evaluation of sensitivities of climate and carbon	Prescribed CO ₂ increased with 1.0 [% yr ⁻¹]	140
	IPPY-BGC	Evaluation of response of carbon cycle to CO ₂ increase	Same as IPPY but only biogeochemical processes "see" the CO ₂ increase	140
	IPPY-RAD	Evaluation of response of carbon cycle to climate change	Same as IPPY but only atmospheric radiative processes "see" the CO ₂ increase	140
OBGC	NO-NR	Evaluation of impacts of riverine N to ocean	Same as CTL-D but ocean is not impacted by riverine N	100
	NO-NRD	Evaluation of impacts of deposition N to ocean, by combining NO-NR	Same as NO-NR but ocean is not impacted by N deposition	100
	NO-FD	Evaluation of impacts of deposition Fe to ocean	Same as CTL-D but ocean is not impacted by Fe deposition	100

*If the biogeochemical process in an experiment was affected by CO₂, climate, or land use change, the letter “O” is present; otherwise, the symbol “–” is used.

†If the ocean biogeochemistry process detected fluxes of riverine nitrogen, atmospheric nitrogen deposition, or atmospheric iron deposition, the letter “O” is present; otherwise, the symbol “–” is used.

580

‡The TypeA DMS emission scheme is the default scheme in MIROC-ES2L, where DMS emission is simulated as being dependent on the ocean biogeochemical states and the mixed-layer depth. TypeB is a scheme employed in the original aerosol component model in which DMS emission is calculated independently of ocean biogeochemical states.

2.2.2. Evaluation of climate and carbon cycle response to CO₂

585

To evaluate the climate and carbon cycle response to CO₂ increase, we used the metrics of transient climate response (TCR), airborne fraction of CO₂ (AF), and TCRC, which have been previously used to characterize the entire climate–carbon cycle response to CO₂ increase in other models (Matthews et al., 2009; Hajima et al., 2012; Gillett et al., 2013). Similar analysis is made in this study and the result is presented in Sect. 3.2.

削除: utilized

590

First, TCRC is defined as the ratio of global mean near-surface air temperature change (T) to cumulative anthropogenic carbon emission (CE) at the level of doubled CO₂ concentration from the preindustrial state (hereafter, 2xCO₂^{P1}):

$$\text{TCRC} = T/\text{CE}, \quad (1)$$

which can be written as follows:

$$TCRE = (CA/CE) \times (T/CA), \quad (2)$$

where CA is the atmospheric carbon increase until reaching 2xCO₂^{PI}. The first term on the right-hand side (CA/CE) is identical to the definition of the cumulative airborne fraction of anthropogenic carbon emission:

$$CA/CE = AF. \quad (3)$$

The second factor (T/CA) can be represented by TCR as follows:

$$T/CA = TCR/CA, \quad (4)$$

given that TCR is defined as T at 2xCO₂^{PI}. Thus, Eq. 2 can be expressed as follows:

$$TCRE = AF \times (TCR/CA). \quad (5)$$

The result of the 1PPY simulation was used to evaluate TCRE, TCR, and AF. As CA is prescribed in the simulation, CE can be diagnosed by CE = CA + CL + CO, where CL and CO represent the change in land and ocean carbon storage, respectively. As shown by Matthews et al. (2009), AF summarizes the carbon cycle response to anthropogenic CE; the second term in Eq. 5 (TCR/CA) captures the global temperature response to CO₂ increase in the models, and TCRE thus summarizes the two, i.e., the global temperature response to anthropogenic CO₂ emission in the model.

To evaluate the strength of carbon cycle feedbacks in the model, the feedback strength is quantified by the so-called β and γ quantities (Friedlingstein et al., 2006; Arora et al., 2013). The former is a feedback parameter for CO₂–carbon feedback (carbon cycle response to atmospheric CO₂ increase), which can be calculated as follows:

$$\beta_L = (CL^{1PPY-BGC} - CL^{CTL})/CA^{1PPY}, \quad (6)$$

$$\beta_O = (CO^{1PPY-BGC} - CO^{CTL})/CA^{1PPY}, \quad (7)$$

where subscripts L and O represent land and ocean, respectively, and the superscripts represent the experiment used for the calculation.

The quantity γ is a feedback parameter for climate–carbon feedback (carbon cycle response to climate change), which can be calculated using the results of the 1PPY-RAD and CTL simulations:

$$\gamma_L = (CL^{1PPY-RAD} - CL^{CTL})/T^{1PPY-RAD}, \quad (8)$$

$$\gamma_O = (CO^{1PPY-RAD} - CO^{CTL})/T^{1PPY-RAD}. \quad (9)$$

3. Results and discussion

625 3.1. Model performance in historical simulation

3.1.1. Global climate: atmosphere and ocean physical fields

To evaluate the physical fields reproduced by MIROC-ES2L, the temporal evolutions of the global mean net radiation balance at the top of atmosphere (TOA) and anomalies of near-surface air temperature (SAT), sea surface temperature (SST), and upper-ocean (0–700 m) temperature were compared with observation datasets; the results are shown in Fig. 2.

The model simulates a reasonably steady state of net TOA radiation balance in the CTL run, showing a trend of -4.6×10^{-5}

W m⁻² yr⁻¹ during the 165-year period. When comparing net TOA radiation balance of the HIST simulation with satellite measurement (CERES EBAF-TOA edition 4.0, constrained by in situ measurements; Loeb et al., 2012, 2018), the model result is -0.63 W m^{-2} (negative means net incoming radiation) during 2001–2010, which is within the range of $-0.5 \pm 0.43 \text{ W m}^{-2}$ estimated by Loeb et al. (2012) for the corresponding period (Fig. 2a).

Following the net increase of incoming radiation, the SAT anomaly increases in the latter half of the 20th century (Fig. 2b). The warming trend during 1951–2011 is simulated as 0.1 K per decade, which is consistent with that of HadCRUT4 (version 4.6; Morice et al., 2012), i.e., 0.11 K per decade (Stocker et al., 2013). Observation datasets of SST (HadSST version 3.1.1; Kennedy et al., 2011) and upper-ocean temperature (Levitus et al., 2012) clearly display increasing trends in the corresponding period, which are successfully reproduced by the model (Fig. 2c and 2d). In addition to the warming trend in the latter half of the 20th century, the model captures the slowdown of SAT increase both in the 1950s and in the 1960s. These changes are likely induced by increased anthropogenic aerosol emissions and resultant cooling through indirect aerosol effects, together with cooling attributable to large volcanic eruptions in the 1960s (Wilcox et al., 2013; Nozawa et al., 2005). However, distinct deviations of the model results from HadCRUT4 are found for SAT and SST, in the 1860s and particularly in the 1900s. This might be due to inevitable asynchronization between the simulation and observations on the phasing of the internal variability of climate, as identified by Kosaka et al., 2016. They reported that there should have been four major cooling events due to tropical Pacific variability in the 20th century, one of which was found in the 1900s. They also reported the other three events were around 1940, 1970, and 2000; however, discrepancies arising from these three events are not so evident in this study, likely because of the single ensemble simulation. The model also exhibits short-term response of the TOA radiation balance following episodic volcanic events (Fig. 2a, vertical dashed lines), with resultant cooling of SAT and SST (Fig. 2a–c) and further propagation into the deeper ocean with extended cooling duration (Fig. 2d). Overall, the historical SAT increase in MIROC-ES2L, taking the difference between the averages of 1850–1900 and 2003–2012, is 0.69 K, while the HadCRUT4-based estimate by Stocker et al. (2013) is 0.78 K for the corresponding period. The model shows good performance in reproducing global physical fields. This is likely attributable to the inherited robust performance of the physical core of the model (MIROC5.2) because MIROC-ES2L has only two feedback pathways of biophysical processes on climate (DMS emission from the ocean and terrestrial processes associated with LAI dynamics) when the model is driven by a prescribed CO₂ concentration. Both processes are likely to change the physical fields locally.

In addition to the radiation/temperature responses against historical external forcing, we briefly describe here the El Niño–Southern Oscillation (ENSO) and Atlantic meridional overturning circulation (AMOC) strength in MIROC-ES2L, both of which can affect interannual–multidecadal carbon cycle processes (Zickfeld et al., 2008; Pérez et al., 2013; Friedlingstein 2015). In the HIST experiment, the standard deviation of monthly SST anomaly in the Niño-3 region (5°S–5°N; 90°–150°W) was 1.57 K in 1950–2009, which is larger than that of HadSST (0.94 K). This unrealistically large ENSO amplitude tends to influence the simulated interannual global temperature variability (Fig. 2b), which is suggestive of further effect on the interannual variability in biogeochemical fields (e.g., CO₂ flux in the tropics). The AMOC intensity, quantified by the North Atlantic Deep Water transport across 26.5°N, was approximately 13 Sv (1 Sv = 10⁶ m³ s⁻¹) as the 1850–2014 average, which is smaller than the observational estimates of 17.2 Sv (McCarthy et al., 2015). In the HIST run, the AMOC strength was weakened at a rate of 0.01 Sv yr⁻¹ (i.e., reduction of 1.7 Sv during the 165 years of HIST), which seems slightly smaller than the recent estimate of AMOC weakening of 3 ± 1 Sv from the mid-twentieth century (Caesar et al., 2018).

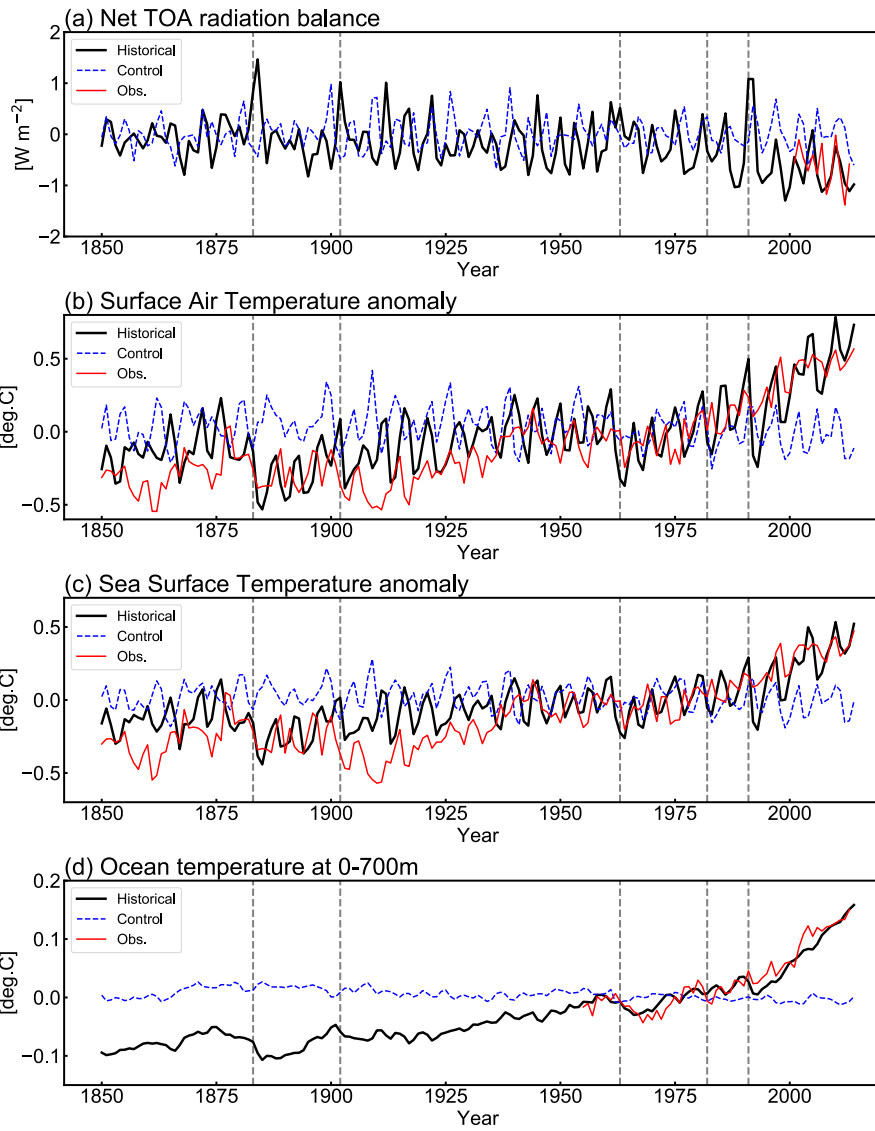

Figure 2

Comparison of HIST simulation results by MIROC-ES2L with observations: [anomalies of](#) (a) net radiation balance at the top of the atmosphere (TOA; upward positive), (b) global mean surface air temperature, (c) global mean sea surface

715 temperature, and (d) global mean ocean temperature at 0–700 m depth. Black, red, and blue lines represent historical
simulations, historical observations, and pi-control simulations, respectively. Vertical dashed lines represent the timing of
major volcanic eruptions (i.e., Krakatau (1883), Santa Maria (1902), Agung (1963), El Chichon (1982), and Pinatubo
(1991)). In panel (a), the simulation results are presented as anomalies from the 1850–2014 average of the CTL run. In
panels (b), (c), and (d), the results are presented as the anomalies from the 1961–1990 averages. Observation data for the
720 radiation balance were obtained from the global product of CERES EBAF-TOA edition 4.0. Observation data for SAT and
SST were obtained from HadCRUT4 (Morice et al., 2012) version 4.6 and HadSST (Kennedy et al., 2011) version 3.1.1,
respectively. Ocean temperature anomaly, updated from Levitus et al. (2012), is used to compare ocean temperature at 0–
700 m depth during the period 1955–2014.

725 Hereafter, we present an overview of the performance of the mean state of the physical fields, atmosphere, and
land/ocean basic variables of the model in comparison with various observational-based data. The variables examined here
are SAT, precipitation, SST, sea ice concentration, land snow cover, and mixed-layer depth, all of which are representative
physical states associated with biogeochemical processes. The mixed-layer depth is defined as the depth at which the
potential density becomes larger than that of the sea surface by 0.125 kg m^{-3} . Fig. 3 shows the climatology of SAT (air
730 temperature at 2 m height) averaged over 1989–2009 for annual, December–February (DJF), and June–August (JJA)
means and the biases in comparison with the ERA-Interim dataset (Dee et al., 2011). The comparison suggests that the
model performs well (biases $<2^\circ\text{C}$) over the tropics and most of the global area in terms of both annual mean and
seasonality. However, obvious warm biases exist over the Southern Ocean and Antarctica. This is a general tendency of
CMIP5-class models, and both MIROC5 (Watanabe et al., 2010) and MIROC6 (Tatebe et al., 2019) also suffer this
735 problem. The warm bias in the Southern Ocean can be attributed mainly to poor representation of cloud radiative
processes (Bodas-Salcedo et al., 2012; Williams et al., 2013; Hyder et al., 2018), but also to poor representations of the
mixed-layer depth and deep convection in the open ocean attributable to the lack of modeled mesoscale processes in the
Antarctic Circumpolar Current (Tatebe et al., 2019). A related warm bias in SST over the Southern Ocean is also
confirmed, which is discussed later.

