Abstract. Biosphere-atmosphere interactions strongly influence the chemical composition of the atmosphere. Simulating these interactions at a detailed process-based level has traditionally been computationally intensive and resource prohibitive, commonly due to complexities in calculating radiation and light at the leaf level within plant canopies. Here we describe a surrogate canopy physics model based on the MEGAN3 detailed canopy model parameterized using a statistical learning technique. This surrogate canopy model is designed specifically to rapidly calculate leaf-level temperature and photosynthetically active radiative (PAR) for use in large-scale chemical transport models (CTMs). Our surrogate model can reproduce the dominant spatiotemporal variability of the more detailed MEGAN3 canopy model to within 10% across the globe. Implementation of this surrogate model into the GEOS-Chem CTM leads to small local changes in ozone dry deposition velocities of less than 5%, and larger local changes in isoprene emissions of up to ~40%, though annual global isoprene emissions remain largely consistent (within 25 5%). These changes to surface-atmosphere exchange lead to small changes in

surface ozone concentrations of ± 1 ppbv, modestly reducing the northern hemispheric ozone bias, in which is common to many CTMs, here from 8 to 7 ppbv. The use of this computationally efficient surrogate canopy model drives emissions of isoprene and concentrations of surface ozone closer to observationally constrained values. Additionally, this surrogate model allows for the further development and implementation of leaf-level emission factors in the calculation of biogenic emissions in the GEOS-Chem CTM. Though not the focus of this work, this ultimately enables a complete implementation of the MEGAN3 emissions framework within GEOS-Chem, which produces 570 Tg yr^{-1} of isoprene in 2012.

35 **1. Introduction**

The biosphere plays an important role in modulating the abundance and variability of trace gases and aerosol in the atmosphere. Direct emissions of gas phase species are drivers of the majority of the natural reactivity in the atmosphere, and are important precursor sources to pollutants and climate relevant species like ozone and particulate matter (Guenther et al., 2012; IPCC, 2013; Safieddine et al., 2017).

On the other hand, vegetation serves as a direct sink for these same species through a process known as dry deposition (Lelieveld and Dentener, 2000; Silva and Heald, 2018). The physical structure of the vegetation can also influence the production and loss of atmospheric constituents through changes to atmospheric turbulent transport and reductions in the actinic flux below the canopy (e.g. Makar et al., 2017). Additionally, chemical reactions occurring within the plant canopy act as a source and sink for reactive species in the above-canopy atmosphere (Goldstein et

al., 2004; Makar et al., 1999). Ultimately, the balance between the role vegetation plays as a chemical source and sink is a controlling factor for the abundance and variability of trace gases and aerosol across many regions of the globe (e.g. Geddes
50 et al., 2016; Silva et al., 2016; Unger, 2014). It is thus important to properly account for these processes when simulating the composition and chemistry of the atmosphere.

Explicitly simulating biosphere-atmosphere interactions necessitates a detailed
55 representation of physical, chemical, and biological processes that occur at the scale of an individual plant. This is typically achieved by integrating a set of energy and radiative balance equations vertically throughout a canopy (e.g. Ashworth et al., 2015, 2016; Goudriaan and Laar, 1994). This sort of physical model of the canopy calculates the environmental parameters that drive the biological and chemical
60 processes which ultimately impact the atmospheric fluxes of trace gases and aerosol (Guenther et al., 2012; Lamb et al., 1996). These canopy models tend to be computationally quite expensive, and are based on measurements taken at very fine resolution (e.g. meter or less), while most atmospheric chemical transport models operate on the 10-200 km scale. Reconciling these differences in scale and
65 addressing the steep computational requirements inherent in both canopy models and atmospheric chemical transport models are critical challenges in simulating chemically relevant interactions between the biosphere and the atmosphere.

Given the computational costs, atmospheric chemical transport models approximate canopy physics and the resulting effects on biosphere-atmosphere interactions

70 through various parameterizations. (e.g. Guenther et al., 2006; Wesely, 1989; Zhang
et al., 2003). Most of these parameterizations are based on observed relationships,
and intended to reduce the computational load around the calculation of the
temperature of leaves and the amount of light (specifically photosynthetically active
radiation, PAR) reaching leaves throughout the canopy. These model
75 parameterizations commonly assume that the temperature of leaves is equal to the
air temperature just above the plant canopy (e.g. Guenther et al., 2006; Millet et al.,
2010) or are based on parameterizations that ignore leaf temperature entirely (e.g.
Wesely, 1989). The parameterizations for leaf level PAR vary widely; from assuming
that the PAR reaching leaves in the canopy is equal to the flux of PAR incident on the
80 top of the canopy, to having some sort of reduced complexity multiplicative factor
that represents the bulk canopy effects (e.g. shading of leaves, Guenther et al., 2006;
Wang et al., 1998). To our knowledge, the overall impact of these parameterized
assumptions on the fidelity of modern chemical transport models has not been
comprehensively characterized. However for biogenic isoprene emissions, these
85 canopy approximations can lead to regional differences of greater than 20% relative
to a fully detailed canopy model (Guenther et al., 2006).

Direct representation of these processes is a necessary step to improve model
reliability and validity, particularly in a rapidly changing Earth System (Committee
on the Future of Atmospheric Chemistry Research et al., 2016). Currently, many
90 processes related to canopy energy and radiative balance are not represented in
models of atmospheric chemistry due to computational constraints. In this work, we
present a reduced complexity canopy model to calculate leaf temperature and PAR

for use in large-scale chemical transport models. This reduced complexity model removes the need for approximating bulk effects of plant canopies on leaf-level PAR and leaf temperature, and it allows for a more explicit process-based representation of these effects on biosphere-atmosphere interactions at the leaf level. Our reduced model reproduces the output of the more detailed vegetation model well, without the large computational overhead.

2. MEGAN3 Canopy Model

We develop and implement a computationally efficient surrogate of the MEGAN3.0 canopy model (<https://bai.ess.uci.edu/megan>, last accessed 04/09/2019), an update from previous versions of MEGAN (Guenther et al., 2006, 2012). This canopy model calculates leaf temperature and leaf-level PAR for a 5-layer plant canopy for both sunlit and shaded leaves, where each canopy layer represents a fraction of the total plant canopy. The model is originally based largely on Goudriaan and Laar (1994) and a brief description follows; for more information see Guenther et al. (1999, 2006, 2012).

In the MEGAN3 canopy model the fraction of sunlit leaves in the canopy decreases exponentially as a function of the local solar elevation angle, canopy leaf area index (LAI), a clustering coefficient that accounts for leaf geometries, and a canopy transparency coefficient representing the fraction of the canopy that does not intercept incident radiation. The leaf temperature is calculated from a system of energy balance equations based on Goudriaan and Laar, (1994) and Leuning et al. (1995), with a maximum absolute difference between air temperature and leaf

115 temperature of 10°C. Leaf-level PAR is computed as a function of incoming radiation
incident to the canopy top, the sunlit fraction of leaves, LAI, and a suite of geometric
and radiative look up table characteristics, predominantly based on Goudriaan and
Laar (1994), Leuning et al. (1995), and Spitters (1986). The full MEGAN3 canopy
model takes as input: time (day and hour), geographical location (latitude and
120 longitude), air temperature, incident radiation on the top of the canopy, wind speed,
humidity, air pressure, LAI, and a set of canopy characteristics (canopy biomass
distribution, clustering coefficients, etc.) in the form of a look up table that varies by
six vegetation types. The six vegetation types are: needleleaf trees, tropical forest
trees, temperate broadleaf trees, shrubs, herbaceous plants, and crops. It is
125 important to note that differing canopy model choice and parameter selection can
result in substantial changes to the ultimate estimates of biosphere-atmosphere
exchange (Keenan et al., 2011).

The MEGAN3 canopy model has been specifically developed for use in simulating
biogenic emissions, and has been extensively applied in related studies (e.g. Chen W.
130 H. et al., 2018; Geron et al., 2016; Guenther et al., 2006). Additionally, the MEGAN
framework has been widely adopted across a variety of regional and global models
(e.g. GEOS-Chem, WRF-CHEM, and CESM). Thus the MEGAN3 canopy model is a
good candidate for surrogate model development because it enables a direct
implementation of improved process-based canopy physics into a variety of 3D
135 models without the need for substantial model architecture development.

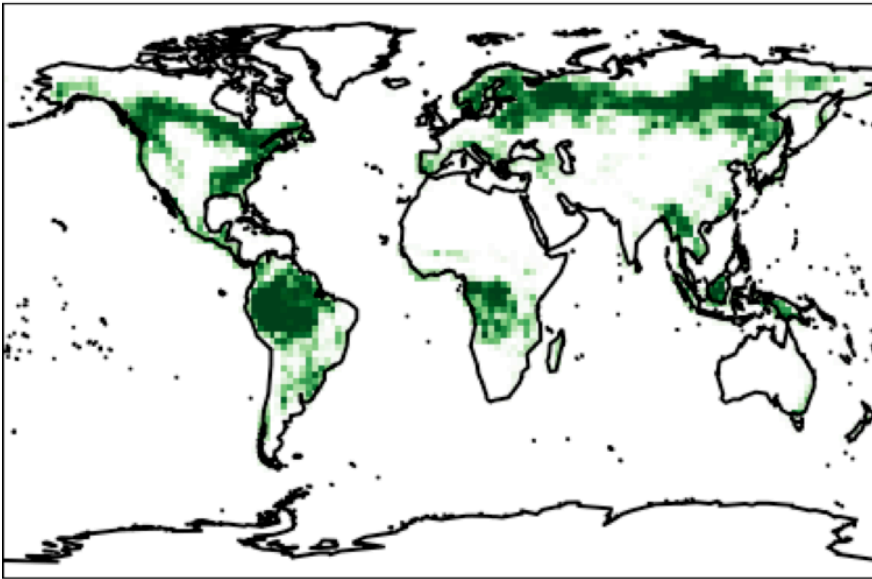

3. Surrogate Model Development

To begin the surrogate model development, we first use a variable selection approach to evaluate and rank which of the suite of model input variables are most important for the simulation of both leaf level PAR and temperature. To do this, we use a machine learning regression method for model simplification and parameterization, specifically LASSO (Least Absolute Shrinkage and Selection Operator, Hastie et al., 2001). As applied here, LASSO is a regression method that calculates linear coefficients through a modified least squares cost function, with the addition of a penalized L1 norm (the sum of the absolute value of the coefficients). While LASSO was originally developed as a complete regression method, we follow the recommendations of Hastie et al. (2001) and use LASSO only for variable importance ranking and dimensionality reduction of the input variable space to the model.

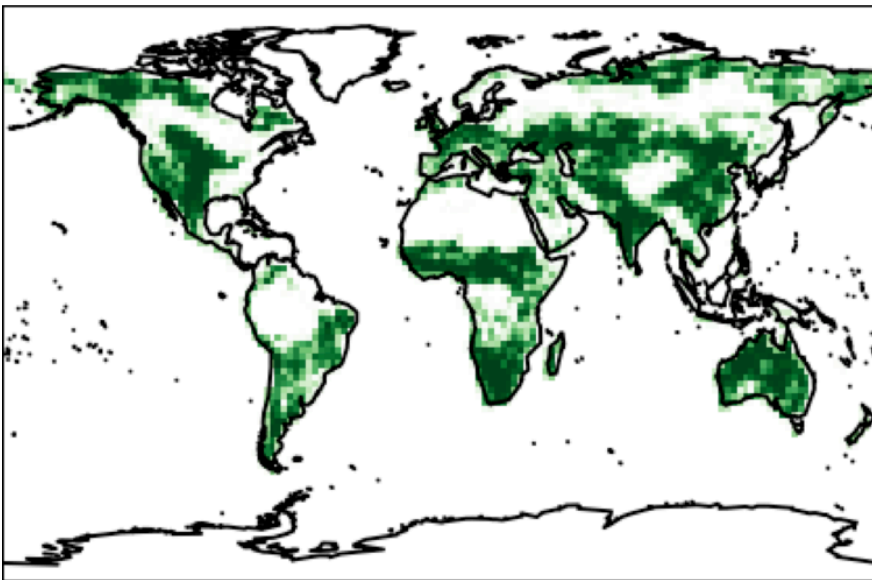

We apply the linear LASSO method for rankings across a full year of 3-hourly simulated canopy physics from the MEGAN3 canopy model at the global scale for the year 2012. Input meteorology is from MERRA-2 assimilated meteorological fields at $2^{\circ} \times 2.5^{\circ}$ horizontal resolution (Gelaro et al., 2017), and the vegetation distribution from the Olson 2001 land maps (Olson et al., 2001). LAI is derived from the MODIS TERRA MOD15A2 Product (Myneni et al., 2002, 2007) re-gridded to $2^{\circ} \times 2.5^{\circ}$ horizontal resolution and a monthly timescale. This input data is identical to that used in the GEOS-Chem chemical transport model (CTM) described below for direct comparison with prior work and ease of implementation into that CTM. The spatial distribution of vegetation and LAI are summarized in Figures 1 and 2, respectively. In general, forested land classes have the highest LAI values, and are spread

160 throughout the tropics and the northern latitudes. Crops, grasses, and shrubs are located predominantly in transitional landscapes and near regions of larger population (e.g. India, Central North America, etc.), and tend to have lower LAI values.

a) Forests

b) Crops, Grasses, and Shrubs

165 **Figure 1.** The percent of each $2^\circ \times 2.5^\circ$ gridbox occupied by each vegetation class used in this work. Panel a) is forested vegetation, and panel b) is crops, grasses, and shrubland.

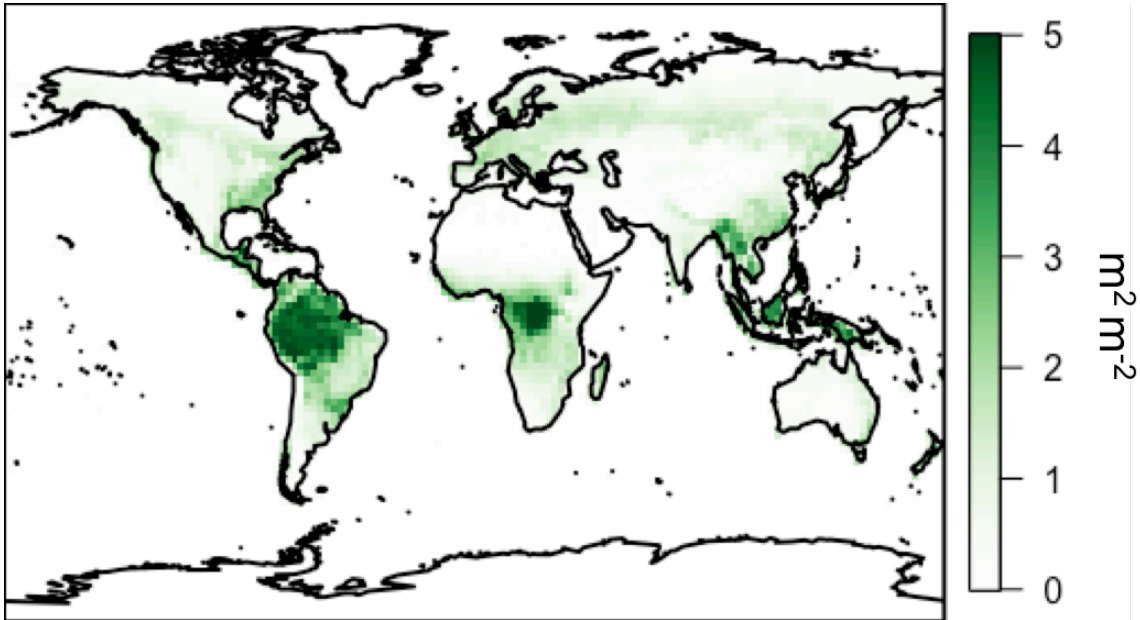

Figure 2. Annual Average LAI from MODIS for the year 2012.

170 The LASSO importance rankings are remarkably consistent for both sunlit and shaded leaves and for all vertical levels of the canopy. For each quantity, the two highest ranked variables are consistent at each layer throughout the canopy, and have substantially larger importance to the final result than any additional variable. For brevity we discuss only those first two variables here. The two most important variables for the calculation of leaf temperature are air temperature and wind speed. Air temperature dominates in importance for the calculation of leaf temperature, with a larger coefficient emerging at a higher L1 norm penalty weighting. Other variables that are physically important in nature (e.g. solar

175

radiation) do not appear important in the LASSO rankings due in part to how they
180 covary with air temperature, and how the rankings are derived separately for sunlit
and shaded leaves. For the calculation of leaf PAR we find that the two most
important variables are PAR out of the lowermost atmospheric gridbox (incident on
the canopy), and the local vegetation LAI. We use these selected variables to develop
a simplified parameterization for leaf temperature and PAR.

185 We model leaf temperature for a given canopy level, i ($T_{i,\text{leaf}}$, K) as linear with 2-
meter air temperature (T_{air} , K):

$$(1) T_{i,\text{leaf}} = A_i + B_i * T_{\text{air}}$$

Where A_i and B_i are fitted parameters per canopy level (i). This ignores the addition
of the second most important variable, wind speed. However, the addition of wind
190 speed to the regression only improves the performance of the model by less than
1% in total bias and R^2 ; thus for simplicity, we neglect this variable.

For the calculation of leaf-level PAR at a given canopy level ($\text{PAR}_{i,\text{leaf}}$, $\mu\text{mol m}^{-2} \text{s}^{-1}$),
we use an exponential Beers-Law analogue, including the influence of Leaf Area
Index (LAI) and the PAR incident to the top of the canopy (PAR_{toc} , W m^{-2}):

195 (2) $\text{PAR}_{i,\text{leaf}} = \text{PAR}_{\text{toc}} * \exp(C_i + D_i * \text{LAI})$.