740 Figure 4 shows the precipitation distribution in the HIST experiment in comparison with the Global Precipitation
Climatology Project (GPCP) dataset (Adler et al., 2003). Generally, the precipitation distribution is reasonably well
represented in the model. The Intertropical Convergence Zone is reproduced well in the experiment, except that the
simulated South Pacific Convergence Zone is shifted equatorward relative to the GPCP, which is the so-called double
Intertropical Convergence Zone syndrome (Bellucci et al., 2010). Over continental areas, the model is effective in
745 capturing the spatial pattern of both the annual mean precipitation and the seasonality. However, positive precipitation
biases are evident in some land tropical regions such as central Africa, South/Southeast Asia, and South America.
Additionally, arid and semiarid regions of central Asia, Australia, and the western side of North America also show
positive precipitation bias although it is unclear in the bias map (see Supplementary Fig. 6 for the comparison with the
absolute precipitation rate of GPCP).

750 When projecting future climate change, it is important for a model to reproduce the observed climatological patterns of
key physical variables, as suggested by Ohgaito and Abe-Ouchi (2009). The biogeochemical tracers are also affected by
the representation of the physical fields. Figure 5 presents the modeled SST and its bias with respect to the World Ocean
Atlas 2013 (WOA 2013; Locarnini et al., 2013). Generally, the model performs well, confirmed by the large extent of the
area with minimal bias (colored white in Fig. 5). However, obvious bias is evident, e.g., the warm bias in the Southern

760 Ocean, as already explained above (Fig. 3). A cold bias is also evident over the western North Pacific Ocean, which is attributable to the lack of narrow and swift western boundary currents owing to the coarse horizontal resolution in the ocean parts of the present ESM.

765 The model performance in simulating sea ice concentration and snow cover over land for both March and September is shown in Fig. 6, in comparison with observational data (Special Sensor Microwave Imager (SSM/I; Kaleschke et al., 2001) for sea ice concentration and Moderate-resolution Imaging Spectroradiometer (MODIS; Hall et al., 2006) for snow cover. Sea ice extent in the Northern Hemisphere is represented well for both months, although the summertime concentration minimum is slightly smaller than observed. In the Southern Hemisphere, however, the sea ice extent is unrealistically underestimated because of the persistent warm bias described above. The extent of the snow-covered area is also well represented, likely owing to the updated scheme for subgrid snow representation (Nitta et al., 2014; Tatebe et al., 2019). However, the fine structure of the snow cover is lost in the simulation, which is likely attributable to the coarse resolution of the modeled atmosphere and land. The reasonable performance in reproducing land snow seasonality in the boreal region is important for land biogeochemistry as well as the physical climate because snowmelt (accumulation) and leaf flush (shedding) processes are mutually associated (Supplementary Fig. 7).

775 Figure 7 shows the mixed-layer depth in comparison with the Mixed-Layer dataset of Argo, Grid Point Value (MILA_GPV; Hosoda et al., 2010). The HIST simulation captures well both the spatial pattern and the seasonality change in mixed-layer depth. In the Northern Hemisphere winter, the structure of the deep mixed layer over the western North Pacific is consistent with observations; however, the actual depth is overestimated owing to the lack of mesoscale eddies. The deep mixed layer in the subarctic North Atlantic is also consistent with observations, except there is less deep water formed in the Labrador Sea. Additionally, the shallow mixed layer in low latitudes is generally captured well by the simulation, and the depth that is maintained at around 100 m over the Southern Ocean is consistent with observations. In austral winter, MILA_GPV shows the mixed layer develops to more than 200 m over the Indian Ocean and the Pacific sector of the Southern Ocean, whereas it is shallow (around 50 m) in the tropics and the Northern Hemisphere (Fig. 7d). The model captures the general pattern in austral winter, although the extent of the simulated deeper mixed-layer depth of more than 200 m in the Southern Ocean is larger than that of MILA_GPV (Fig. 7c).

3.1.2. Global carbon budget

Simulated net CO₂ uptake by land and ocean in cumulative values (i.e., changes in total carbon of land and ocean) is shown in Fig. 8a and 8b, respectively. For land, the CTL run shows slight reduction of carbon of 7.6 PgC during the 165 years (i.e., 4.6 PgC per century), which is within the acceptable range for the CMIP6 exercise (10 PgC per century; Jones et al., 2016). The dashed gray line in Fig. 8a is the result from HIST-NOLUC, and shows a natural land carbon sink in MIROC-ES2L of 200 PgC during 1850–2014. This is comparable with the estimate of 185 ± 50 PgC by Le Quéré et al. (2018) for the same period (vertical gray bar in Fig. 8a), which was obtained from multiple offline terrestrial ecosystem models with fixed land use. Additionally, LUC is one of the factors that change drastically the historical land carbon amount because positive (negative) LUC emission is linked directly with reduction (increase) of land carbon. Based on bookkeeping methods, Le Quéré et al. (2018) estimated the cumulative CE derived from LUC during 1850–2014 as 195 ± 75 PgC, whereas the simulated cumulative emission by MIROC-ES2L that is diagnosed by the difference in land carbon amount between HIST-NOLUC and HIST is 156 PgC.

削除: The simulated

削除: , showing

削除: 166

削除: well

削除: In addition

削除: to

削除: ,

削除:

Through being affected by both environmental changes and LUCs, MIROC-ES2L demonstrates in the HIST simulation that land carbon is reduced by approximately 60 PgC from the beginning of the simulation up until the middle of the 20th century (black line in Fig. 8a). This reduction should reflect LUC during this period because HIST-NOLUC does not show such a trend of decrease in the corresponding period (dashed gray line in Fig. 8a). From the 1960s, the model shows continuous carbon sequestration on land, which results in positive net CO₂ uptake of 2.4 PgC yr⁻¹ in the 2000s (Table 3).

削除: resulting

This continuous increase in the latter half of the 20th century is due to the combined effects of CO₂ fertilization,

850 vegetation recovery associated with LUC, and the increase of nitrogen input via deposition and the use of fertilizer. This is displayed clearly in Fig. 8c, where the historical land carbon change is decomposed into the responses to (1) CO₂ increase (blue line, diagnosed by “HIST-NOLUC + HIST-BGC – HIST”; see Table 2), (2) climate change (red line, by “HIST – HIST-BGC”), and (3) LUC (green line, by “HIST – HIST-NOLUC”). In the latter half of the 20th century, land carbon sequestration accelerated by CO₂ stimulation is clear, while climate change and the resultant terrestrial carbon loss also become evident. Additionally, land carbon reduction induced by LUC is slightly weakened in the corresponding period. During the historical period, MIROC-ES2L simulates total land carbon change (CL) of 44 PgC. This number drops to within the independent estimate range of 10 ± 90 PgC (vertical black bar in Fig. 8a), where estimation uncertainties take into account both the terrestrial natural carbon sink and LUC emission (calculated as $(\sigma_{LUC}^2 + \sigma_{SINK}^2)^{0.5}$, where σ_{LUC} and σ_{SINK} represent the uncertainty range of LUC emission and the land sink, respectively, in Le Quéré et al. (2018). The possible range for CL can be changed if we estimate it as the residual of other global carbon budgets (i.e., $CL = FF - CA - CO$, where FF is the cumulative fossil fuel carbon emission). Using the estimated ranges of FF, CA, and CO reported by Le Quéré et al. (2018) (i.e., 400 ± 20 , 235 ± 5 , and 150 ± 20 PgC respectively; the budget imbalance of 25 PgC is ignored here), the CL range is suggested to be 15 ± 29 PgC. In this case, the result of MIROC-ES2L (44 PgC) is still within the estimation boundaries although it is at the upper end of the suggested range.

860 For the ocean, the model shows an increase in carbon accumulation in the CTL run (Fig. 8b). This is partly because of carbon removal by the sedimentation process that is newly introduced into MIROC-ES2L. In this process, an amount of carbon is extracted from the ocean bottom, which should be compensated by an equivalent input of carbon from the atmosphere through gas exchange processes. In the CTL run, the rate of carbon extracted from the ocean bottom is 0.068 PgC yr⁻¹ (Table 4), which suggests that the process removes 11 PgC throughout the entire simulation period of CTL (165 years). It is noted that Cias et al. (2013) suggested that the ocean was a net source of CO₂ in the preindustrial era to an amount of 0.7 PgC yr⁻¹, whereas our model shows it as a net sink in the same condition. This is likely attributable to the lack of a process of riverine carbon input in our model. For example, Cias et al. (2013) estimated that the ocean obtains an external carbon input of 0.9 PgC yr⁻¹ from rivers, of which 0.2 PgC yr⁻¹ is removed by ocean sedimentation and 0.7 PgC yr⁻¹ is lost from the ocean to the atmosphere via gaseous exchange. The sedimentation process cannot explain all the increase of oceanic carbon in the CTL run (30 PgC). Therefore, the remainder should be attributed to other reasons, e.g., the shortness of the spin-up period or imperfect mass conservation in the ocean biogeochemical component.

875 The HIST run shows the cumulative carbon uptake by the ocean, which is driven predominantly by CO₂ increase (Fig. 8b and 8d). In comparison with land, ocean carbon shows a relatively small response to climate change (red line in Fig. 8d), which is consistent with analysis of the carbon cycle feedback in an idealized scenario (Arora et al., 2013). Furthermore, the model shows weak or almost no response against LUC (green line in Fig. 8d), although the ocean component in the model actually receives increased nitrogen input from rivers attributable to LUC and agriculture (Fig. 9, Table 4). This suggests that the increase of riverine nitrogen input due to LUC and agriculture would not induce significant global-scale impact on ocean carbon uptake in the historical period. The model simulates cumulative carbon uptake of 163 PgC for 1850–2014, which is within the range of 150 ± 20 PgC (vertical black bar in Fig. 8b) reported by Le Quéré et al. (2018).

885 Overall, MIROC-ES2L qualitatively captures the temporal evolution of carbon dynamics in the historical period; the cumulative carbon uptake by both land and ocean is within the range of the estimates by Le Quéré et al. (2018). However, the model might overestimate net carbon uptake by the land and/or ocean, or underestimate LUC emissions. This is because the cumulative fossil fuel emission, diagnosed from the simulated atmosphere–land/ocean CO₂ fluxes and

prescribed CO₂ concentration change (FF = CA + CL + CO; Appendix D), was 447 PgC, i.e., larger than the estimate of 400 ± 20 PgC of Le Quéré et al. (2018). Additionally, this speculation is also supported by the diagnosed CO₂ concentration at the end of the HIST run (Appendix D); the diagnosed concentration is 376 ppmv, which is lower (by 22 ppmv) than that actually monitored. We note, however, the likely biases in land/ocean carbon uptake, suggested by the larger diagnosed emission/lower diagnosed CO₂ concentration, could be alleviated partially if the model were driven by anthropogenic CO₂ emissions. This is because in emission-driven mode, the relatively stronger land/ocean carbon uptake leads to lower atmospheric CO₂ concentration, which could weaken the land and ocean sink through negative CO₂-carbon feedback. Indeed, in emission-driven mode, the atmospheric CO₂ concentration in the historical run (“esm-historical”, Jones et al., 2016) is simulated to be 384 ppmv in 2014 (as an average of three ensemble experiments; data not shown but available via the Earth System Grid Federation servers), which is closer to the actual level monitored (but still lower by 14 ppmv). Additionally, in emission-driven mode, land and ocean are mutually interlinked via the atmospheric CO₂ concentration; thus, strong bias of CO₂ flux in one component can be modulated by the other. This mechanism might reduce the bias of CO₂ fluxes of land and ocean simultaneously, or it might exacerbate CO₂ flux by imposing the flux bias of one onto the other. For more detail, simulations and multimodel analyses based on emission-driven configurations are necessary, as designed in C4MIP (Jones et al., 2016).

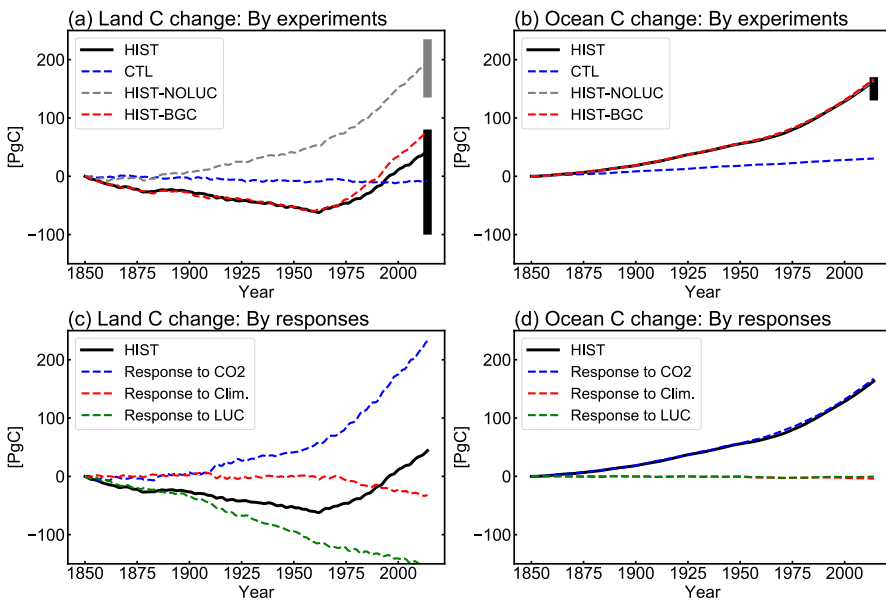

Figure 8

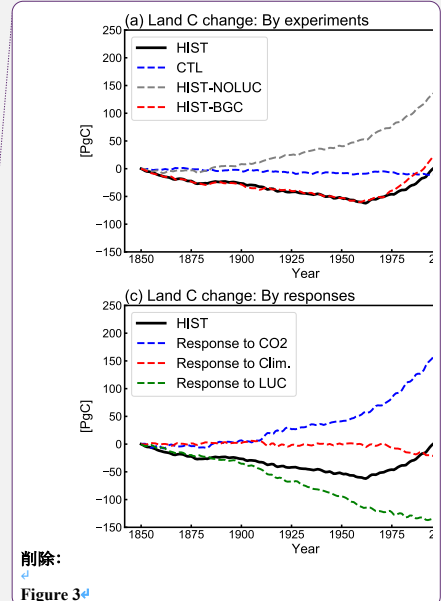

Figure 3

945 Land and ocean carbon change (i.e., cumulative net carbon uptake by land and ocean) in historical simulations. Upper panels present simulation results of historical (HIST, black lines), historical without land-use change (HIST-NOLUC, dashed gray), historical without climate change (HIST-BGC, dashed red), and control (CTL, dashed blue) runs. For land calculation, carbon amount change in product pools for land use is considered. Vertical bars represent uncertainty ranges estimated from Le Quéré et al. (2018). Black bars correspond to HIST (1850–2014) run result, and gray bar represents the uncertainty range for natural carbon sink of land, which corresponds to HIST-NOLUC run in this study. In the lower panels, the HIST run result is shown again (black lines) together with the decomposed response of land/ocean carbon driven only by CO₂ increase (dashed blue), climate change (dashed red), and LUC (dashed green). Note that the ocean in MIROC-ES2L considers carbon removal via sedimentation process onto ocean floor; thus, the model exhibits continuous carbon uptake, even in the CTL experiment.