Where C_i and D_i are fitted parameters per canopy level (i). This exponential
functional form is chosen due to the observed and simulated relationships between

LAI and canopy light interception (Engel et al., 1987; Goudriaan and Monteith, 1990) following a similar functional form.

200 We fit equations 1 and 2 for all layers of the canopy and for sunlit and shaded leaves, resulting in 20 total free parameters necessary to model the entire plant canopy across the globe. In this regression method, we ignore the role of differing vegetation classes and apply the regression agnostic to vegetation type. This is done to keep the total necessary number of free parameters low (20 versus 120), and
 205 because this more parsimonious model performs quite well (see Section 3.1) without the need for additional vegetation type specific coefficients. The resulting surrogate model coefficients are summarized in Table 1.

Canopy Level		A	B	C	D
Sunlit Leaves	1	-13.891	1.064	1.083	0.002
	2	-12.322	1.057	1.096	-0.128
	3	-1.032	1.031	1.104	-0.298
	4	-5.172	1.050	1.098	-0.445
	5	-5.589	1.051	1.090	-0.535
Shaded Leaves	1	-12.846	1.060	0.871	0.015
	2	-11.343	1.053	0.890	-0.141
	3	-1.068	1.031	0.916	-0.368
	4	-5.551	1.051	0.941	-0.592
	5	-5.955	1.053	0.956	-0.743

210 **Table 1. Regression Coefficients for the Canopy Surrogate Model. Canopy level 1 represents the top of the canopy.**

The final quantity necessary for the canopy model is the fraction of sunlit and shaded leaves. Here, that fraction in each layer of the plant canopy is calculated

directly following the MEGAN3 code, (see Guenther et al., 2006, 2012), without any model simplification. The sunlit fraction is calculated as follows:

215 (3) $K_b = 0.5 * \frac{C_1}{\sin \beta} \frac{\alpha_1}{\sin \beta}$

(4) $\text{Sunlit Fraction} = \exp \left(K_b * \frac{LAI}{1-\alpha_2} * f \right)$

Where β is the solar angle above the horizon, K_b is the extinction coefficient for black leaves, C_1 is the canopy clustering coefficient, C_2 is the canopy transparency, and f is the fraction of biomass in the canopy light travels through to reach a given
220 leaf (the vector [0.05, 0.23, 0.5, 0.77, 0.95]). Consistent with the MEGAN3 parent canopy model, we assume a Gaussian distribution of biomass in the canopy, centered in the middle canopy layer, and a canopy transparency of 0.2, and a leaf-clustering coefficient of 0.9.

From this relatively simple three-function parameterization (Leaf Temperature,
225 Leaf PAR, and Sunlit Leaf fraction), we are able to implement more physically realistic parameterizations for biosphere-atmosphere interactions in atmospheric chemical transport models.

3.1. Surrogate Model Performance

Here, we evaluate the surrogate model performance for all vegetation globally.

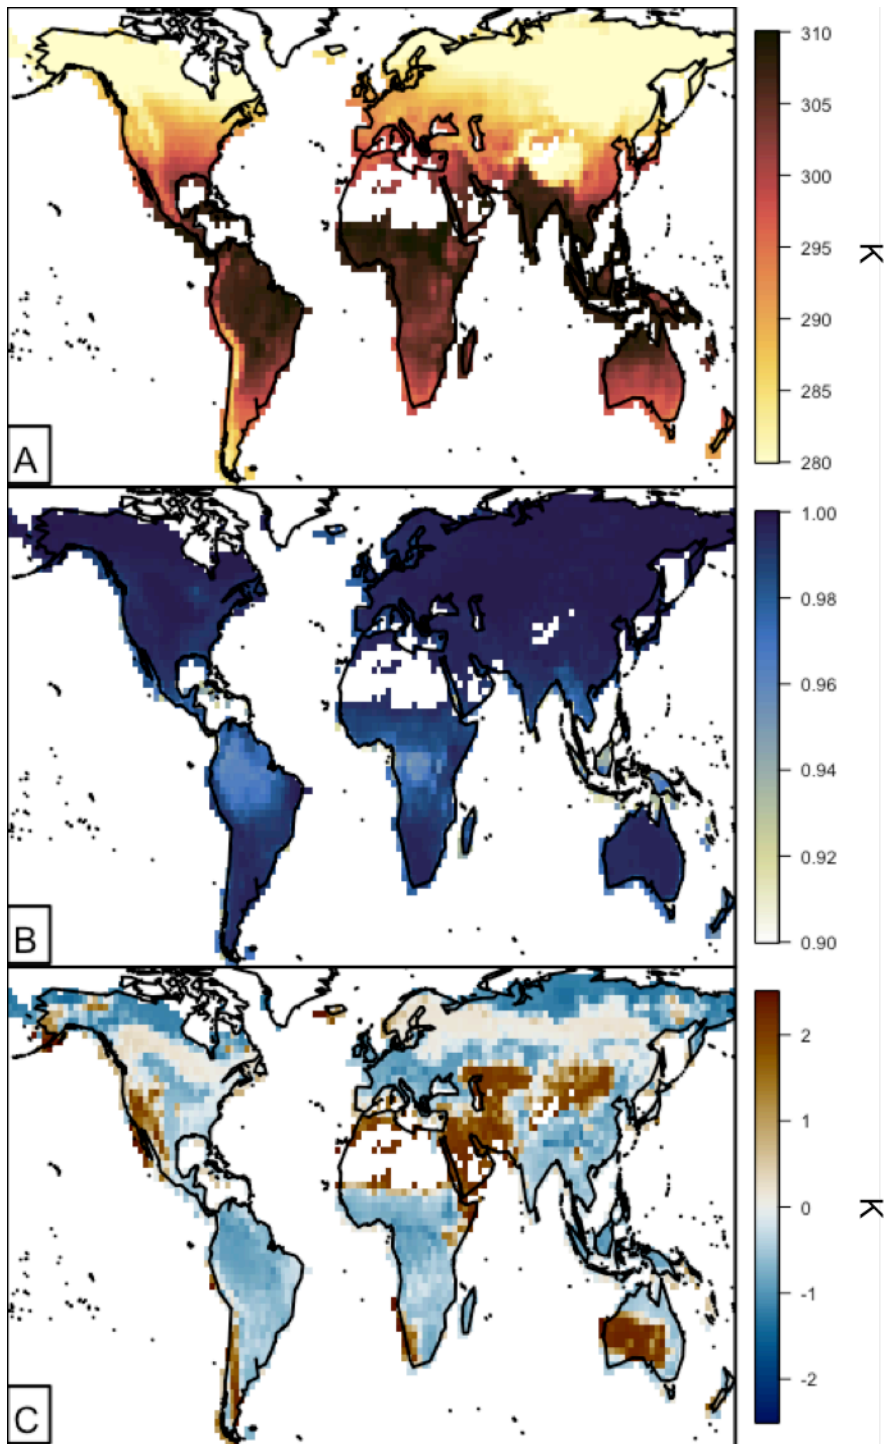

230 **3.1.1 Temperature**

The surrogate model simulated annual canopy average leaf temperature distribution and performance for 2012 is summarized in Figures 3 and 4. In Figure

3, the average for each canopy layer is calculated as a sum of the sunlit and shaded leaves, weighted by the sunlit fraction of that layer. In turn, the canopy average is
235 calculated as the weighted sum of the layer averages, weighted by the fraction of the canopy biomass in each layer. The annual average temperature is shown in Figure 3a, where it largely follows a latitudinal gradient. The warmest temperatures are ~310 K in the tropics, and the coldest average leaf temperatures are ~280 K in the northern high latitude boreal regions. The surrogate model is linear with the 2-
240 meter “near-surface” air temperature, and therefore follows that spatial distribution directly.

The surrogate model for leaf temperature performs well, with the annual average spatial R^2 and mean bias relative to the full model shown in Figures 3b and 3c, respectively. Across all regions, the R^2 is very high, indicating that a linear
245 relationship between 2-meter air temperature and canopy average temperature is a good approximation for capturing the variability of the full MEGAN3 canopy model. The temperature R^2 drops below 0.90 only in coastal regions/gridboxes that contain very little vegetation, representing less than 5% of all vegetated areas. The temperature surrogate bias is also generally quite low, as shown in Figure 3c. The
250 majority of regions have an absolute mean bias of less than 1 K, and more than 90% of the annual average mean biases are less than 2 K. The surrogate model generally computes temperatures that are biased cool over highly vegetated tropical and subtropical regions, and slightly overestimates temperature over northern boreal forests (by ~0.1 K). The most substantial overestimations occur in or near the hot
255 and arid regions of the globe, and always in regions where there is little vegetative

cover at all. On a relative scale these biases are quite small; all are less than 1% of the total magnitude. The model development process described in Section 3 removed the vegetation type discrimination in the parent MEGAN3 canopy model. This leads to some spatial coherence in the global bias patterns, where regions 260 dominated by coniferous forests, grasses, and shrubs (e.g. boreal northern hemisphere and the western United States) tend to be slightly biased warm, and the other vegetation types are biased slightly cool.

265

Figure 3. Surrogate model performance for the annual canopy average leaf temperature in 2012. Panels are as follows: A) Annual average surrogate model leaf level temperature (Kelvin), B) R^2 between the surrogate and the full model leaf level temperature, C) Annual average leaf level temperature bias (surrogate-full model, K)

The vertical profile of annual average leaf temperature is shown in Figure 4a. The broad shape of the canopy profile is consistent across vegetation types and the globe.

270 The upper canopy layers are cooler than the lower canopy layers, as an insulating effect from air temperature occurs within the canopy. The higher order variability (e.g. small differences between adjacent layers at the top and bottom of the canopy) stems from the more detailed representation of canopy energy balance in the full MEGAN3 model, which includes the influence of terms like PAR, relative humidity, 275 LAI, and wind speed. However this higher order variability is quite consistent, allowing for it to be reproduced in the simplified surrogate model.

Similar to the spatial performance, the overall surrogate model performs well throughout the canopy. The surrogate model temperature R^2 is shown in Figure 4b. The values are all near 1.0, with the lowest value of 0.97 in the middle of the canopy, 280 where the transition from cooler to warmer leaves is slightly more difficult for the surrogate model to capture. As demonstrated in Figure 4c, the bias throughout the canopy is low as well. On a global annual average, the surrogate model is biased cool, but only slightly (on both a relative and absolute scale). The highest magnitude bias is at the top canopy layer, at -0.04 K.

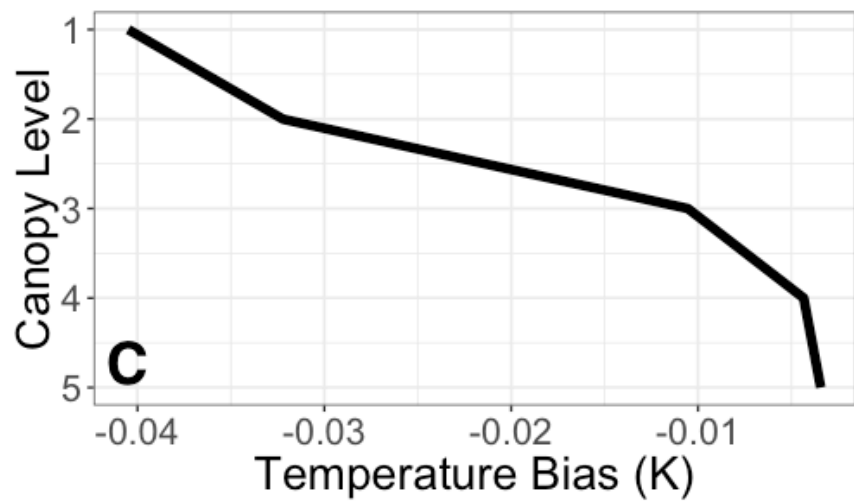

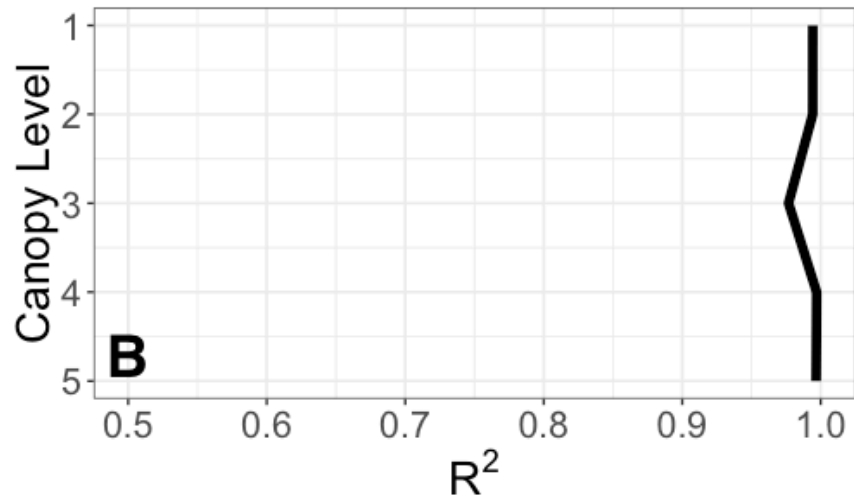

Figure 4. Surrogate model performance for the annual average vertical canopy temperature profile in 2012. Panel A shows the vertical average surrogate model leaf-level temperature (Kelvin). Panel B shows the surrogate model R^2 against the full model. Panel C shows the leaf level temperature bias (K) of the surrogate model compared to the full model.

290 3.1.2 Photosynthetically Active Radiation

The annual canopy average leaf-level PAR for 2012 is shown spatially in Figure 5a.

In Figure 5, canopy temperature averages are calculated using the same method as for canopy temperature. Annual average PAR varies from $\sim 200 \mu\text{mol m}^{-2} \text{s}^{-1}$ to greater than $600 \mu\text{mol m}^{-2} \text{s}^{-1}$. This spatial variability is a function of both PAR

295 incident on the top of the canopy (largely related to cloud cover and solar angle) and the canopy LAI. Leaf level PAR in the surrogate model varies linearly with incident PAR, and decreases exponentially with LAI. Additionally, the reduction under high LAI is exacerbated due to a higher fraction of shaded leaves in high LAI canopies, which have substantially lower average PAR. The highest leaf-level PAR values are
300 generally located in arid regions, where LAI and the number of cloudy days are quite low. The lowest values are located in the equatorial tropical rainforests and the northern boreal forests. The low leaf level PAR values in the rainforest are coincident with the highest LAI values globally, leading to very strong shading effects below the first canopy layer. The northern boreal forests have low leaf level
305 PAR in part due to relatively high LAI, but also due to reduced incoming PAR in the winter months when the solar angle is low.

The annual average performance of the surrogate leaf-level PAR relative to the full model is shown in Figures 5b and 5c. The temporal R^2 over a full year in Figure 5b, is generally quite high indicating that the surrogate formulation captures the majority
310 of the temporal variability inherent in the full model. The R^2 values range from 0.92

to 1.0. The highest R^2 values are in regions with low LAI, where the effects of shading and other canopy physical processes are greatly reduced. The worst model R^2 performance is over two characteristic regions: higher elevations with low vegetation densities (i.e. global deserts in Central Asia and South America), and
315 those with the highest LAI. Both regions represent extreme scenarios for canopy radiative physics. The higher elevation regions with low vegetation densities have very little leaf shading at all throughout the year, and thus the canopy physics represented with a simple exponential decay is no longer as relevant. In the high LAI regions, the elevated importance of shading and resulting complexity in the PAR
320 calculation is more challenging for the simplified representation of the surrogate model. However, this poor performance still has a quite high R^2 , with the lowest value of 0.92. The annual average model biases are generally within $\pm 40 \mu\text{mol m}^{-2} \text{s}^{-1}$, with a few more extreme values reaching $\pm 200 \mu\text{mol m}^{-2} \text{s}^{-1}$. The surrogate model is broadly biased high over regions with lower LAI and slightly low over regions
325 with high LAI. In a relative sense, these changes are nearly all within 10-15%, with a maximum normalized mean bias of 0.4.