3.1.3. Global nitrogen budget

MIROC-ES2L can simulate the global nitrogen cycle under interaction with climate and the carbon cycle, and the global N budget of land and ocean in the HIST simulation is shown in Fig. 9 as component fluxes. Comparison of the terrestrial nitrogen budget in the 2000s with the preindustrial condition (Table 3) reveals the annual inputs of nitrogen via deposition and fertilizer, which are controlled by forcing data, increase to 65.5 and 114 TgN yr⁻¹, respectively. Additionally, BNF is also increased by 40% (39 TgN yr⁻¹), which is caused by areal expansion of agriculture for N-fixing crops (Fig. 9, Supplementary Fig. 8). Previous studies have shown similar levels of increase. For example, Gruber and Galloway (2008) reported a value of 35 TgN yr⁻¹, and the absolute magnitude of agricultural BNF in the present-day condition was estimated as 50–70 TgN yr⁻¹ by Herridge et al. (2008) and 40 TgN yr⁻¹ by Galloway et al. (2008).

For terrestrial nitrogen efflux, Gruber and Galloway (2008) reported N₂ emission in the unperturbed state was 100 TgN yr⁻¹, i.e., larger than found in this study (72 TgN yr⁻¹). However, in the present-day condition, they estimated the absolute magnitude of N₂ emission as 115 TgN yr⁻¹, which is reasonably close to our model result (111 TgN yr⁻¹). MIROC-ES2L simulates the historical increase of N₂O emission from soil as 4.3 TgN yr⁻¹ from the preindustrial condition to the 2000s, which is comparable with the estimate of approximately 4 TgN yr⁻¹ for 1861–2015 derived from a model comparison study (Tian et al., 2018). However, the absolute magnitude of terrestrial N₂O emission fluxes in preindustrial and present-day conditions are likely overestimated (Table 3; Hashimoto, 2012).

Although it is difficult to obtain observation-based estimates on how much nitrogen was accumulated by the land ecosystem in the historical period, the model demonstrates net nitrogen uptake by land in the 2000s as 37 TgN yr⁻¹ (Table 3). This positive uptake is likely caused by increased total nitrogen input into the land ecosystem. In addition to the increasing N input, the net positive N uptake by land is likely accelerated by the increased nitrogen demand by plants and soils that have higher C:N ratios under elevated CO₂ concentrations. This is because the net increase of land N uptake is also found in IPPY-BGC (Supplementary Table 1), even though the N inputs such as BNF, fertilizer, deposition, and climate condition in the IPPY-BGC simulation are almost unchanged from the CTL run. This suggests that atmospheric CO₂ increase in HIST has changed the C:N ratios in plants and soil and hence stimulated ecosystem nitrogen demand. The model demonstrates nitrogen loss by LUC at a rate of >50 TgN yr⁻¹ (Fig. 9). It is because the harvested biomass in the model is translocated to product pools, and the nitrogen contained in the biomass is assumed lost with implicit chemical form, together with carbon loss as CO₂.

Compared with land, the model simulates relatively stable dynamics of the oceanic nitrogen budget but with larger interannual variation (Fig. 9b). In the 2000s, oceanic BNF is simulated as 126 TgN yr⁻¹, which is almost at the same level (slightly below) that of the preindustrial state, i.e., 129 TgN yr⁻¹ (Table 4). This number is close to previously reported estimates of approximately 130 TgN yr⁻¹ (Eugster and Gruber, 2012). The invariant behavior of BNF in the model suggests that the historical change in nitrogen input into the ocean is attributable primarily to two external sources: deposition and riverine input. Nitrogen deposition into the ocean, which is prescribed in the forcing data, shows an increase from 14 TgN yr⁻¹ in the preindustrial condition to 35 TgN yr⁻¹ in the 2000s. Riverine nitrogen input at river mouth is shown to increase from 17.5 TgN yr⁻¹ in the preindustrial condition to 33.9 TgN yr⁻¹ in the 2000s (Table 4; this is discussed further in Sect. 3.1.5 and Sect. 3.2.3). In this study, the gross nitrogen input into the ocean in the present-day condition is simulated as 195 TgN yr⁻¹. The value is reasonably close to the estimate of 200 TgN yr⁻¹ by Wang et al. (2019) and that of 209 TgN yr⁻¹ by Galloway et al. (2004); however, it is smaller than other published estimates (e.g., 294

1045 TgN yr⁻¹; Codispoti et al. (2001) and 270 TgN yr⁻¹; Gruber and Galloway (2008)). Denitrification, the main source of
 ocean nitrogen loss, is simulated as 142 TgN yr⁻¹ for the preindustrial condition and 165 TgN yr⁻¹ for the 2000s. These
 values are within the wide range of total denitrification rate estimated by previous studies, i.e., 145–450 TgN yr⁻¹ (Eugster
 and Gruber, 2012). It should be noted that the present model used in this study does not include sedimentary
 denitrification. Thus, the expected N flux by sedimentary denitrification is imposed on water-column denitrification, and
 1050 the rate of water-column denitrification is likely overestimated. Overall, the model exhibits oceanic N imbalance of 26.1
 TgN yr⁻¹ in the present-day condition (Fig. 9, Table 4).

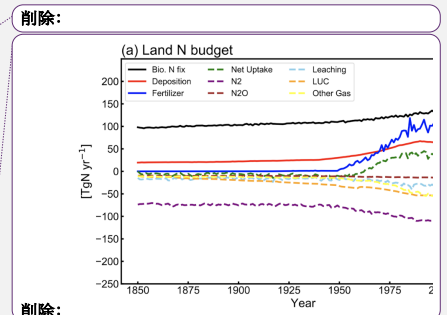

1055 **Figure 9**

Rate of change of global nitrogen budget in (a) land and (b) ocean in the HIST simulation. Solid lines represent the
 nitrogen input into the land/ocean, and dashed lines represent its fate. Positive (negative) values mean flux into (out of) the
 land/ocean. In panel (a), BNF (black line) considers both natural and agricultural fluxes. LUC (dashed orange line) is an
 emission derived from the decay of biomass in the LUC-product pools. Other gases (yellow line) represent the sum of
 1060 NH₃ emission and flux from abiotic sources. For the ocean, denitrification (purple line) includes both N₂ and N₂O
 emissions. The rate of nitrogen loss by the sedimentation process onto the ocean floor is not shown in the figure because
 of the small size of the flux (<0.015 TgN yr⁻¹). All nitrogen gas emissions are diagnosed and thus have no effect on the
 radiative balance in the atmosphere or on air quality change.

1065 **3.1.4. Land biogeochemistry**

Model performance in relation to land biogeochemistry is evaluated based on the spatial distributions of three
 fundamental variables of the land carbon cycle in comparison with observation-based products. First, GPP in the HIST
 simulation is compared with the global product by Jung et al. (2011) (Fig. 10a–c). The model simulates high productivity
 1070 (>2000 gC m⁻²) in the tropical forests of central Africa, Southeast Asia, and Southern America, although the productivity
 in these regions is generally still underestimated in comparison with the observation-based product. This underestimation
 is likely attributable to the use of the parameter values of photosynthetic capacities (K_{PSAT1} and K_{PSAT2} in Appendix A)
 from Kattge et al. (2009). This is because Kattge et al. (2009) also showed such substantial depression of photosynthetic

削除: **<#>Climate: atmosphere and ocean physical fields**
 Here, we present an overview of the performance of the mean state of the physical fields, atmosphere, and land/oceanic basic variables of the model in comparison with various observational based data. The variables examined here are SAT, precipitation, SST, sea ice concentration and land snow cover, and mixed-layer depth, all of which are representative physical states associated with biogeochemical processes. Shown in Fig. 5 is the climatology of SAT (air temperature at 2-m height) averaged over 1989–2009 for annual, December–February (DJF), and June–August (JJA) means, and the biases in comparison with the ERA-Interim dataset (Dee et al.,

削除: 2011). The comparison suggests that the model performs well (biases <2°C) over the tropics and most of the global area in terms of both annual mean and seasonality. However, obvious warm biases exist over the Southern Ocean and Antarctica. This is a general tendency of state-of-the-art general circulation models, and both MIROC5 (Watanabe et al., 2010) and MIROC6 (Tatebe et al., 2019) also suffer this problem. The warm bias in the Southern Ocean can be attributed to the difficulty of expressing cloud cover in the region (Hyder et al., 2018) and poor representations of the mixed-layer depth and deep convection in the open ocean attributable to the lack of modeled mesoscale processes in the Antarctic Circumpolar Current (Tatebe et al., 2019). A related warm bias in SST over the Southern Ocean is also confirmed, which is discussed later.

削除: ... [1]

書式変更: フォント: 斜体
 削除: higher

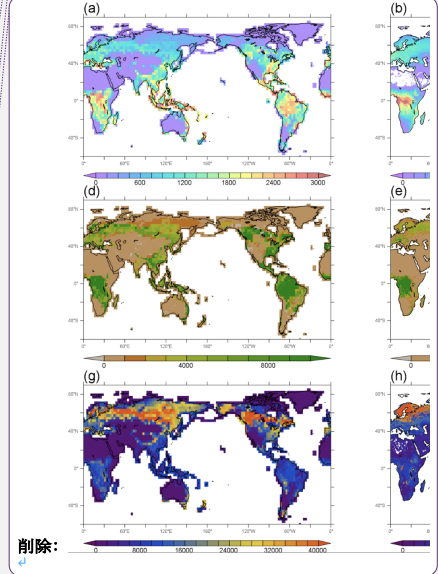

1155 capacity in the tropics. The model captures well the moderate productivity of vegetation in savanna regions such as the eastern side of South America and the marginal region surrounding central Africa. Moderate GPP is also found in the Northern Hemisphere in the region 20°–45°N, where a large proportion of land cover is dominated by both natural and agricultural vegetation (Supplementary Fig. 2). The GPP gradient from moderate to lower GPP in boreal to tundra regions of Eurasia and North America is captured well by the model. The model estimates global GPP at 124 PgC yr⁻¹ in the 2000s (Table 3), which is within the range of 106–140 PgC yr⁻¹ produced by the CMIP5 ESMs and is reasonably close to the value of 119 PgC yr⁻¹ derived from an observation product (1986–2005 average; Jung et al., 2011). The simulated GPP seasonality is also compared with that of Jung et al. (2011) (Supplementary Fig. 9). It reveals a reasonable summertime peak and the seasonality of GPP in the extratropical Northern/Southern Hemisphere, where vegetation phenology is controlled primarily by air temperature. However, the region around 40°N displays a longer growing season than that of Jung et al. (2011), and the tropics (20°S–20°N) show less seasonality, suggesting room for improvement of the phenology-related processes and surface climate fields in the corresponding region/biome types.

To evaluate the simulated vegetation carbon, we compare the model results of forest carbon, not total vegetation carbon, with those of Kindermann et al. (2008) (Fig. 10d–f). The model reproduces the reasonably high density of biomass in tropical forests, although the values are smaller than the observation product (Fig. 10f). This is attributable partly to the underestimation of GPP in this region, as described above. In high-latitude regions of the Northern Hemisphere (around 50°N), the model overestimates biomass density, particularly in terms of the evergreen coniferous forests that extend across western Siberia and North America. GPP in these regions is captured reasonably well by the model (Fig. 10a and 10b), and thus the overestimation of boreal forest biomass is likely due to the underestimated turnover rate of forest carbon. Slight overestimation of biomass is also found in the region where intensive cultivation has occurred, i.e., Europe, Southeast–East Asia, and eastern America. The model estimates global vegetation carbon content including all types of vegetation at 543 PgC (Table 3).

In Fig. 10g–i, the model results of soil organic carbon (SOC) are compared with two different types of SOC products: harmonized soil property values for broadscale modeling (WISE30sec) by Batjes (2016) and the Northern Circumpolar Soil Carbon Database version 2 (NCSCDv2) by Hugelius et al. (2013). The former is a global dataset that represents soil column SOC down to the depth of 2 m, whereas the latter targets only the high-latitude region of the Northern Hemisphere at different soil depths (~1, ~2, and ~3 m). Comparison with WISE30sec confirms that the model successfully captures the spatial distribution of lower carbon accumulation in arid and tropical regions and higher SOC in boreal regions in the Northern Hemisphere. However, the simulated zonal mean SOC in the boreal regions is about half that of WISE30sec (Fig. 10i). This is likely attributable to different treatment of frozen carbon in deeper soils in permafrost regions, i.e., WISE30sec covers the total SOC down to 2 m depth including frozen carbon, while the model does not consider the frozen carbon and instead simulates only upper SOC as litter form and lower SOC as humus. The model result in the boreal region is comparable with the NCSCDv2 estimation for 1 m depth. We note, as mentioned by Todd-Brown et al. (2012), large uncertainty remains in the estimation of SOC amount, especially in boreal regions. Globally, SOC is simulated as 1491 PgC (Table 3) in this study, which is smaller than the value of 2060 ± 215 PgC of WISE30sec (Batjes, 2016) but comparable with the range of 890–1660 PgC, as estimated by Todd-Brown et al. (2012) based on the Harmonized World Soil Database v1.2 (FAO/IIASA/ISRIC/ISS-CAS/JRC, 2012).

1220 3.1.5. Ocean biogeochemistry

In this section, we evaluate the simulated surface and vertical distributions of nitrate, phosphate, dissolved Fe, NPP, oxygen, DIC, and alkalinity against observations (Fig. 11). Additionally, ocean CO_2 flux is also compared with observation-based estimation (Fig. 12). The observations comprise the World Ocean Atlas 2013 (WOA2013; Garcia et al., 2014a, 2014b) for macronutrients and oxygen, GEOTRACES dataset (updated to its 2015 version; Tagliabue et al., 2012) for dissolved iron, Global Ocean Data Analysis Project version 2 (GLODAPv2; Lauvset et al., 2016) for DIC and alkalinity, and SeaWiFS (Behrenfeld and Falkowski, 1997) satellite observations for NPP.

1225

1235 Owing to the long spin-up, the drift in global averaged concentrations of biogeochemical tracers becomes close to zero. The linear drift of dissolved oxygen, NO_3^- , and Alk-DIC over the final 250 years of the spin-up is less than $3\% \text{ kyr}^{-1}$ (Supplementary Table 3). This small bias is significant in providing results on ocean biogeochemistry and carbon cycle feedbacks that are quantitatively more correct (Séférian et al., 2016).