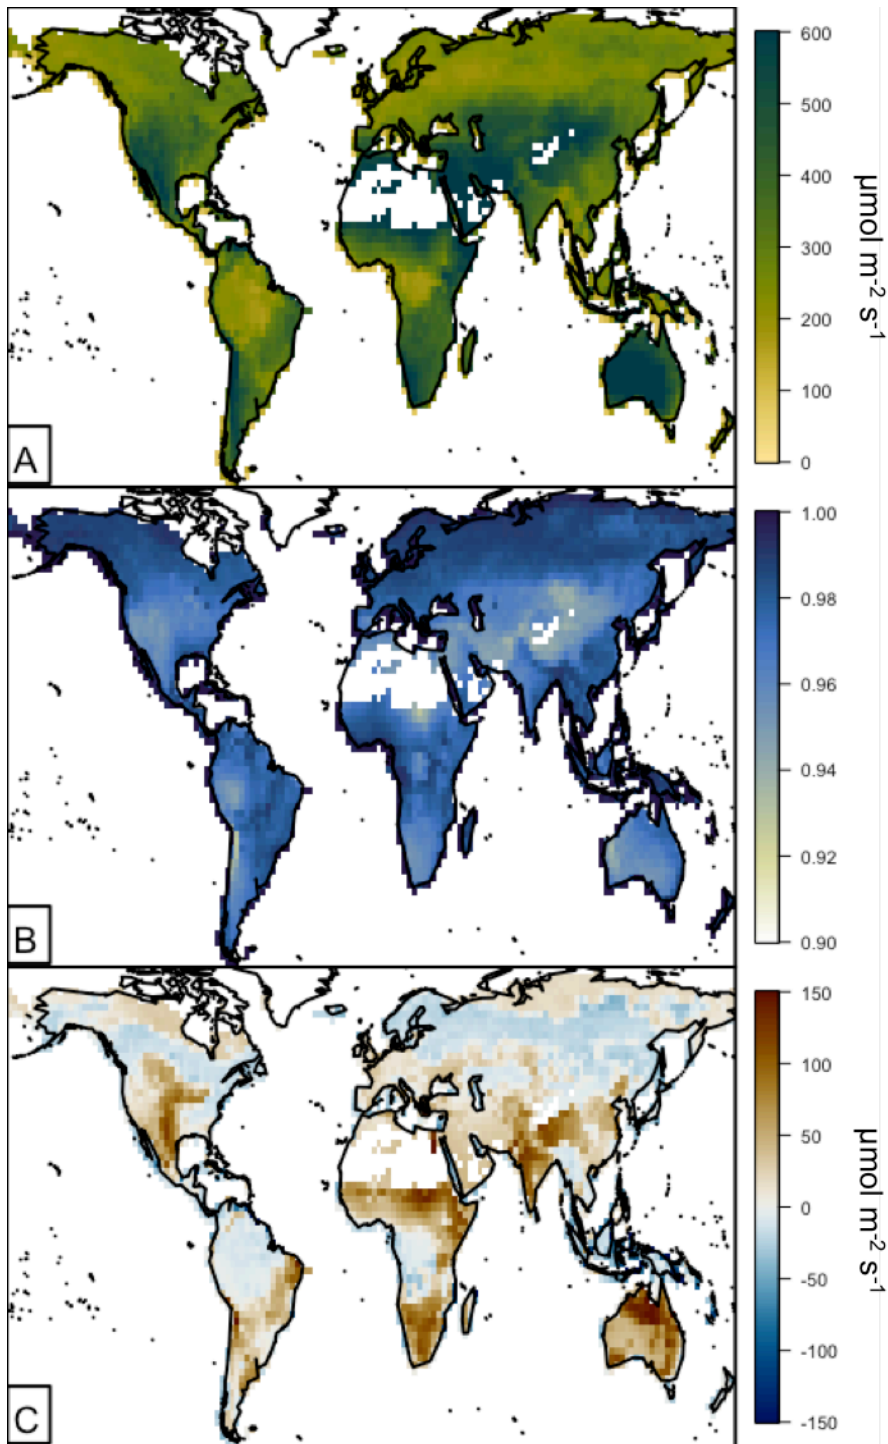

Figure 5. Surrogate model performance for the annual canopy average leaf PAR in 2012. Panels are as follows: A) Annual average surrogate model leaf level PAR ($\mu\text{mol m}^{-2} \text{s}^{-1}$), B) R^2 between the leaf level PAR simulated using the surrogate and the full model, C) Annual average leaf level PAR bias (surrogate - full model, $\mu\text{mol m}^{-2} \text{s}^{-1}$).

330

The average vertical distribution of leaf-level PAR throughout the canopy and the associated surrogate model performance are shown in Figure 6. To explore the additional dependence on LAI, the quantities shown are separated into three LAI
335 ranges. These are as follows: a low range with LAI less than 0.5, a midrange with LAI between 0.5 and 5, and a high LAI range containing canopies with total LAI greater than 5. The low LAI range represents ~40% of all vegetation throughout the year, the middle range represents nearly 60%, and the high LAI range contains only a small fraction of all vegetation (~1%).

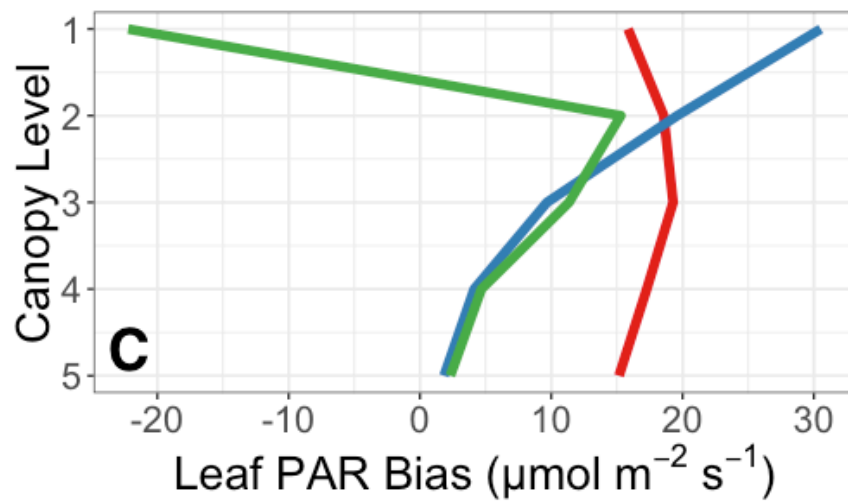

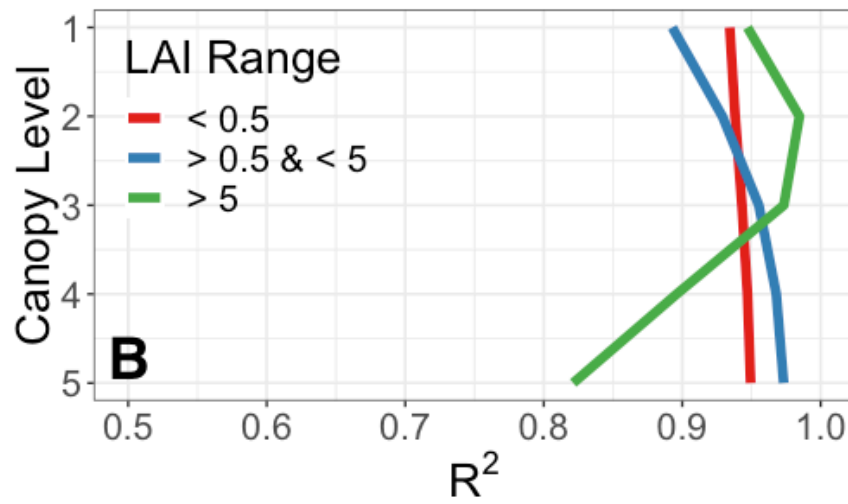

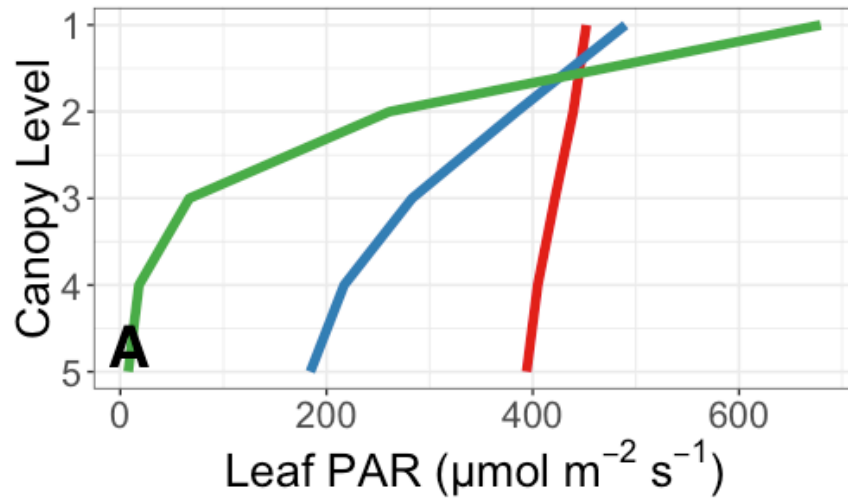

340 The average distribution of PAR across canopy levels is shown in Figure 6a. As LAI increases, there is a substantial reduction in leaf level PAR deeper into the vegetated canopy. This is particularly obvious with the high LAI range, consistent with substantial shading and light interception above the bottom of densely vegetated canopies. On the other hand, the variability throughout the low LAI canopies is quite
345 small. This LAI dependence explains in part the relatively low canopy average leaf-level PAR throughout the tropical forests in Figure 5a. The variability in the PAR at the top canopy layer (Canopy Level 1 in Figure 6a) stems from two major sources. The first is simply the spatial distribution of these LAI ranges in relationship to the annual average incident PAR to the canopy top. Very high LAI values occur primarily
350 over the tropics, where sunlight is consistently high throughout the year, and the seasonal effects of changing solar angles is small. The opposite is true for many of the regions with smaller LAI values, which are distributed more evenly across the globe. A second order effect in the MEGAN3 canopy model is that of in-layer attenuation of light and shading throughout the canopy, where leaves in a given

355 layer may intercept light and shade leaves lower within that same layer. This has the effect of reducing the layer average leaf-level PAR as a function of leaf geometries and LAI, and explains why the highest canopy layer average leaf-level PAR is not the same as the average PAR incident on the top of the canopy.