書式変更: 下付き
削除: 3

1240 The simulated surface distributions of nitrate and phosphate are generally in agreement with the WOA2013 datasets (Fig. 11a and 11b). The surface macronutrient concentrations in HNLC regions (e.g., the Southern Ocean, North Pacific Ocean, and eastern equatorial Pacific Ocean) are higher than produced by the ocean biogeochemical component of our previous model (Watanabe et al., 2011) and they are more consistent with the observed values. This increase of macronutrients in HNLC regions is reasonable because the implementation of the iron cycle and the iron limitation on phytoplankton growth can reduce macronutrient utilization in these regions. Ocean circulation also influences the distribution of nutrient concentrations. In the Southern Ocean, the deep mixed-layer depths simulated by the model can cause overestimation of nutrient entrainment to the surface and thus produce high nutrient bias (Fig. 7). The simulated global mean vertical profile of nitrate concentrations compare reasonably well with observed values likely because the ocean circulation is represented adequately (Fig. 11a). To check the influence of ocean circulation on the tracer distributions, we compared the apparent oxygen utilization (AOU) between the model and observations (Supplementary Fig. 10). Although the model captures the observed AOU distributions, the strong and deep AMOC causes underestimation of AOU values in the Atlantic Ocean deep water. The largest bias is underestimation in the North Pacific Ocean, which is caused by the strong deep circulation of the Pacific Ocean. It should be noted that the difficulty of simulating the Pacific Ocean deep circulation appears to be a general problem in present coarse-resolution models (Hasumi et al., 2010). Model-data agreement of vertical nitrate concentrations is also the result of the near balance between nitrogen cycle sources (i.e., nitrogen fixation, atmospheric nitrogen deposition, and riverine nitrogen input) and sinks (i.e., denitrification, N_2O emission, and sedimentary loss) over the long spin-up period.

1255 The concentration of dissolved iron in the open ocean is highest in the subtropical North Atlantic Ocean and in the Arabian Sea (Fig. 11c), which is consistent with the pattern observed in GEOTRACES. Such high concentrations are caused by enhanced dust deposition from the Sahara Desert. In the remainder of the open ocean, dissolved iron concentrations are generally $<0.2 \mu\text{mol m}^{-3}$, especially in HNLC regions. The model captures well the main observed patterns in the surface ocean. The very high iron concentrations ($>1 \mu\text{mol m}^{-3}$) both observed and simulated along coasts and over continental margins are the result of iron input from sediment. The average simulated dissolved Fe concentration in the surface ocean (0–100 m) is $0.39 \mu\text{mol m}^{-3}$, which is lower than observed ($0.52 \mu\text{mol m}^{-3}$) but within the range of the iron model intercomparison project (FeMIP; Tagliabue et al., 2016). One factor not accounted for in our model is the variation in the solubility of iron in aerosols, which depends not only on the source chemical composition but also on atmospheric processing during transport (Ito et al., 2019). Consideration of different degrees of atmospheric Fe processing could reduce the overestimations of dissolved Fe concentration in the North Atlantic Ocean and North Pacific Ocean (Ito et al., accepted). Our model also neglects variations in sedimentary iron flux. Observations found iron release or burial in sediment is dependent on the oxygen concentration of bottom water (Noffke et al., 2012), ambient temperature (Sanz-Lázaro et al., 2011), and amount of OM that reaches the sea floor and is remineralized therein (Elrod et al., 2004). To simulate more realistic iron distributions, these processes should be considered in future studies.

削除: depend

1270 Reproducing the spatial pattern of nutrient limitation on phytoplankton growth is crucial for accurate prediction of primary production and for reflecting in the simulations the consequences of ongoing anthropogenic perturbations to oceanic nutrient cycles (Moore et al., 2013). The model reasonably reproduces the HNLC regions because of the iron

1280 limitation in the subarctic North Pacific Ocean, the equatorial Pacific Ocean, and the Southern Ocean (Supplementary Fig. 11), although the subarctic North Pacific Ocean and the equatorial Pacific Ocean have larger HNLC zones than observed upwelling regions. This is likely because of underestimation of surface iron concentrations and/or a relatively high half-saturation constant for iron uptake (Appendix B). Nitrogen limitation occurs throughout much of the low-latitude surface ocean where nitrogen supply from the subsurface is relatively slow.

- 削除: due to
- 削除: surface
- 削除:

1285 Based on the distribution pattern of nutrients and the limitations, annual NPP is simulated as 28.6 PgC yr⁻¹ (Table 4). This value is lower than a satellite-based estimate of 35–78 PgC yr⁻¹ (Carr et al., 2006) and it is also lower than the range of 30.9–78.7 PgC yr⁻¹ derived from the CMIP5 models (Bopp et al., 2013). This is likely attributable to the high half-saturation constant for iron uptake, as mentioned above. Although intense primary productivity in coastal regions is not resolved by the coarse grid, the modeled NPP agrees with the basin-scale patterns of observation-based NPP. The values
1290 of both modeled and observed NPP are high in regions of equatorial upwelling, the North Atlantic Ocean, and the Southern Ocean north of the polar front, whereas they are low in subtropical gyres (Fig. 11g). Global export production is estimated as 7.9 PgC yr⁻¹, which is the upper bound of the CMIP5 models (4.9–7.9 PgC yr⁻¹; Bopp et al., 2013).

1295 Simulated surface distribution of dissolved oxygen compares reasonably well with observations (not shown). This is because the surface oxygen concentration is close to its solubility value and it is strongly constrained by SST. At depth, oxygen minimum zones, in the eastern equatorial Pacific Ocean, eastern tropical Atlantic Ocean, Arabian Sea, and Bay of Bengal are reproduced well (Fig. 11f). However, the model produces oxygen concentration values higher than observed; thus, it underestimates the hypoxic volume ($[O_2] < 80 \text{ mmol m}^{-3}$) by a factor of three in comparison with data-based estimates (Bianchi et al., 2012). Note that existing global ocean biogeochemical models have difficulty in reproducing oxygen minimum zones owing to their coarse resolution and simple globally tuned parameterizations of vertical fluxes of
1300 OM (Cocco et al., 2013; Bopp et al., 2013). The positive bias in oxygen might be driven by wintertime mixing in the Southern Ocean and the North Pacific Ocean that is too intense (Fig. 7), which transports too much oxygen from the surface to depth.

- 削除: OMZs
- 削除:) and
- 削除: oxygen

The model also captures the global-scale patterns of observed DIC and alkalinity (Fig. 11d and 11e). High values of these tracers in subtropical gyres (and in the Southern Ocean for DIC) are found in the model output and observations. Salinity bias as well as parameterization of calcium carbonate production in the model can contribute to the alkalinity bias. Overestimation of alkalinity in subtropical gyres leads to overestimation of DIC because alkalinity affects the ocean's capacity to take up and store atmospheric CO₂.

Figure 12a shows the simulated annual mean air–sea CO₂ fluxes for the period 1985–2014 with observational estimates by Landschützer et al. (2014). Generally, the simulated spatial pattern is consistent with the data-derived estimates. The strongest carbon source to the atmosphere is found in the equatorial Pacific Ocean and the most intense carbon sink is found in the North Atlantic Ocean. Model outgassing is weaker than the observational estimate in the North Pacific and equatorial Indian oceans. The model–data discrepancies are pronounced in the seasonal cycle of air–sea CO₂ fluxes in the Southern Ocean and the North Atlantic Ocean (Fig. 12b and 12c). In the Southern Ocean, the model simulates an opposite CO₂ flux seasonal phase, which could be driven by the bias in SST variability (Kessler and Tjiputra, 2016). In the North Atlantic Ocean, although the simulated seasonal phasing of CO₂ fluxes agrees with the observational estimate, the amplitude is overestimated. The processes driving the seasonal cycle should be investigated in future studies because simulating a proper regional seasonal cycle of air–sea CO₂ fluxes is important for future projection (Kessler and Tjiputra, 2016; Goris et al., 2018).

1350

1355 3.2. Sensitivity analysis

3.2.1. Sensitivity of land biogeochemistry

To evaluate the sensitivities of modeled land biogeochemistry, we focus on GPP and its response to external forcing in the terrestrial system because this carbon flux is the primary driver of land carbon input. GPP change was calculated by taking the difference of the 2005–2014 averages between the HIST and CTL runs. Then, as diagnosed in Fig. 8c, the GPP change was decomposed into the response to (1) CO₂ increase, (2) climate change, and (3) LUC and agricultural change (Fig. 13) based on the simulation results of HIST, HIST-NOLUC, and HIST-BGC (Tables 1 and 2). Additionally, the GPP changes were further decomposed into the contributions from non-crop (i.e., contribution of primary/secondary vegetation, urban, and pasture) and crop tiles by weighting the GPP of each tile by their areal fractions on a grid.

1360

Fig. 13d–f shows that CO₂ increase in the historical period is the main driver of change in the land carbon cycle, and that the CO₂ fertilization effect prevails over most land areas except desert regions. Conversely, GPP response to climate change shows both positive and negative signs (Fig. 13g–i) with relatively smaller magnitudes. Mid-high-latitude regions of the Northern Hemisphere show positive change in GPP, that is likely attributable to lengthening of the vegetation growth season, enhanced plant growth following accelerated soil mineralization due to warming, and other mechanisms (e.g., soil water increase via precipitation and permafrost melting). In semiarid regions (i.e., Africa, South Asia, Northern

1365

- 删除: In contrast
- 删除: - to
- 删除: shows
- 删除: ,
- 删除: due
- 删除: of the Southern Hemisphere

1380 Australia, and the eastern side of South America), GPP shows slight reduction. As these regions have less precipitation in comparison with the tropics, the reduction in GPP is likely associated with precipitation change.

In addition to the responses to CO₂ increase and climate change, the model demonstrates spatial variation in the response of GPP to LUC (Fig. 13j). Historical LUC reduces the non-crop GPP contribution (Fig. 13k), while the crop contribution is enhanced (Fig. 13l). In the tropics, LUC reduces the non-crop GPP but weakly increases crop GPP, which results in net negative reduction of GPP as grid averages (Fig. 13j). Meanwhile, regions with intensive agriculture with nitrogen fertilizer input (e.g., Western Europe, East Asia, and parts of North America) show net positive change of GPP as grid averages, where increases in the crop contribution overcome reductions in the non-crop contribution (Fig. 13k and 12l). In the model, the crop contribution to GPP can be intensified by the following: 1) increasing the areal fraction of the crop tile following LUC forcing; 2) changing the vegetation type from natural vegetation to crop, whereby the latter has higher photosynthetic capacity than natural plant functional types (given as parameters that relate photosynthetic capacity with leaf nitrogen concentration, Appendix A); 3) applying nitrogen fertilizer to crop tiles; and 4) increasing nitrogen input via nitrogen-fixing crops, which is considered in the model as a subcategory of crop tiles. Indeed, the total area of cropland increases in the 20th century in the HIST simulation (Supplementary Fig. 2), which is reflected by the model producing an increase of nitrogen input via fertilizer application and biological fixation on the global scale (Fig. 9a).

1395 By responding to CO₂ increase, climate change, and LUC, most land areas show increased GPP in the historical period (Fig. 13a) and regions with intensive agriculture show greater increase in GPP than induced solely by the CO₂ fertilization effect (Fig. 13a and 13d). This suggests modeled GPP is sensitive to land use and agricultural management forcing in addition to the increase of CO₂, and that this might be one of the reasons for the slowing of LUC-induced land carbon reduction in the latter half of the 20th century in the HIST simulation (green line in Fig. 8c).

3.2.2. Sensitivity of ocean biogeochemistry

In this section, we investigate the sensitivity of oceanic NPP to external nutrient inputs from atmospheric deposition and river discharge processes under preindustrial conditions because these processes are newly incorporated into the ESM. Through combination of the simulation results of CTL-D, NO-NR, NO-NRD, and NO-FD (Tables 1 and 2), the impacts of

1425 nutrient input on both nutrient concentration and primary productivity are analyzed (Fig. 14 for N input assessment and
Fig. 15 for Fe), and the spatial patterns of simulated nutrient limitation on NPP in the four experiments are examined (Fig.
16). Here, NO_3^- , Fe, and PO_4^{3-} limitation is diagnosed using the equations $\text{NO}_3^-/(\text{kN} + \text{NO}_3^-)$, $\text{Fe}/(\text{kFe} + \text{Fe})$, and $\text{PO}_4^{3-}/(\text{kP} +$
1430 $\text{PO}_4^{3-})$, respectively, as simulated in MIROC-ES2L (Equation (B17)); Fig. 16 presents the strength of each limitation
visualized by the intensity of each of the three primary colors (red, blue, and green). In the simulations, because changes
in NPP and surface nutrient concentrations continued to change over several decades following the abrupt switching-off
manipulation, the average over the final 10 years is used for the following analysis. The rapid response of NPP to changes
in nutrient input is consistent with that found in previous research (Somes et al., 2016).

First, the impacts of riverine N input on the surface nutrient concentration and NPP are assessed by subtracting the
zero-input scenario NO-NR from the control experiment CTL-D (Tables 1 and 2). Surface NPP is increased by riverine N
1435 input (by $>10 \text{ gC m}^{-3} \text{ yr}^{-1}$) in coastal areas such as the North Brazil Shelf and Gulf of Mexico (Fig. 14a). In comparison
with the pattern of distribution of nutrient limitation (Fig. 16a and 16b), it is clear that strong NPP increase in the open
ocean occurs mainly in the Atlantic Ocean, which is under an N-limited condition. Conversely, NPP decreases in Fe-
limited regions because the NPP increase in N-limited regions consumes surface dissolved Fe. Surface NO_3^- concentrations
increase only slightly in N-limited regions because NO_3^- is immediately consumed locally by phytoplankton. Remarkable
1440 increase in surface NO_3^- concentrations is found in Fe-limited regions such as the Kara Sea, North Atlantic Ocean, Hudson
Bay, and Subantarctic Ocean. Global NPP increases by 0.7 PgC yr^{-1} (by 2.5% in comparison with NO-NR). This value is
comparable with the finding of da Cunha et al. (2007), who estimated a 5% increase in primary production due to riverine
nutrient input. Note that nutrient retention in estuarine areas is not considered in our model. Thus, most nitrogen supplied
from river mouths can easily be conveyed to the open ocean. Given that a recent modeling study estimated that
1445 approximately 75% of riverine nitrogen globally escapes from shelf areas to the open ocean (Sharples et al., 2016), our
results on the impact of riverine N on NPP should be viewed as an upper limit for the estimation.

Second, the effects of atmospheric N deposition on surface nutrient concentration and NPP are evaluated by subtracting
the zero-input scenario NO-NRD from the NO-NR experiment (Tables 1 and 2). Similar to riverine N input, atmospheric
N deposition causes an increase of NPP in N-limited regions and a global increase in NO_3^- (Figs. 14b, 16a, and 16c).
1450 According to deposition flux, significant changes in NPP are found in coastal areas and low-latitude regions of the Pacific
Ocean. Global NPP increases by 0.3 PgC yr^{-1} (by 1% in comparison with NO-NR), which is consistent with previous
estimates (Duce et al., 2008; Moore et al., 2013).

1460

1465

1470

1475

Finally, changes in surface nutrient concentration and NPP, driven by atmospheric Fe deposition, are calculated by subtracting the zero-input scenario NO-FD from the control experiment CTL-D (Tables 1 and 2). In contrast to N input, atmospheric Fe deposition causes an increase of NPP in Fe-limited regions and a decrease in N-limited regions (Figs. 15, 16a, and 16d). Significant Fe increase is found in N-limited regions. Global NPP and export production increase by 1.8 and 0.8 PgC yr⁻¹, respectively (by 6.7% and 11%, respectively, in comparison with NO-FD). These percentage increases are consistent with previous estimations by Moore et al. (2013). However, the sensitivity of export production to Fe deposition from dust is higher than reported by Tagliabue et al. (2014), who estimated export production increases by 0.06–0.11 PgC yr⁻¹. Therefore, it seems difficult to obtain robust sensitivity both of iron and of the biological cycle to iron input because of the high uncertainty regarding the iron cycle among models. Although nitrogen input from both deposition and rivers has little effect on the spatial patterns of distribution of nutrient limitation (Fig. 16a–c), iron input from the atmosphere changes the pattern in low-latitude regions from iron limitation to nitrogen limitation (Fig. 16a and 16d).