Figures 6b and 6c summarize the statistical performance of the surrogate model
360 vertically through the canopy in terms of the R^2 and the mean bias, respectively. Overall, the surrogate model reproduces the PAR variability as compared to the full parent model well. For both the low and middle LAI ranges (LAI less than 5), all R^2 values are greater than ~ 0.9 . The only substantially lower R^2 are from the lower canopy in high-LAI regions, where PAR is generally quite small (see Figure 6a). The
365 surrogate model struggles somewhat to capture this lower canopy variability due in large part to the increased complexity of resolving canopy shading and radiative physics in high LAI canopies. However, the ultimate influence on the total canopy-scale bias is generally low.

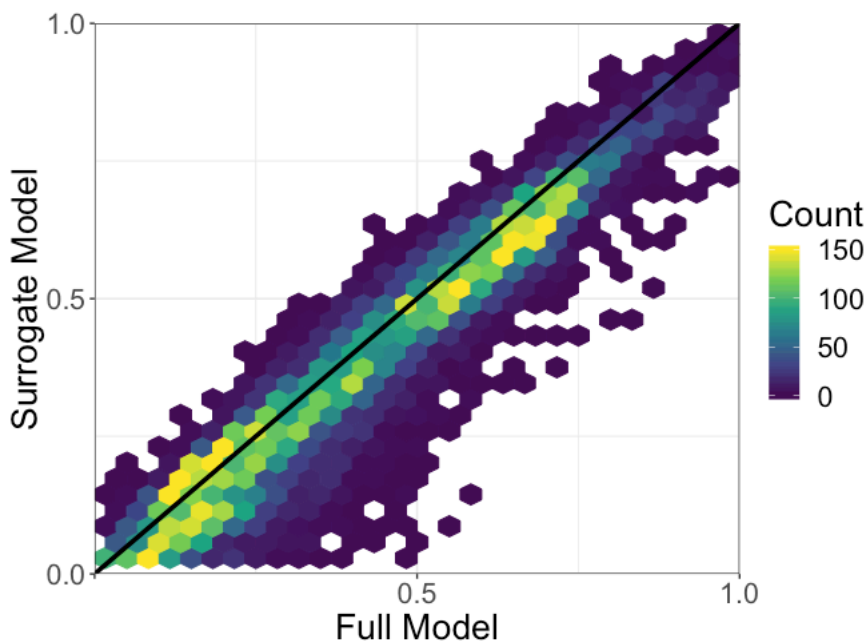

The vertical distribution of that bias is shown in Figure 6c. Broadly, the absolute
370 PAR bias is low (less than 5% on a relative scale) and decreases throughout the canopy. All biases are positive except for the top canopy layer for high LAI range canopies, and this poor fit is likely related to the limited representation of high LAI regions in the full dataset (only $\sim 1\%$ of all vegetated area), and isn't present if a lower cutoff for high LAI ranges is used (e.g. LAI > 3). The decreasing magnitude
375 throughout the canopy is largely related to the decreasing overall leaf-level PAR (see Figure 6a). It important to note that the bias terms are all sensitive to the choice of

LAI bin ranges, and the variability in bias at each level can be quite large (e.g. above 50 $\mu\text{mol m}^{-2} \text{s}^{-1}$ in the top canopy layer). For both the high and middle LAI ranges, the absolute magnitude of the PAR bias decreases throughout the canopy, and the bias remains relatively constant for low LAI range vegetation. On a relative scale, these biases are all quite small with a normalized mean bias usually less than 5%. The exception to this is the lowest layer of the high LAI range canopies. In this low canopy layer the magnitude of the bias is quite low, as is the total magnitude of leaf-level PAR, the resulting difference between small numbers leads to a relatively large normalized mean bias of ~ 0.3 .

390 **Figure 6. Surrogate model performance for the annual average vertical canopy PAR profile in 2012, as a function of LAI. Panel A shows the vertical average surrogate model leaf-level PAR ($\mu\text{mol m}^{-2} \text{s}^{-1}$) for low LAI (red), mid-range LAI (blue) and high LAI canopies. Panel B shows the surrogate model R^2 against the full model. Panel C shows the leaf level PAR bias ($\mu\text{mol m}^{-2} \text{s}^{-1}$) of the surrogate model compared to the full model. Level 1 is the top of the canopy.**

An essential function of canopy models used in CTMs is to calculate the amount of light that falls on already light-saturated leaf surfaces. This regulates the effect of a change in PAR incident on the canopy on various biological and physical processes
395 (e.g. biogenic emissions). We estimate the fraction of leaves that are light-saturated using the γ_{PAR} formulation from the MEGAN algorithm (Guenther et al 2006, 2012). This variable aims to capture the amount of light saturation on a given leaf, and ranges from 0 to 1, with higher values corresponding to more saturated leaves. To explore light saturation, we examine cases where the γ_{PAR} value is greater than 0.9. A
400 scatterplot of the annual average fraction of leaves that are light-saturated ($\gamma_{\text{PAR}} \geq 0.9$) per model gridbox for both the full model and the surrogate model throughout the canopy is shown in Figure 7. The surrogate model reproduces the full model fraction of light-saturated leaves well, generally to within $\sim 5\%$, with a median bias of -2% .

405

Figure 7. The annual grid box average fraction of light saturated leaves as simulated by the full and surrogate models throughout the canopy for the year 2012. The colorbar represents the number of observations in a given hex. The 1:1 line is shown in black.

Ultimately, this assessment demonstrates that the surrogate model reproduces the
 410 parent MEGAN3 canopy model well for both leaf temperature and leaf-level PAR.

The exponential relationship between leaf-level PAR and canopy incident PAR and
 the linear relationship between leaf temperature and near-surface air temperature
 captures the majority of the information inherent in the parent model. Some higher
 order variability in absolute magnitude of the variables is missing from this
 415 surrogate model, however the biases are generally all within ~10%.

4. Chemical Transport Model Description

We evaluate the impact of the canopy model parameterization on atmospheric
 composition using the GEOS-Chem v12.3.0 chemical transport model ([26](http://www.geos-</p>
</div>
<div data-bbox=)

chem.org). GEOS-Chem is a computational model for simulating atmospheric
420 chemistry, including a detailed HO_x-NO_x-BrO_x tropospheric chemical mechanism
(Bey et al., 2001; Mao et al., 2013; Travis et al., 2016). We drive GEOS-Chem with
MERRA-2 Meteorology at 2°x2.5° spatial resolution, with 47 vertical layers (Gelaro
et al., 2017). The timesteps for convection and chemistry are 10 and 20 minutes,
respectively. Identically to the canopy model input data, we use LAI values from the
425 MODIS-Terra MOD15A2 product (Myneni et al., 2002, 2007), and plant functional
types from the Olson 2001 dataset (Olson et al., 2001). Fire emissions are from the
Global Fire Emissions Database v4 (GFED4, Giglio et al., 2013), and global
anthropogenic emissions are from the Community Emissions Data System inventory
(CEDS, Hoesly et al., 2018). Regional emissions over the United States, Africa, and
430 Asia are from the NEI 2011 (Travis et al., 2016), DICE-Africa (Marais and
Wiedinmyer, 2016), and MIX (Li et al., 2017) emissions inventories, respectively.
Soil NO_x emissions are calculated following Hudman et al. (2012). Simulations are
shown for the years 2012 and 2013, with the first year discarded for spin up when
considering gas-phase chemical impacts.

435 **4.1 MEGAN Emissions**

The biogenic emissions scheme in GEOS-Chem v12.3.0, MEGAN2.1, is based on
Guenther et al. (2006, 2012) and Millet et al. (2010). The emissions of a given
compound are calculated from base canopy-level emission factors multiplied by
“activity factors” representing standard processes that govern biogenic emissions
440 (temperature, PAR, light-dependence, etc.), and “stress factors” modeling the effect
of vegetative stress (heat, drought, etc.) on biogenic emissions. Each of these activity

and stress factors vary with the environmental state. The base emission factor itself varies with vegetation type, and these activity factors respond to leaf temperature, leaf-level PAR, leaf age, leaf area index, soil moisture, and atmospheric CO₂

445 concentrations. The base emission factors used in this work are consistent with those used in GEOS-Chem v12.3.0; an example for isoprene is shown in Figure 8. The emission factors are highest in forested regions, and lowest over areas with little vegetation (e.g. deserts). These emission factors are regridded from the original resolution of 0.25°x0.3125° to match the GEOS-Chem resolution of 2°x2.5°.

450 **Figure 8. Base Isoprene emission factors used in this work.**

As GEOS-Chem v12.3.0 has no representation of plant canopy physics, the LAI, temperature, and PAR activity factors are all re-parameterized following Guenther et al. (2006) in the standard model. In this parameterization, leaf temperature is assumed to equal air temperature in the calculation of the temperature activity factor. The LAI and PAR activity factors are calculated in an approach known as the Parameterized Canopy Environment Emission Activity (PCEEA) approach that does

not include any description of the vertical distribution of vegetation, and only includes response to the LAI, PAR incident to the top of the canopy, and the solar
460 zenith angle.

We modify the MEGAN implementation in GEOS-Chem to allow for the representation of canopy physics described in Section 3. In order to properly scale all emission factors to the plant canopy using a canopy model, a normalization factor must be applied at a set of standard environmental and ecological conditions
465 (Guenther et al., 2006, 2012). This normalization factor varies depending on the choice of those standard conditions and the canopy model used. In MEGAN2.1 these standard conditions are: LAI of 5, current air temperature of 303K, current incident PAR at the canopy top of $1500 \mu\text{mol m}^{-2} \text{s}^{-1}$, and a 10%/80%/10% split of growing, mature, and senescent leaves (Guenther et al., 2012; Kaiser et al., 2018). We
470 calculate other necessary standard conditions, specifically the 24-hour average air temperature and PAR, from the meteorological fields conditional on locations that meet the previously described standard conditions. In situations where all of the previous instantaneous standard conditions (e.g. Current Temperature = 303K, Current PAR = $1500 \mu\text{mol m}^{-2} \text{s}^{-1}$, and LAI = 5) are jointly met to within $\pm 10\%$, we
475 calculate the 24-hour average prior meteorological conditions from the global reanalysis fields, and use the mean of those calculations as the standard 24-hour average conditions. The resulting standard conditions for 24-hour average temperature and 24-hour average PAR are 298.5 K and $740 \mu\text{mol m}^{-2} \text{s}^{-1}$, respectively. These standard conditions result in a normalization factor of 0.21
480 using the surrogate canopy model surrogate developed in this work. The value of

0.21 is lower than those used in implementations of previous MEGAN model versions in other models such as CLM (0.3) and WRF-Chem (0.57) (Guenther et al., 2012). It is important to note that the normalization factor approximately scales with the square of the current temperature conditions and linearly with the current PAR conditions. For the 24-hour average conditions, the scaling is reduced to approximately linear for temperature and as a square root for PAR. Given this, small deviations from these standard conditions (e.g. those that could arise from different 24-hour averaging methodology) can lead to substantial changes in the normalization factor. Additionally, consistent with previous work these standard conditional calculations are likely variable across model meteorological configurations and should be recalculated on a model-specific basis (Guenther et al., 2012). Since this normalization factor is applied consistently to all emissions globally at all times, it linearly modulates all biogenic emissions. As such, the total emissions calculated by the MEGAN2.1 emissions framework are highly sensitive to the parameter choices made in this normalization processes.

In GEOS-Chem v12.3.0 we update the activity factors associated with PAR, LAI, and temperature as well as the normalization to take advantage of our new canopy surrogate model. This enables a full implementation of the most recent MEGAN3 emission activity algorithm in the GEOS-Chem model. In the PCEEA implementation of MEGAN in the base version of GEOS-Chem, activity factors are calculated separately for PAR (γ_P), LAI (γ_{LAI}), and temperature (γ_T), and then multiplied together following Guenther et al. (2006):

$$(5) \gamma_{PCEEA} = \gamma_{LAI} \gamma_T \gamma_P$$

Following MEGAN3 (<https://bai.ess.uci.edu/megan>), we implement PAR and
505 temperature activity factors that are calculated jointly per canopy level and summed
together weighted by the vertical canopy biomass distribution. In this work, as in
previous non-PCEEA versions of the MEGAN framework (Guenther et al., 2006,
2012), the effect of LAI is calculated through direct multiplication of the emission
factor by LAI as opposed to an activity factor formulation, along with a canopy
510 normalization factor (C_{CE}):

$$(6) \gamma_{Canopy} = C_{CE} LAI \gamma_{TP}$$

$$(7) \gamma_{TP} = \sum_{l=1}^5 w_l \gamma_P \gamma_T$$

These activity factors for PAR, LAI, and temperature are the same as those in
Guenther et al. (2012), as averages throughout the canopy weighted by the biomass
515 fraction within a given canopy layer (w_l). There is an additional canopy depth
emission activity response applied to the light dependent activity factors which is
intended to model the variability of emissions throughout the canopy (e.g. Harley et
al., 1996). This canopy depth activity factor is a multiplicative factor that varies
linearly as a function of LAI and canopy depth, with a value between 0 and 1.3. For
520 clarity, we refer to the MEGAN emissions implementation in GEOS-Chem using the
 γ_{PCEEA} activity factors as “MEGAN_{PCEEA}” and those using the γ_{Canopy} activity factors
as “MEGAN_{Canopy}”. While γ_T in the MEGAN_{PCEEA} approach follows a similar functional
form to that in MEGAN_{Canopy}, the lack of vertical canopy structure in the MEGAN_{PCEEA}

configuration leads to a very different treatment of the joint effects of Temperature,
525 PAR, and LAI on emissions. Specifically, the MEGAN_{PCEEA} approach aims to
approximate the joint effects of shading and temperature change within a canopy,
whereas MEGAN_{Canopy} aims to directly simulate those processes. We use the canopy
physics surrogate model described in Section 3 to calculate the leaf temperature and
PAR in the MEGAN_{Canopy} implementation.

530 Though stress factors in the MEGAN framework allow for the additional capability
to evaluate the impact of vegetative stress processes on emissions (e.g. Geron et al.,
2016), we do not enable those processes in this study. The other activity factors
(leaf age, soil moisture, and CO₂ inhibition) are the same in both the MEGAN_{Canopy}
and MEGAN_{PCEEA}.

535 **4.2 Dry Deposition**

Dry Deposition in GEOS-Chem v12.3.0 is calculated through a resistor-in-series
approach based on the Wesely (1989) parameterization, originally described and
implemented in Wang et al. (1998). In this approach, the dry depositional flux of gas
phase species is calculated as the surface concentration of that gas multiplied by a
540 transfer velocity known as the “dry deposition velocity”. A recent assessment of the
dry deposition velocity parameterization in GEOS-Chem found that biases in
simulated dry deposition velocities are in general quite low, though there is
evidence that missing key processes may be responsible for missing variability in
the simulation (Silva and Heald, 2018).

545 Prior to this work, canopy effects were not directly considered in GEOS-Chem dry
deposition, and only approximated in bulk using a polynomial decomposition
scheme (Wang et al., 1998) that calculated a single constant jointly representing
both a multiplicative factor ($1 + b/\text{PAR}_{\text{leaf}}$, $b = 50 \mu\text{mol m}^{-2} \text{s}^{-1}$) to the stomatal
resistance from Baldocchi et al. (1987) based on leaf-level PAR and a normalization
550 of the stomatal resistance by LAI. Here, we replace the polynomial decomposition
scheme and use the leaf-level PAR calculations from the canopy surrogate to directly
calculate the multiplicative factor, and then explicitly normalize by LAI. The LAI
normalization in the original polynomial decomposition calculates values that are a
factor of ~ 1.7 higher than those calculated through direct normalization when using
555 the surrogate model. To maintain the same magnitude of the simulated dry
deposition velocities as in the standard model, which are generally unbiased (Silva
and Heald, 2018), we scale the stomatal resistance by a factor of 0.6.