Circles in (a) represent observed limiting nutrients from nutrient addition experiments (Moore et al., 2013).

1510 Here, we examine model sensitivity against global inputs of both N and Fe into the ocean through atmospheric deposition and river discharge in the preindustrial condition. We note, however, these two types of nutrient input have increased significantly since the preindustrial era because of human activities (Duce et al., 2008; Seitzinger et al., 2010; Krishnamurthy et al., 2010). Additionally, ongoing nutrient input increase can lead to future increase in biological production, which might partly negate the production decrease driven by global warming. Conversely, the resultant increase in export of OM would accelerate CO₂-induced ocean acidification and warming-induced deoxygenation in subsurface waters, which leads to major environmental pressures. Thus, the combined effects of global warming and anthropogenic nutrient input on ocean biogeochemical cycles should be explored in the future.

3.2.3. Sensitivity of riverine nitrogen

1520 The coupling of land and ocean ecosystems via riverine nitrogen is one of the new features of MIROC-ES2L, and the potential impact of the process on ocean biogeochemistry has already been examined and discussed in Sect. 3.2.2. Here, we examine the response of river nitrogen loading itself against anthropogenic forcing by comparing the results of the CTL, HIST-NOLUC, and HIST simulations.

削除:

1525 As mentioned in Sect. 3.1.3, the global flux of riverine nitrogen input into the ocean is simulated at 17.5 TgN yr⁻¹ in the CTL experiment (Table 4), and the flux is almost doubled in the 2000s at 33.9 TgN yr⁻¹ in the HIST run. This number is larger than previous estimates of 19–25 TgN yr⁻¹ for the present-day condition (Smith et al., 2003; Mayorga et al., 2010; Dumont et al., 2005). This overestimation might be caused by the inability of the model to simulate all forms of nitrogen in rivers. For example, the model simulates only dissolved inorganic nitrogen (DIN) flux; thus, the expected nitrogen flux with non-DIN forms (e.g., dissolved organic and particulate matter) might be partly imposed on the DIN flux in the simulations. Indeed, global total nitrogen flux, including DIN, dissolved organic nitrogen, and particulate nitrogen is estimated at 37–66 TgN yr⁻¹ (Beusen et al., 2016; Mayorga et al., 2010; Boyer et al., 2006; Seitzinger et al., 2005), which is closer to the result of MIROC-ES2L.

削除: already

1530 Another possible reason for the above overestimation is precipitation bias, which results in overestimation of BNF on land. As mentioned in Sect. 3.1.1, the model has positive precipitation bias on land, in arid/desert regions (Supplementary Fig. 6). As the scheme for natural BNF flux employed in MIROC-ES2L is modeled to be controlled by the actual evapotranspiration rate (Cleveland et al., 1999), the precipitation bias in arid regions could easily lead to overestimation of the BNF flux and increase of riverine nitrogen loading. This is also evident when decomposing the global riverine flux into river basins and comparing the findings with a previous study by Dumont et al. (2005) (Fig. 17). MIROC-ES2L overestimates the DIN fluxes of large rivers such as the Amazon, Mississippi, and Yangtze rivers, even in the CTL experiment, in which all anthropogenic forcings are fixed at preindustrial levels. This suggests the necessity of improvement of the baseline flux of riverine nitrogen in the model. For more in-depth discussion, it will be necessary to simulate explicitly the organic and particulate nitrogen fluxes in rivers, and it might be necessary to simulate the explicit sedimentary and chemical-reaction processes in freshwater and coastal zone systems.

削除: where

1540 In Fig. 17, the difference between the results of CTL and HIST-NOLUC mainly reflect the change induced by nitrogen deposition (and historical climate change) (Table 2), and the model demonstrates that deposition has increased N fluxes in many rivers. Additionally, the difference between HIST-NOLUC and HIST demonstrates the impact of LUC and agricultural management change (Table 2), and regions that have intensive agriculture within their watersheds (e.g., the

削除: Although bias exists in the magnitude of riverine nitrogen flux both globally and locally, we confirm the model capable of capturing qualitatively the changes in riverine nitrogen flux during the historical period. In Fig. 16,

削除: In addition

565 basins of the Mississippi, Indus, Yellow, and Yangtze rivers) are simulated as strongly affected by the forcing change. The
 570 DIN discharge in each river is not always smaller in HIST-NOLUC than in HIST. This is because LAI in HIST-NOLUC
 is different to that in HIST, which sometimes is accompanied by slight change in the surface climate via biophysical
 feedback. If soil temperature is slightly warmer in HIST-NOLUC than in HIST, the soil mineralization rate in HIST-
 NOLUC should be accelerated and thus the DIN loadings of rivers could be increased. This simulated trend in the
 historical period is qualitatively consistent with previous studies (Gruber and Galloway, 2008). Furthermore, the model
 simulates the global riverine flux to be increased by 16.4 TgN yr⁻¹ in the historical period. This value is quantitatively
 consistent with previous estimates, e.g., 16 TgN yr⁻¹ by Dumont et al. (2005) for DIN flux, and 18 and 19 TgN yr⁻¹ by
 Beusen et al. (2016) and by Green et al. (2004), respectively, for total N flux. Although bias exists in the magnitude of
 575 riverine nitrogen flux both globally and locally, we confirm the model can qualitatively capture the changes in riverine
 nitrogen flux during the historical period.

 largest rivers. Vertical gray bars represent observations (Dumont et al., 2005); blue, green, and yellow bars correspond to
 the results of the HIST, HIST-NOLUC, and CTL experiments, respectively.

3.2.4. TCR, AF, and TCRE

585 Here, the model sensitivity of the global climate-carbon cycle against CO₂ increase is analyzed by calculating TCR, AF,
 and TCRE from the results of the IPPY, IPPY-BGC, and IPPY-RAD experiments (see Sect. 2.2.2 for the method). These

削除: We have evaluated the performance of MIROC-ES2L in terms of climate and biogeochemistry using the HIST simulation results (chapter 3.1), and we have explored how the model responds to forcing by comparing the results of different simulations (chapter 3.2).

quantities summarize the total performance of the climate, carbon cycle, and coupled climate–carbon cycle system in the models, which enables us to compare them with existing ESMs.

The TCR, AF, and TCRE derived from the 1PPY simulation are displayed in Table 5. The TCR of MIROC-ES2L is 1.5 K, which is lower than the multimodel mean of the CMIP5 ESMs but within the range of spread (1.8 ± 0.5 K; Gillett et al., 2013). Compared with our previous ESM (i.e., MIROC-ESM; Watanabe et al., 2011), the TCR has decreased by 32% because of the replacement of the physical core of the ESM from the MIROC3-based model to that of MIROC5 (Watanabe et al., 2010). The value of AF, which is a quantity that characterizes the carbon cycle response in an ESM but is dependent on TCR, was simulated at 0.61 in MIROC-ESM. This value is reduced to 0.52 in MIROC-ES2L, i.e., the new model has a stronger carbon sink than the previous version. The value of AF in the new model is of similar magnitude to the CMIP5 model average (0.53 ± 0.06 ; Gillett et al., 2013). The lowered TCR and the moderate AF cause the new model to have moderate TCRE (1.3 K EgC^{-1}), which is smaller than that of the CMIP5 model average ($1.6 \pm 0.5 \text{ K EgC}^{-1}$) by 19%. Using TCRE, we can approximate the value of CE until the global temperature exceeds a specific mitigation target; CE for the 2°C warming target should be approximately 1540 PgC for MIROC-ES2L, 910 PgC for MIROC-ESM, and 950–1820 PgC for the CMIP5 models.

Table 5.

Comparison of TCR, AF, and TCRE between MIROC-ES2L, MIROC-ESM, MIROC5.2, and CMIP5 ESMs in the 1PPY simulation. For MIROC-ES2L, both TCR and AF are calculated based on 20-year means of T2, CL, and CO centered on the 70th year of the 1PPY simulation (i.e., the time when the CO₂ concentration is doubled from the preindustrial condition), and TCRE is calculated based on TCR and AF. Numbers for the CMIP5-ESMs were obtained from Gillett et al. (2013) and are presented as the multimodel mean $\pm 1\sigma$.

削除:

書式変更: フランス語

To further explore why AF is lowered in MIROC-ES2L, the strengths of the carbon cycle feedbacks were analyzed using the 1PPY-BGC and 1PPY-RAD simulation results (Table 6), and the findings were compared with the CMIP5 ESMS (Arora et al., 2013). The strength of CO₂-carbon feedback (β) of land is simulated to be 0.52 PgC PgC⁻¹, which is slightly higher than the CMIP5 model average (0.43 ± 0.21 PgC PgC⁻¹) and larger than that of MIROC-ESM by 48%. The strength of oceanic CO₂-carbon feedback in the CMIP5 ESMS displays less spread among the models (0.38 ± 0.03 PgC PgC⁻¹) and the result of MIROC-ES2L is within this spread (0.35 PgC PgC⁻¹). The absolute magnitude of the climate-carbon feedback (γ) for land and ocean in MIROC-ES2L is -71 and -4.5 PgC K⁻¹, respectively, both of which are less negative than the result of MIROC-ESM by 20% for land and 63% for ocean. Consequently, the land γ in MIROC-ES2L is within the range of the CMIP5 ESMS (-58 ± 29 PgC K⁻¹), while the ocean γ is slightly larger than the upper range of the CMIP5 ESMS (-7.8 ± 2.9 PgC K⁻¹).

As the quantities β and γ have different units, it is difficult to conclude which feedback process contributes most to the AF change. To compare them with the same unit, we used the quantity “u” proposed by Gregory et al. (2009). This quantity, which is defined as $u_{\beta} = \beta$ and $u_{\gamma} = \gamma \times T/CA$, has the unit PgC PgC⁻¹, and it can relate the carbon cycle feedback parameters to AF, as $AF = 1/(1 + u_{\beta,L} + u_{\beta,O} + u_{\gamma,L} + u_{\gamma,O})$ (see Appendix E for the derivation). When comparing the u quantities of MIROC-ES2L with the CMIP5 models (Fig. 18), it is evident that the ocean component of MIROC-ES2L is less sensitive than the previous model for both CO₂-carbon and climate-carbon feedbacks. These two changes almost counteract each other; thus, the ocean component does not explain the reduced AF in the new model (Table 5). For land, the climate-carbon feedback (u_{γ}) in MIROC-ES2L is intermediate, while MIROC-ESM was one of the most sensitive models of the CMIP5 ESMS. Additionally, the magnitude of the land CO₂-carbon feedback (u_{β}) is increased from MIROC-ESM to MIROC-ES2L by 48% ($u_{\beta} = \beta$). Therefore, the land component is the main cause for the lower AF, making the magnitude of both the CO₂-carbon and the climate-carbon feedbacks more positive and less negative, respectively, i.e., strengthening the land carbon sink.

Table 6

Comparison of CO₂-carbon and climate-carbon feedback parameters between MIROC-ES2L, MIROC-ESM, and the CMIP5 ESMS. As presented in Arora et al. (2013), TCR, AF, and TCRE are calculated at the time when CO₂ concentration is quadrupled from the preindustrial condition (i.e., the 140th year in the 1PPY simulation) by taking the anomaly from the CTL run. Numbers of CMIP5 ESMS were obtained from Arora et al. (2013) and are presented as the multimodel mean ± 1 σ .

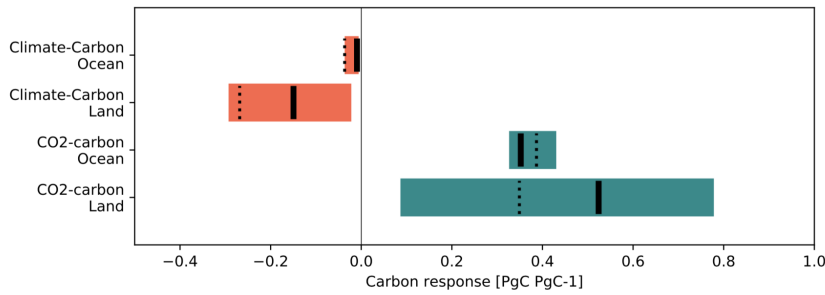

Figure 18

Comparison of strength of CO₂-carbon and climate-carbon feedbacks between MIROC-ES2L and the CMIP5 models evaluated using the 1PPY, 1PPY-BGC, and 1PPY-RAD experiments. Vertical solid and dotted black bars represent MIROC-ES2L and MIROC-ESM, respectively, and the horizontal bars represent the range of the CMIP5 ESMS (mean ± 1.65σ). To compare the two types of feedback strength with the same unit, land and ocean carbon storage change were both normalized by dividing the atmospheric carbon change, which corresponds to the “u” quantity proposed by Gregory et al. (2009): $CE = CA(1 + u_{\beta} + u_{\gamma})$, where $u_{\beta} = \beta$, $u_{\gamma} = \gamma \times \alpha$. If $u > 0$ ($u < 0$), the feedback sign is negative (positive). The calculations were based on the anomaly from the CTL run at the time of quadrupled CO₂ concentration from the preindustrial condition (i.e., the 140th year of the 1PPY, 1PPY-BGC, and 1PPY-RAD simulations).

1695

1700

1705 4. Summary and conclusions

In this study, a new Earth system model (MIROC-ES2L) was developed using a state-of-the-art climate model (MIROC5.2) as the physical core. This new ESM embeds a terrestrial biogeochemical component with explicit carbon-nitrogen interaction (VISIT-e) that accounts for the nutrient limitation of nitrogen on plant growth and therefore the change in the land carbon fluxes. Additionally, the ocean biogeochemical component (OECO2) is largely updated to simulate the biogeochemical cycles of carbon, nitrogen, phosphorus, iron, and oxygen such that oceanic primary productivity in the model is now controlled by multiple nutrient limitations. As a new challenge, land and ocean nitrogen cycles were coupled via river discharge processes; thus, marine productivity is now also affected by the riverine nitrogen input. Furthermore, iron-related processes such as emission, atmospheric transport, deposition, and utilization in the marine ecosystem are newly included to represent the micronutrient limitation on phytoplankton productivity. This is necessary to reproduce the HNLC regions and simulate ecosystem variability in response to changes in external iron inputs.

1710

1715

To evaluate the performance of the new model, a historical simulation following CMIP6 protocols and forcing datasets was performed for the 1850–2014 period, and the results were compared with observation-based products. The model reasonably reproduces the global changes in net TOA radiation balance, SAT, SST and upper-ocean temperature.

1730 Considering the few biophysical feedbacks on climate in the model, the MIROC-ES2L's good performance in simulating the physical fields is inherited from its original climate model (MIROC5.2), although persistent problems remain such as the warm bias in the Southern Ocean, as found in some climate models. Global carbon and nitrogen budgets in the historical simulation were also examined and discussed by comparing the results with existing studies. The model successfully captured the observation-based estimates of contemporary air–sea and air–land carbon fluxes in terms of cumulative values. The component fluxes of global nitrogen between land, atmosphere, and ocean are also reasonably reproduced by the model. The spatial distributions of fundamental variables of the land carbon cycle were also assessed through comparison with observation-based products, and the model produced reasonable patterns for primary productivity, forest carbon, and SOC. The spatial patterns of oceanic macro- and micronutrients, total inorganic carbon, alkalinity, oxygen, primary productivity, and oceanic CO₂ flux were all captured well in the historical simulation.

1740 To assess the global climate–carbon cycle feedback in MIROC-ES2L, a sensitivity analysis was performed in which atmospheric CO₂ concentration was prescribed to increase by 1% yr⁻¹. Then, the values of TCR, AF, and TCRC were calculated and compared with those of the CMIP5 ESMs. TCR in the new model is reduced to 1.5 K, which is approximately 70% of the previous model used for CMIP5, through the replacement of the physical core from the MIROC3-based model to that of MIROC5.2. AF is also reduced by 15%. Further feedback analysis of the carbon cycle

1745 revealed that most of the AF reduction should be attributable to the intensified land carbon sink in the new model, which results in a level of AF that is close to the average of the CMIP5 ESMs. TCRC, which is a quantity that aggregates the temperature response as a result of the entire climate–carbon cycle processes against anthropogenic CO₂ emissions, is 1.3 K EgC⁻¹ in MIROC-ES2L. This is reduced from the value seen in the model used for CMIP5 by 32% and it is slightly smaller than the multimodel mean of the CMIP5 ESMs. Thus, MIROC-ES2L might be an “optimistic” model in terms of

1750 simulating global climate and carbon cycle change, considering that some CMIP6-class models are likely to have higher climate sensitivity (Voosen et al., 2019). A multimodal comparison on feedback strengths using CMIP6 ESMs is necessary to clarify whether the climate and carbon cycle sensitivities in MIROC-ES2L are realistic, and to establish constraints on each feedback process based on observations (e.g., Wenzel et al., 2016; Goris et al., 2018).

In the new model, the terrestrial nitrogen cycle processes and the interaction with the carbon cycle are modeled explicitly. By performing several types of simulation, it was demonstrated clearly that agricultural management such as fertilizer application has changed the carbon cycle (GPP) in the historical period, which suggests that the nitrogen cycle in the model alters the land carbon cycle. The model simulated the change in the total land carbon content during 1850–2014 at 44 PgC, which is within the estimated range of Le Quéré et al. (2018). However, historical terrestrial carbon change is highly uncertain because the change is processed by multiple responses against the external forcing of CO₂, LUC, and climate change, each of which has its own estimation uncertainty. Thus, as performed in this study, decomposition of the impact of these forcings in historical simulations and in multimodel comparisons would be helpful in specifying the processes that produce the large simulation spread of the land carbon budget among the ESMs. Furthermore, although we confirmed that the nitrogen cycle alters the carbon cycle in the model, this study did not quantify the extent to which the soil nutrient deficit could down-regulate plant growth and reduce the natural carbon sink. For this, a sensitivity analysis associated with carbon–nitrogen interaction is planned in CMIP6 (Jones et al., 2016), and the multimodel comparison study will reveal the strength of the carbon–nitrogen feedback in MIROC-ES2L relative to other CMIP6-class ESMs.

790 In the new model, the ocean nitrogen cycle is modified to be an open system and thus the model can reflect the
 influences of external sources of nitrogen via atmospheric deposition and river discharge. Our sensitivity analyses under
 the preindustrial condition suggested minor contributions of these two external sources to primary productivity on the
 global scale. However, regions in which primary productivity is constrained by nitrogen availability showed a strong
 positive NPP response to the relaxation of nitrogen limitation. It accelerates the use of other nutrients within the marine
 ecosystem in such regions and it reduces iron and phosphorus availability in other regions. Furthermore, by switching on
 795 the process of iron deposition into the ocean, the model showed an increase of approximately 7% in primary production
 under the preindustrial condition, which suggests that iron input has a relatively stronger impact than nitrogen. Coupling
 of iron cycle processes in the model led to successful reproduction of HNLC regions, and it will enable the model to
 project future biogeochemical changes induced by anthropogenic iron emissions associated with the use of fossil fuels and
 biomass burning. We note, however, as an atmospheric chemistry module is not included in MIROC-ES2L, the
 1800 atmospheric chemical reaction of iron-containing aerosols is ignored and the iron solubility to seawater is simply assumed
 constant. Considering the relatively strong impact of iron deposition on marine primary productivity in the model, we need
 further detailed evaluation and modification of the iron cycle processes in terms of both aerosol transport and marine
 biogeochemical responses.

删除: inputs
 删除: global

1805 In addition to such improvements in terms of the iron cycle, other factors should also be improved/extended in the ESM
 for future simulation study. First, a freshwater biogeochemistry module is required. In the present model, the chemical
 form of riverine nitrogen is assumed inorganic, but actual river flow contains OM and particulate matter that undergo
 biogeochemical processing during transport. Thus, inclusion of the transport of organic/inorganic matter and the modeling
 of freshwater biogeochemistry might be necessary. This conclusion is supported by the sensitivity analysis that showed
 relatively strong regional-scale impact of riverine nitrogen on marine primary productivity, although the global-scale
 1810 impact was demonstrated to be minor. Second, MIROC-ES2L can simulate natural emissions of nitrous oxide; however,
 the emissions did not change the radiative balance in the atmosphere. Nitrous oxide is one of the strongest greenhouse
 gases with a long lifetime. As diagnosed in this study, future nitrous oxide emissions could be controlled by land use and
 agriculture, as well as climate change. Therefore, full coupling of the nitrous oxide cycle with other associated
 atmospheric chemical processes should be incorporated in the next-generation ESM, together with the methane cycle, as
 1815 suggested in previous studies (e.g., Collins et al., 2018). Third, a mechanistic model for the denitrification process in
 ocean sediment should be included in a future model. The present model simulates only the denitrification rate of water
 column, and the flux from sediment is likely imposed on the water-column denitrification. As the timescale of the
 sedimentary process is likely longer than that of water-column denitrification, explicit modeling of sedimentary
 denitrification will be important, particularly for long-term simulations over timescales of millennia. Finally, we partly
 1820 demonstrated the importance of external sources of nutrients for marine productivity, although its evaluation was
 performed under the preindustrial condition. As anthropogenic nutrient inputs under that condition are much smaller than
 under the present-day condition and could be amplified or mitigated in the future, a similar set of sensitivity simulations
 should be undertaken for present-day and future conditions.

1825 ESMs represent powerful tools to investigate interactions between climate, biogeochemistry, and human activities, and
 they have facilitated climate projections and quantifications of future emissions of greenhouse gases for achieving climate
 change mitigation goals. Such models are also valuable for examining how Earth system components might respond to
 different levels of mitigation policies/scenarios spanning from the business-as-usual scenario to one employing intensive
 measures such as geoengineering techniques. Furthermore, state-of-the-art ESMs can reproduce some of the dominant
 1830 long-term environmental changes on Earth that are becoming evident/doubted in association with climate change, e.g.,

1850 | ocean acidification and hypoxia, global nitrogen loading, air pollution, and habitable zone changes in ecosystems. ESMs
can simulate such problems and their interactions in a holistic and consistent manner. Such simulations have potential to
elucidate sustainable ways to mitigate climate change with less environmental stress. To support such applications, further
efforts should be made to improve ESMs and to constrain model performance in collaboration with observation studies.

5. Appendices

1855 Appendix A. Land ecosystem/biogeochemical component

A.1 Nitrogen cycle

The structure of carbon and nitrogen compartments and the flux calculations in VISIT-e mostly follow the original version of the model (Ito and Inatomi, 2012a). For N cycle and LUC processes, some major changes were brought to VISIT-e to couple the model with MIROC-ES2L; the details are described below.

1860

A.1.1. N compartment structure in VISIT-e

Terrestrial N dynamics in VISIT are simulated based on three major compartment groups of N storage: vegetation N (N_{VEG}), soil organic matter (N_{SOM}), and soil inorganic matter (N_{IOM}). The component N_{VEG} is composed of canopy N (N_{CAN}) and storage N (N_{STG}):

1865

$$N_{VEG} = N_{CAN} + N_{STG}.$$

The mass conservation equations for N_{CAN} and N_{STG} are as follows:

$$dN_{CAN}/dt = FN_{SBNF, CAN} + FN_{UPTK, CAN} + FN_{RALC} - FN_{MORT, CAN}, \quad (A1)$$

$$dN_{STG}/dt = FN_{SBNF, STG} + FN_{UPTK, STG} + FN_{WTHD} - FN_{MORT, STG}, \quad (A2)$$

1870 where FN represents nitrogen flux, and the subscripts SBNF, UPTK, RALC, WTHD, and MORT represent symbiotic biological N fixation, N uptake by plants, reallocation of storage N to the canopy, withdrawal of canopy N to storage, and loss of N by mortality, respectively. In this study, biological N input into vegetation (represented by FN_{SBNF}) is modified from the original model; the detail is described in Sect. A.1.2.

The component N_{SOM} is composed of the three nitrogen pools of litter (N_{LIT}), humus (N_{HUM}), and microbes (N_{MCR}):

$$N_{SOM} = N_{LIT} + N_{HUM} + N_{MCR}. \quad (A3)$$

1875

The N conservation equations for the pools are as follows:

$$dN_{LIT}/dt = FN_{MORT, CAN} + FN_{MORT, STG} + FN_{SBNF} - FN_{HUMF} - FN_{MNRL, LIT}, \quad (A4)$$

$$dN_{HUM}/dt = FN_{HUMF} + FN_{MORT, MCR} - FN_{MNRL, HUM}, \quad (A5)$$

$$dN_{MCR}/dt = FN_{IMBL} - FN_{MORT, MCR}, \quad (A6)$$

where subscripts NBNF, HUMF, MNRL, and IMBL represent nonsymbiotic BNF, humification of litter, mineralization of litter/humus, and immobilization by microbes, respectively. The components FN_{NBNF} and FN_{HUMF} are new components of flux, which are described in Sect. A.1.2 and Sect. A.1.3, respectively.

1885 The inorganic nitrogen is assumed to consist of N pools of NH_4^+ (N_{NH4}) and NO_3^- (N_{NO3}):

$$N_{\text{IOM}} = N_{\text{NH4}} + N_{\text{NO3}}. \quad (\text{A7})$$

The budget equation for N_{NH4} is as follows:

$$\begin{aligned} dN_{\text{NH4}}/dt = & FN_{\text{DEPO, NH4}} + FN_{\text{FERTL, NH4}} + FN_{\text{MNRL, LIT}} + FN_{\text{MNRL, HUM}} \\ & - FN_{\text{UPTK, NH4}} - FN_{\text{IMBL}} - FN_{\text{N2ON}} - FN_{\text{NTRF}} - FN_{\text{NH3V}} - FN_{\text{ALOS, NH4}}, \end{aligned} \quad (\text{A8})$$

1890 where subscripts DEPO, FRTL, N2ON, NTRF, NH3V, and ALOS represent deposition, fertilizer, N_2O emission of nitrification process, nitrification of NH_4^+ , NH_3 volatilization, and abiotic N loss, respectively.

The budget equation for N_{NO3} is as follows:

$$\begin{aligned} dN_{\text{NO3}}/dt = & FN_{\text{DEPO, NO3}} + FN_{\text{FERTL, NO3}} + FN_{\text{NTRF}} \\ & - FN_{\text{UPTK, NO3}} - FN_{\text{N2OD}} - FN_{\text{N2}} - FN_{\text{LECH}} - FN_{\text{ALOS, NO3}}, \end{aligned} \quad (\text{A9}),$$

1895 where subscripts N2OD and N2 represent N_2O and N_2 emissions in the denitrification process, respectively and LECH presents N leaching.

In the above two equations, FN_{DEPO} and FN_{FERTL} are forced by external datasets, while FN_{ALOS} is the process newly introduced in this study, which is described in Sect. A.1.4.

1900 A.1.2. Biological N fixation

BNF is calculated based on the actual evapotranspiration rate (Cleveland et al., 1999). In the original version of VISIT, all nitrogen fixed through BNF (FN_{BNF}) was assumed available for plants. As this assumption makes vegetation in the model less dependent on soil nutrient availability, the model is modified in that only a portion of BNF-N is made directly available for plant. For this, FN_{BNF} is decomposed into symbiotic BNF (FN_{SBNF}) and nonsymbiotic BNF (FN_{NBNF}):

$$1905 \quad FN_{\text{BNF}} = FN_{\text{SBNF}} + FN_{\text{NBNF}} \quad (\text{A10})$$

and

$$FN_{\text{SBNF}} = \alpha_{\text{SBNF}} \times FN_{\text{BNF}}, \quad (\text{A11})$$

$$FN_{\text{NBNF}} = (1 - \alpha_{\text{SBNF}}) \times FN_{\text{BNF}}, \quad (\text{A12})$$

where α_{SBNF} is the portion of N of symbiotic BNF. Here, α_{SBNF} is assumed as 0.5 as the landscape-level parameter.

1910 Nitrogen fixed by the symbiotic process is used directly by plants, while N fixed by nonsymbiotic microbes is assumed to directly form part of the litter. The BNF in cropland is modeled differently, as shown in Sect. A.2.3.

A.1.3. Mineralization, humification, and immobilization

The mineralization rate of litter is same as that in the original version, and it is calculated as follows:

1915
$$FN_{MNRL, LIT} = N_{LIT} \times (FC_{MNRL, LIT}/C_{LIT}), \quad (A13)$$

where $FC_{MNRL, LIT}$ is the C mineralization rate of litter and C_{LIT} is the amount of C in the litter pool.

The humus N mineralization rate is similar to that of litter but it is modified to be dependent on the humus CN ratio (CN_{HUM}):

$$FN_{MNRL, HUM} = N_{HUM} \times (FC_{MNRL, HUM}/C_{HUM}) \times (1 - f_{CN}(CN_{HUM})) \quad (A14)$$

1920 and

$$f_{CN}(CN_{HUM}) = S_{min} \times \exp((\log S_{max} - \log S_{min})/(R_{max} - R_{min}) \times (CN_{HUM} - R_{min})). \quad (A15)$$

Here, S_{max} and S_{min} are the maximum and minimum fractions of mineralized N that eventually move to the inorganic N pool (N_{NH4}), respectively. R_{max} and R_{min} are the maximum and minimum CN ratios in the humus pool, respectively. The term $1 - f_{CN}(CN_{HUM})$ controls the humus CN ratio to be between R_{max} and R_{min} , by accelerating humus N mineralization under a lower CN ratio and decreasing it under a higher CN ratio. Here, the values of $S_{max} = 0.95$ and $S_{min} = 0.05$ are assumed, and R_{max} and R_{min} are set to the values of 40 and 10, respectively.

1925

Immobilization rate is simplified in VISIT-e and it is modeled as a function of the mineralization rate of litter N, depending on the CN status in the humus:

$$FN_{IMBL} = FN_{MNRL, LIT} \times f_{CN}(CN_{HUM}). \quad (A16)$$

1930 Thus, N immobilization is accelerated if the humus has a high CN ratio and it decreases under a lower CN condition.

N flux by humification (N flow from litter to humus, $FN_{HUMF, LIT}$) is newly introduced in VISIT-e and it is modeled as follows:

$$FN_{HUMF, LIT} = N_{LIT} \times (FC_{HUMF, LIT}/C_{LIT}), \quad (A17)$$

where $FC_{HUMF, LIT}$ is the rate of C flux in the humification process, which is simulated in the C cycle part of the model.

1935

A.1.4. Abiotic N loss

Abiotic N loss from soil ($FN_{ALOSS, NH4}$ and $FN_{ALOSS, NO3}$) is newly introduced in VISIT-e to prevent infinite N accumulation in deserts and arid regions, where much N removal thorough biotic and hydrological processes cannot be expected. This new scheme is based on the findings of McCalley and Sparks (2009) and it is modeled as follows:

1940
$$FN_{ALOSS, NH4} = S_{ALOSS} \times \exp(K_{ALOSS}(T_{sfc} - 50)) \times N_{NH4}, \quad (A18)$$

$$FN_{ALOSS, NO3} = S_{ALOSS} \times \exp(K_{ALOSS}(T_{sfc} - 50)) \times N_{NO3}, \quad (A19)$$

where S_{ALOSS} is a specific rate of abiotic loss that is set to the value of 7.26×10^{-3} (ngN m⁻² s⁻¹) (Schaeffer et al., (2003)), and K_{ALOSS} is a constant to normalize the rate at 50°C. Here, the emitted gas is assumed an inert form of N.

1945 A.1.5. N limitation on plant productivity

To simulate soil nutrient (soil inorganic nitrogen) control on plant growth, VISIT-e is modified from the original model as follows.

First, the photosynthetic capacity (P_{CSAT}), which used to be given as the fixed parameter, is modified such that it is controlled by N concentration in the leaf (N_{FOL}):

$$1950 \quad P_{CSAT} = K_{PSAT1} \times N_{FOL} + K_{PSAT2} \quad (A20)$$

and

$$N_{FOL} = N_{CAN}/LAI, \quad (A21)$$

where K_{PSAT1} and K_{PSAT2} are the slope and intercept, respectively, of the empirical relationship between N_{FOL} and P_{CSAT} , and LAI is the leaf area index. In this study, the parameters K_{PSAT1} and K_{PSAT2} were obtained from a meta-analysis study of Kattge et al., (2009). The leaf-level photosynthetic capacity is upscaled using the analytical method of the Monsi–Saeki theory, assuming a vertically uniform distribution of canopy N.

Second, actual N uptake by plants (FN_{UPTK}) is determined by the balance between N demand by plants (FN_{DMND}) and the potential supply from the soil (FN_{SPPL}), which allows the model to have a flexible CN ratio in plant organs:

$$FN_{UPTK} = \min\{FN_{SPPL}, FN_{DMND}\}. \quad (A22)$$

1960 Here, FN_{SPPL} is assumed simply as the total amount of inorganic N in soil ($=N_{NH4} + N_{NO3}$). The component FN_{DMND} is the sum of the demand from plant organs:

$$FN_{DMND} = FN_{DMND, CAN} + FN_{DMND, ROT} + FN_{DMND, STM} \quad (A23)$$

and

$$FN_{DMND, CAN} = (FC_{TRNS, CAN} - FC_{GRSP, CAN})/(C_{CAN}/N'_{CAN}), \quad (A24)$$

$$1965 \quad FN_{DMND, ROT} = (FC_{TRNS, ROT} - FC_{GRSP, ROT})/(R_{ROT}), \quad (A25)$$

$$FN_{DMND, STM} = (FC_{TRNS, STM} - FC_{GRSP, STM})/(R_{STM}). \quad (A26)$$

In the above, FC_s represents the carbon flux of translocation of primary production (with subscript TRNS) and the carbon lost by growth respiration (GRSP). Subscripts CAN, ROT, and STM represent canopy, root, and stem, respectively. R_{ROT} and R_{STM} are fixed parameters used as reference CN ratios in the root and stem, respectively, obtained from White et al., (2000). N'_{CAN} is the canopy N that maximizes canopy productivity, which is determined numerically by considering the balance between GPP and canopy (foliage) respiration.

A.2. Land use change

A.2.1. Structure of LUC tiles

1975 LUC forced by external forcing and its impact on land biogeochemistry are simulated with five main types of tile (primary vegetation, secondary vegetation, urban, cropland, and pasture) in each land grid. The same structure of C and N compartments is shared among the tiles and each tile has its own areal fraction in a grid (f_{LUC}):

$$f_{LUC, PV} + f_{LUC, SV} + f_{LUC, UR} + f_{LUC, CR} + f_{LUC, PS} = 1 \quad (A27)$$

The crop tile further holds two subtiles and their areal fractions: nitrogen-fixing crops and others.

$$1980 \quad f_{LUC, CR} = f_{LUC, CRN} + f_{LUC, CRO} \quad (A28)$$

where $f_{LUC, CRN}$ is the areal fraction for the N-fixing crop and $f_{LUC, CRO}$ is for the others. This subtile-level fraction is used for the estimation of nitrogen fixation by crops (see Sect. A.2.3).

A.2.2. Product pool and decomposition

1985 The carbon and nitrogen in biomass removed by crop harvesting and by land use conversion (P) are allocated to three product pools with different turnover rates (1 year, 10 years, and 100 years):

$$dM_{PROD, 1yr}/dt = \epsilon_{1yr} \times P - FM_{LUCE, 1yr}, \quad (A29)$$

$$dM_{PROD, 10yr}/dt = \epsilon_{10yr} \times P - FM_{LUCE, 10yr}, \quad (A30)$$

$$dM_{PROD, 100yr}/dt = \epsilon_{100yr} \times P - FM_{LUCE, 100yr}, \quad (A31)$$

1990 where M_{PROD} is the harvested biomass of C or N stored in the three product pools and P is harvested mass of C or N. Here, ϵ is the allocation fraction among the product pools (set in this study as $\epsilon_{1yr} = 0.5$, $\epsilon_{10yr} = 0.45$, and $\epsilon_{100yr} = 0.05$). FM_{LUCE} represents the volatilization rates of carbon (as CO_2) or nitrogen (as an inert form) from the three pools, which are calculated as follows:

$$FM_{LUCE, 1yr} = K_{LUCE, 1yr} \times M_{PROD, 1yr}, \quad (A32)$$

$$1995 \quad FM_{LUCE, 10yr} = K_{LUCE, 10yr} \times M_{PROD, 10yr}, \quad (A33)$$

$$FM_{LUCE, 100yr} = K_{LUCE, 100yr} \times M_{PROD, 100yr}, \quad (A34)$$

where K_{LUCE} is the specific emission rate in each product pool, which is set to reduce the carbon/nitrogen in each pool by 99.9% within 1 year, 10 years, and 100 years.

2000 A.2.3. LUC status-driven impact on biogeochemistry

Even if the areal fraction of each land use tile were fixed in a simulation, there could still be impacts of land use on land biogeochemistry, referred to here as the status-driven impact. This impact is specific to each tile and it is summarized as follows:

(1) prohibition of plant growth on an urban tile;

2005 (2) increased mortality of plants by grazing pressure on pasture tiles, assuming a 20% increase of mortality rate for foliage;

(3) annual crop harvesting on crop tiles (assuming 10% of foliage is harvested) and loss of C and N from the product pools;

(4) nitrogen fixation by N-fixing crop on crop tiles.

2010 For (4), the total BNF rate on crop tiles (FN_{SBNF}) is modeled as follows:

$$FN_{SBNF} = FN_{SBNF, CRO} \times f_{LUC, CRO} + FN_{SBNF, CRN} \times f_{LUC, CRN}, \quad (A35)$$

where $FN_{\text{SBNF, CRO}}$ represents the rate of nitrogen fixation on non-N-fixing crop tiles, which is assumed the same as that in natural vegetation. $FN_{\text{SBNF, CRN}}$ is the rate of nitrogen fixation on N-fixing crop tiles, which is calculated simply to satisfy a fixed ratio of BNF-derived N to all N taken up by N-fixing crops (=0.66; from Herridge et al. (2008)).

2015

A.2.4. LUC transition-driven impact on biogeochemistry

When the areal fractions of tiles are made to change following the forcing dataset, the apparent mass densities of C and N on a grid can be changed. For example, when a portion of a grid area is converted from category X to category Y in a year, the mass conservation between the “before (t)” and “after (t+1)” on a grid should be as follows:

$$2020 \quad M_X^t \times f_X^t + M_Y^t \times f_Y^t = M_X^{t+1} \times f_X^{t+1} + M_Y^{t+1} \times f_Y^{t+1} + P, \quad (\text{A36})$$

and

$$M_X^t = M_X^{t+1}, \quad (\text{A37})$$

where M is the mass density per unit tile area, subscripts X and Y represent categories of land use type, and superscript t denotes time. By presenting the areal fraction change as Δf and the change in apparent mass density in category Y as ΔM_Y ,

2025

$$M_X^t \times f_X^t + M_Y^t \times f_Y^t = M_X^t \times (f_X^t - \Delta f) + (M_Y^t + \Delta M_Y) \times (f_Y^t + \Delta f) + P, \quad (\text{A38})$$

and

$$P = \Delta f \times M_X^t \times K_{\text{HARV}}, \quad (\text{A39})$$

where K_{HARV} determines the fraction of mass that enters the product pools instead of the tile of category Y. Here, K_{HARV} is always set to zero for litter and soil pools and $K_{\text{HARV}} = 1$ for vegetation pools in specific transition patterns (e.g., $K_{\text{HARV}} = 1$ if the LUC transition type is urbanization, whereas $K_{\text{HARV}} = 0$ if the LUC conversion is pasture abandonment). By solving the equations for ΔM_Y , we obtain the following:

2030

$$\Delta M_Y = (\Delta f \times (M_X^t - M_Y^t) - P) / (f_Y^t + \Delta f). \quad (\text{A40})$$

If $\Delta M_Y > 0$ (< 0), the apparent mass density in tile Y is increased (decreased). The changes in apparent mass density lead to mass imbalance of C and N and therefore the storage of both C and N starts to move toward a rebalanced status under the given environmental conditions.

2035

2040 **Appendix B. Ocean ecosystem/biogeochemical component**

B.1. Governing equations

The ocean ecosystem component (OE2) embedded within the ocean circulation model is based on nutrient–phytoplankton–zooplankton–detritus (NPZD) type with four prognostic variables: nitrate (NO₃), “ordinary” nondiazotrophic phytoplankton (Phy), zooplankton (Zoo), and particulate detritus (Det). In addition, phosphate (PO₄), dissolved oxygen (O₂), dissolved iron (Fe), nitrous oxide (N₂O), and diazotrophic phytoplankton (nitrogen fixers, Diaz) are included. Biogeochemical tracers associated with the carbon cycle, i.e., dissolved inorganic carbon (DIC), alkalinity (Alk), calcium carbonate (CaCO₃), and calcium (Ca) are also included. Constant (~Redfield) stoichiometry relates the C, N, P, Fe, and O content of the biological variables and their exchanges with the inorganic variables (NO₃, PO₄, Fe, O₂, N₂O, Alk, and DIC).

2050 Each variable changes its concentration C according to the following equation:

$$\frac{\partial C}{\partial t} = Tr + S, \quad (B1)$$

where Tr represents all transport terms associated with the physical processes, including advection, isopycnal and diapycnal diffusion, and convection, and S denotes the source minus sink terms that include the surface and bottom fluxes. Using the variables and parameters listed in Tables B1 and B2, the source minus sink terms for each prognostic variable can be obtained as follows.

First, the source minus sink term for NO₃ $S(\text{NO}_3)$ is given by the following:

$$S(\text{NO}_3) = G_{\text{NO}_3}(1 - 0.8R_{O:N}\Gamma_{\text{NO}_3}^{\text{NO}_3}) + \text{Dep}_{\text{NO}_3} + \text{Riv}_{\text{NO}_3}, \quad (B2)$$

where Dep_{NO_3} (Riv_{NO_3}) represents nitrogen deposition from the atmosphere (riverine input) and

$$G_{\text{NO}_3} = (\mu_D \text{Det} + \mu_P^* \text{Phy} + E_Z \text{Zoo} - J_o \text{Phy} - u_N J_D \text{Diaz}),$$

$$2060 \Gamma_{\text{NO}_3} = \begin{cases} 1 & \text{if } \text{NO}_3 > \text{NO}_{3,\text{crit}}, \\ 0 & \text{if } \text{NO}_3 < \text{NO}_{3,\text{crit}}, \end{cases}$$

where J_o (J_D) is the growth rate of “ordinary” nondiazotrophic (diazotrophic) phytoplankton (see Appendix B2). The nitrate uptake rate is given by $u_N = \text{NO}_3 / (k_N^{\text{Diaz}} + \text{NO}_3)$ (Schmittner et al., 2005). Denitrification (Denit) can be expressed as follows:

$$\text{Denit} = G_{\text{NO}_3}(-0.8R_{O:N}\Gamma_{\text{NO}_3}^{\text{NO}_3}) - P_{\text{N}_2\text{O}},$$

2065 where $P_{\text{N}_2\text{O}}$ is the source term of N₂O, which is discussed later. The source minus sink terms for Phy and Diaz, i.e., $S(\text{Phy})$ and $S(\text{Diaz})$, respectively, can be expressed as follows:

$$S(\text{Phy}) = J_o \text{Phy} - \mu_P^* \text{Phy} - m_{\text{phy}} \text{Phy}^2 - \text{Graze}_{\text{phy}}, \quad (B3)$$

$$S(\text{Diaz}) = J_D \text{Diaz} - m_{\text{diaz}} \text{Diaz} - \text{Graze}_{\text{diaz}}. \quad (B4)$$

The term $S(\text{zoo})$ is estimated as follows:

$$2070 S(\text{Zoo}) = \gamma(\text{Graze}_{\text{phy}} + \text{Graze}_{\text{diaz}}) - E_Z \text{Zoo} - m_{\text{zoo}} \text{Zoo}^2. \quad (B5)$$

Then, $S(\text{Det})$ is given by the following:

$$S(\text{Det}) = (1 - \gamma) (\text{Graze}_{\text{Phy}} + \text{Graze}_{\text{Diaz}}) + m_{\text{Phy}} \text{Phy}^2 + m_{\text{Diaz}} \text{Diaz} + m_{\text{Zoo}} \text{Zoo}^2$$

$$-\mu_D \text{Det} - \text{Fsed}_{\text{Det}} - \frac{\partial \text{Sink}_{\text{Det}}}{\partial z}, \quad (\text{B6})$$

$$\text{Sink}_{\text{Det}} = \begin{cases} w_D \text{Det} & \text{if } z < 200\text{m} \\ \text{Sink}_{\text{Det}200} \left(\frac{z}{200}\right)^{0.875} & \text{if } z > 200\text{m} \end{cases}$$

2075 where Fsed_{Det} represents the net flux of detritus between the ocean and ocean sediment (Kobayashi and Oka, 2018) and $\text{Sink}_{\text{Det}200}$ is the flux of sinking detritus at the depth of 200 m (Kawamiya et al., 2000).

Using the molar P:N ratio of organic matter, $R_{P:N}$, and the riverine input of phosphate (Riv_{PO_4}), the source minus sink term for PO4 becomes:

$$S(\text{PO}_4) = R_{P:N} G_{\text{NO}_3} + \text{Riv}_{\text{PO}_4}. \quad (\text{B7})$$

2080 As the land ecosystem model cannot simulate the phosphorus cycle, it is assumed that phosphate is brought to the river mouth at a rate to satisfy $\text{Riv}_{\text{NO}_3} : \text{Riv}_{\text{PO}_4} = 16 : 1$, similar to the Redfield ratio. The term $S(\text{O}_2)$ can be estimated as follows:

$$S(\text{O}_2) = -\Gamma_{\text{O}_2} R_{O:N} G_{\text{NO}_3} + \text{Fsf}_{\text{O}_2}, \quad (\text{B8})$$

$$\Gamma_{\text{O}_2} = \begin{cases} 1 & \text{if } \text{O}_2 > \text{O}_{2\text{crit}}, \\ 0 & \text{if } \text{O}_2 < \text{O}_{2\text{crit}}, \end{cases}$$

2085 where Fsf_{O_2} is the dissolved oxygen exchange with the atmosphere, according to the OMIP protocol (Orr et al., 2017). The term $S(\text{Fe})$ can be expressed as follows:

$$S(\text{Fe}) = R_{\text{Fe}:N} G_{\text{NO}_3} + \text{Scav} + \text{Dustin} + \text{Sedin} + \text{HTin}, \quad (\text{B9})$$

where Scav represents scavenging (Moore et al., 2004; Moore and Braucher, 2008), Dustin is the iron input from dust, Sedin is the iron input from sediment following both Moore et al. (2004) and Aumont and Bopp (2006), and HTin is the hydrothermal dissolved iron flux following Tagliabue et al. (2010).

2090 The source minus sink term for N₂O is linked to the consumption of oxygen during the remineralization of OM (Ilyina et al., 2013):

$$S(\text{N}_2\text{O}) = r_{\text{N}_2\text{O}} \Gamma_{\text{O}_2} R_{O:N} (\mu_D \text{Det} + \mu_P^* \text{Phy} + E_Z \text{Zoo}) + \text{Fsf}_{\text{N}_2\text{O}}, \quad (\text{B10})$$

where $\text{Fsf}_{\text{N}_2\text{O}}$ is the N₂O exchange with the atmosphere according to Orr et al. (2017).

2095 The source minus sink term for DIC can be expressed as follows:

$$S(\text{DIC}) = R_{C:N} G_{\text{NO}_3} (1 - 0.8 R_{O:N} r_{\text{SO}_3}^{\text{NO}_3}) - G_{\text{CaCO}_3} + \text{Fsf}_{\text{DIC}}, \quad (\text{B11})$$

where Fsf_{DIC} is the DIC exchange with the atmosphere according to the OMIP protocol (Orr et al., 2017) and $G_{\text{CaCO}_3} = Pr_{\text{CaCO}_3} - Di_{\text{CaCO}_3}$.

Then, $S(\text{Alk})$, $S(\text{CaCO}_3)$, and $S(\text{Ca})$ can be estimated, respectively, as follows:

$$2100 \quad S(\text{Alk}) = -2G_{\text{CaCO}_3} - G_{\text{NO}_3}, \quad (\text{B12})$$

$$S(\text{CaCO}_3) = G_{\text{CaCO}_3}, \quad (\text{B13})$$

$$S(\text{Ca}) = -G_{\text{CaCO}_3}. \quad (\text{B14})$$

Molar P:N ratio	$R_{P:N}$	0.0625	N.D.
Molar Fe:N ratio	$R_{Fe:N}$	4.4167×10^{-5}	N.D.

Appendix C. Forcing data

External forcing used for HIST experiment is summarized in Table C1.

2135

Table C1.

List of forcing datasets for HIST simulation: categories, variables, and references for the data creation and description of how the datasets are applied in the HIST simulation in MIROC-ES2L.

Category	Variables	Reference	Treatment in MIROC-ES2L
GHG concentration	CO_2 , CH_4 , N_2O , CFC11, CFC12, CFC113, CFC114, CFC115, HCFC22, HCFC123, HCFC141b, HCFC142b, HFC32, HFC125, HFC134a, HFC143a, SF_6 , CCl_4 , C_2F_6	Meinshausen et al. (2017)	Same as Tatebe et al. (2019): given as globally averaged annual concentration
Anthropogenic SLCF emission	BC, OC, SO_2	Hoesly et al. (2018)	Same as Tatebe et al. (2019): given as monthly emissions
Open biomass burning emission	BC, OC, SO_2	van Marle et al. (2017)	Same as Tatebe et al. (2019): given as monthly emissions
Atmospheric chemical composition for aerosol scheme	H_2O_2 , OH radical, NO_3	Pre-calculated from atmospheric chemistry model CHASER: Sudo et al. (2002)	Same as Tatebe et al. (2019): given as three-dimensional concentration with monthly interval
Anthropogenic dissolved iron emission	Dissolved Fe	Biomass burning emission diagnosed from BC emission (van Marle et al., 2017; Ito, 2011); fossil fuel and biofuel emission (Hoesly et al., 2018; Ito et al., 2018)	Given as monthly emission of biomass burning emission and fossil fuel/biofuel emissions
Nitrogen deposition	NO_y (wet and dry), NH_y (wet and dry)	IGAC/SPARC CCMI: http://blogs.reading.ac.uk/ccmi/forcing-databases-in-support-of-emp6/	Given as wet plus dry monthly deposition for both NO_y and NH_y
Land use	Status, transition, fertilizer	Ma et al. (2019)	Given as two types of land use status (non-agriculture and

			agriculture) for energy/hydrology processes; given as transition matrix among five land use types (primary, secondary, urban, crop, and pasture) for biogeochemistry; given as cropland fertilizer
Stratospheric aerosol	Extinction coefficient	Thomason et al. (https://www.wcrp-climate.org/)	Same as Tatebe et al. (2019): monthly vertically integrated extinction coefficients for each radiation band
Ozone concentration	O ₃	Hegglin et al. (in prep.)	Same as Tatebe et al. (2019): given as three-dimensional concentration with monthly interval
Solar	Solar spectral irradiance	Matthes et al. (2017)	Same as Tatebe et al. (2019): given as monthly solar irradiance spectra

Appendix D. Diagnosis of cumulative fossil fuel emission and atmospheric CO₂ concentration

The global carbon budget can be written as follows:

$$CE = CA + CL + CO,$$

2145

where CE is the cumulative emission derived from fossil fuel and industry. CA, CL, and CO represent the changes in carbon amount in the atmosphere, land, and ocean, respectively. When models are forced with prescribed CO₂ concentration (CA), both CL and CO are diagnosed in the simulations. By expressing the prescribed CA as CA^P, the budget equation can be described as:

$$CE^D = CA^P + CL + CO, \tag{C1}$$

2150

where CE^D is a diagnosed fossil fuel/industrial carbon emission, as analyzed in Jones et al. (2013).

If we can obtain the prescribed emission (CE^P) that is consistent with historical atmospheric CO₂ concentration change, we can diagnose CO₂ concentration (CA^D) as follows:

$$CA^D = CE^P - CL - CO. \tag{C2}$$

2155

For CMIP6, CE^P during 1850–2014 was approximately 403 PgC, and the values of CL and CO in this study were 44 and 163 PgC, respectively. Thus, CA^D in this study was 193 PgC. This is equivalent to the CO₂ concentration change of 91 ppmv determined using a conversion factor of 2.12 (PgC ppmv⁻¹). Consequently, we can obtain the diagnosed CO₂ concentration at the end of the simulation (2014), i.e., 376 ppmv. We note the estimate of anthropogenic CO₂ emission of fossil fuel and industry has its uncertainty range, e.g., Le Quéré et al. (2018) estimate the cumulative emission as 400 ± 20 PgC for 1850–2014; however, it was not considered in this study. Additionally, there is a budget imbalance of 25 PgC in Le Quéré et al. (2018), which was also ignored in this study.

Appendix E. Feedback parameters of carbon cycle with same unit

As in Appendix D, the global carbon budget can be written as follows:

$$CE = CA + CL + CO. \tag{E1}$$

Following Gregory et al. (2009), this carbon budget equation can relate the feedback parameters of land and ocean to AF. First, following the definition, CL and CO can be expressed by the feedback parameters of CO₂-carbon and climate-carbon feedbacks (β and γ , respectively) as follows:

$$CL = \beta_L CA + \gamma_L T, \quad (E2)$$

$$CO = \beta_O CA + \gamma_O T, \quad (E3)$$

where CA is the carbon increase in the atmosphere and T is global temperature change (T). Using Eqs. E1–E3, the global carbon budget equation can be written as follows:

$$CE = CA + CA(\beta_L + \beta_O) + T(\gamma_L + \gamma_O). \quad (E4)$$

Dividing both sides of the equation by CA leads to the following:

$$CE/CA = 1 + (\beta_L + \beta_O) + T(\gamma_L + \gamma_O)/CA. \quad (E5)$$

Then, we define $T/CA = \alpha$, as used by Friedlingstein et al. (2006) or Arora et al. (2013), and we replace CE/CA by $1/AF$ (because $AF = CA/CE$):

$$1/AF = 1 + (\beta_L + \beta_O) + \alpha(\gamma_L + \gamma_O). \quad (E6)$$

The “u” quantity proposed by Gregory et al. (2009) is $u_{\beta L} = \beta_L$; $u_{\beta O} = \beta_O$; $u_{\gamma L} = \alpha \gamma_L$; and $u_{\gamma O} = \alpha \gamma_O$. Through replacement with the u terms, Eq. E6 can be expressed as follows:

$$1/AF = 1 + u_{\beta L} + u_{\beta O} + u_{\gamma L} + u_{\gamma O}, \quad (E7)$$

and thus we obtain the following:

$$AF = 1/(1 + u_{\beta L} + u_{\beta O} + u_{\gamma L} + u_{\gamma O}). \quad (E8)$$

As AF has the unit of PgC PgC⁻¹, the unit of the u parameters is also dimensionless.

6. Author contributions

TH was responsible for the development and description of MIROC-ES2L and VISIT-e, executed the spin-up and experiments, and undertook global analyses of climate–biogeochemistry and the terrestrial analysis. MW, AY, and MN contributed to the development and description of OECO2, as well as the analysis of ocean biogeochemistry. HT developed MIROC5.2 and supervised the physical modeling and engineering. MA contributed to the DMS emission modeling, preparation of the forcing dataset, and conversion and archiving of the output. RO contributed to the examination of model performance, postprocessing of the output, and analysis of the physical fields. AI¹ contributed to the development of atmospheric iron transport, preparation of iron emission forcing, and its description. DY contributed to river nitrogen modeling and its analysis. HO contributed to the coupling of OECO2. AI³ provided the original model VISIT and supervised the modeling and analysis of the terrestrial biogeochemistry. KT supervised the modeling of the terrestrial physical processes. KO supervised and supported the software engineering. SW determined the primitive design of MIROC-ES2L and supervised the entire system. MK organized the project, supervised the entire system, and contributed to the background section.

7. Competing interests

The authors declare that they have no conflict of interest.

8. Code and data availability

The code of MIROC-ES2L are not publicly archived because of the copyright policy of MIROC community. Readers are requested to contact the corresponding author if they wish to validate the model configurations of MIROC-ES2L and conduct replication experiments. The source codes, required input data, and simulation results will be provided by the modeling community to which the author belongs. The model output of the control, historical, and 1%CO₂ increase simulations performed in this study will be distributed and made freely available through the Earth System Grid Federation (ESGF). Details on the ESGF can be found on the website of the CMIP Panel (<https://www.wcrp-climate.org/wgcm-cmip/wgcm-cmip6>, last access: 28 August 2019).

9. Acknowledgments

This work was supported by TOUGOU/SOUSEI, the “Integrated Research Program for Advancing Climate Models (Grant Number JPMXD0717935715)”/“Program for Risk Information on Climate Change”, by the Ministry of Education, Culture, Sports, Science, and Technology of Japan. This work was also partly supported by JSPS KAKENHI Grant Number 17K12820 and by scientific collaboration in GCOM-C RA (JX-PSPC-500211). The Earth Simulator and JAMSTEC Super Computing System were used for the simulations, and the administration staff provided much support. The authors are grateful for the programming support provided by Tsuyoshi Hasegawa and Shinichi Toshimitsu and for the engineering advice offered by Hiroaki Kanai. Osamu Arakawa provided powerful support and services on data archiving and server management. Kengo Sudo and Tomoko Nitta kindly provided the forcing data and the forcing preparation system, respectively. Kaoru Tachiiri and Prabir Patra provided helpful and encouraging comments. This work was based on the long-term endeavor of members of the MIROC community. We greatly appreciate the valuable

Supplementary Figure 1

2805 Structure of nitrogen pool and flow in the land ecosystem component model. Boxes colored green, red, and blue represent vegetation N, soil organic N, and inorganic N, respectively. Arrows indicate internal N flow within land ecosystem (black), N flow into ecosystem (orange), and N flow out of ecosystem (cyan). Bold characters represent the names of N cycle processes/pools and the italic text indicates variable names.

Supplementary Figure 2

Distributions of (a) vegetation types used for VISIT-e (b) crop fraction (%) in 1850, and (c) crop fraction (%) in 2014. Vegetation types are based on MODIS vegetation cover category: 1 = evergreen needleleaf forest, 2 = evergreen broadleaf forest, 3 = deciduous needleleaf forest, 4 = deciduous broadleaf forest, 5 = mixed forest, 6 = closed shrubland, 7 = open shrubland, 8 = woody savanna, 9 = savanna, 10 = grassland, 11 = permanent wetland, and 12 = desert. Cropland is not included in the vegetation map, but it is simulated as one of the model tiles, the areal fraction of which follows CMIP6 forcing (LUH2 (Ma et al., 2019); <http://luh.umd.edu>).

2830 Historical emissions of labile Fe from biomass burning (red lines) and fossil fuel and biofuel combustion (black lines) during 1750–2014.

Supplementary Figure 5

History of MIROC-ES2L development and the spin-up presented by changes in (a) global mean 2 m air temperature, (b) atmosphere–land CO₂, and (c) atmosphere–ocean CO₂ flux (for CO₂ flux, positive means uptake). Colors represent experimental sets in development phases. Spin-up started at January 2017 (Exp. 01, black line) with a fully integrated system (i.e., physical core plus biogeochemical components). Spin-up ended at January 2019 after a series of final phase spin-up (Exp. 15, 16, 17, and 18 colored gray, brown, green, and blue, respectively). All simulations performed in this study were initiated from the endpoint in the plots. Vertical dashed lines represent the time at which part of the initial conditions of MIROC-ES2L was replaced by that created by the offline component models. For example, at year 7283, the initial condition of ocean biogeochemistry was replaced by that created by the offline OECOV2 spin-up after 3000 years with majorly updated source code. After the beginning of Exp. 15 (gray line, started at year 7283), continuous spin-up was performed by MIROC-ES2L for 2483 years with minor source code modifications.

Supplementary Figure 6.

Same as Fig. 4 but absolute precipitation rate of GPCP is shown in the right.