5. Surrogate Model Integration into GEOS-Chem

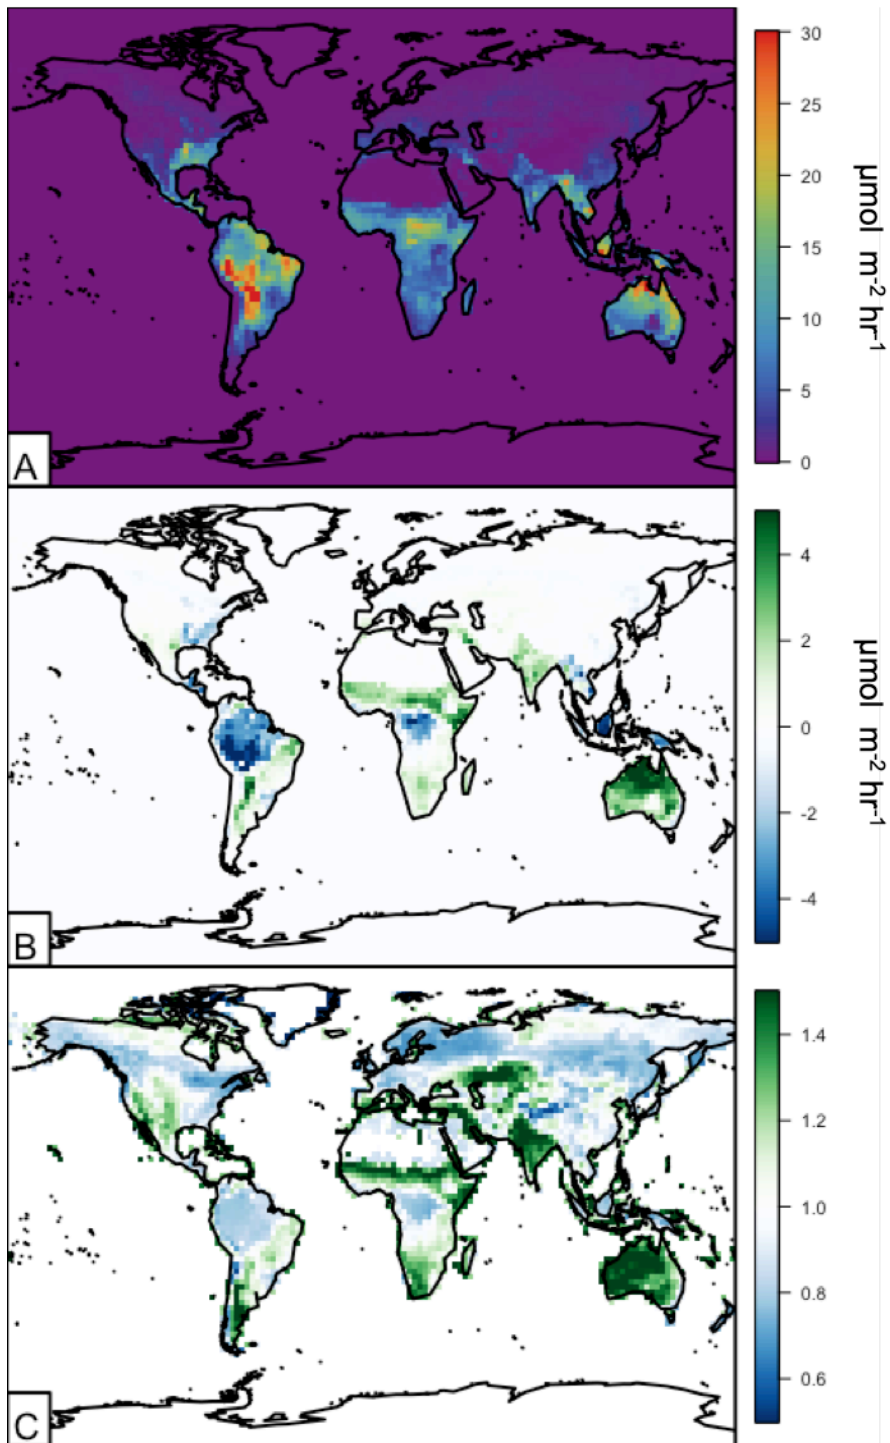

Implementing the updated canopy surrogate in a global model directly impacts the
560 surface-atmosphere exchanges processes of biogenic emissions and dry deposition,
which together influence the chemical composition of the atmosphere. In this
section we outline the changes to both surface processes, focusing on isoprene
emissions and ozone dry deposition, followed by the changes to surface level ozone
concentrations in the GEOS-Chem model.

565 The impact of the canopy model on isoprene emissions in 2012 is summarized in
Figure 9. The annual average isoprene emissions using the $\text{MEGAN}_{\text{canopy}}$ emissions

implementation are shown in Figure 9a, with the highest emissions in the tropics and subtropics, as well as the Southeast United States. Though not distinct in Figure 9, the boreal forests are a substantial emitter of biogenic species during the summer months. The relatively small emissions from this region during the winter months reduce the prominence of these emissions on the annual average. The global annual total of isoprene emitted in 2012 from the MEGAN_{Canopy} configuration is ~350 Tg C yr⁻¹.

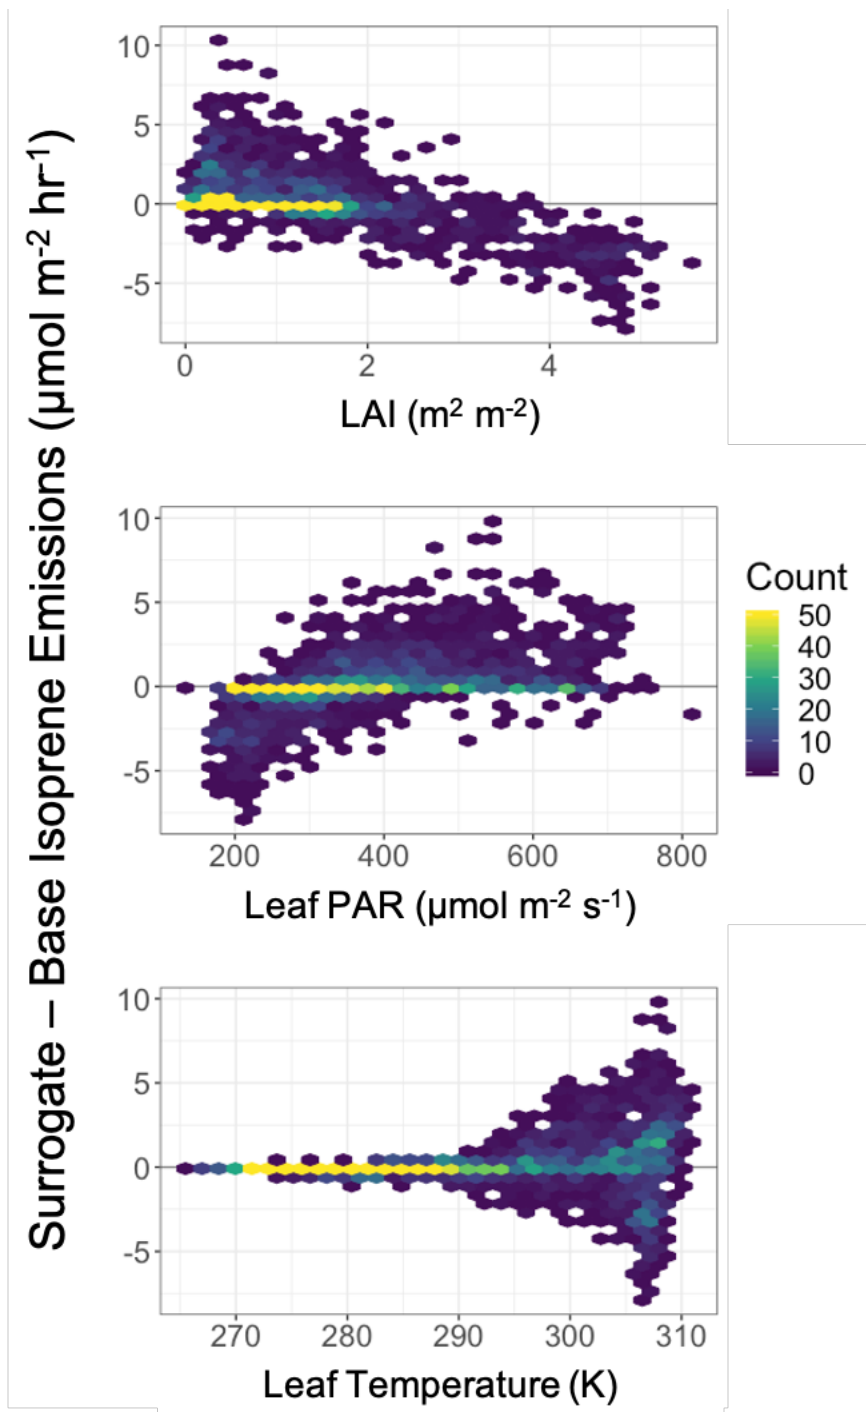

The annual average differences in the simulated isoprene emissions following implementation of the surrogate canopy model (MEGAN_{Canopy} - MEGAN_{PCEEA}) are shown in Figure 9b. In general, emissions decrease over forested regions and increase over non-forested (grasses, crops, and shrubland) areas. The highest absolute changes are the decrease in the Equatorial Amazon and the increase in Northern Australia. On a relative scale, the forested and non-forested differences are more apparent. This relative change (MEGAN_{Canopy}/MEGAN_{PCEEA}) is shown in Figure 9c. While there are relatively modest decreases in tropical and boreal forests, the emissions increase in heavily cropped Indian Subcontinent and sub-Saharan Africa show the largest relative change. Though the spatial variability in relative difference is substantial, the annual global isoprene emissions from the canopy model are within 5% of the original model version (~340 Tg C yr⁻¹). These results are consistent with those from Guenther et al. (2006) who found that the global total biases in isoprene emissions were low, but spatial variability was large, when using a parameterized approach (MEGAN_{PCEEA}) over a direct canopy model implementation in the MEGAN framework (as in the surrogate model application,

590 MEGAN_{Canopy}). On aggregate, these changes are all well within the stated uncertainty of the MEGAN isoprene emissions of approximately a factor of 2 (Guenther et al., 2012).

595 **Figure 9. Annual average (2012) isoprene emissions simulated in GEOS-Chem driven by the surrogate model canopy physics (MEGAN_{canopy}). Panel A shows the annual average emissions. Panel B shows the difference between the surrogate model and base version of simulated emissions. Panel C shows the relative difference between the surrogate model and base version of simulated emissions (surrogate/base model).**

It is not possible to directly parse the individual process contributions to the total
600 emissions changes due to the fundamentally different coupled treatments of the influence of temperature, PAR, and canopy structure on biogenic emissions through the activity factors in both the MEGAN_{canopy} and the MEGAN_{PCEE} configurations. However, a comparison of the isoprene differences between the two simulations against LAI, leaf-level PAR, and leaf temperature (Figure 10) indicates that the
605 changes are most strongly driven by the leaf-level PAR and LAI effects. The isoprene emissions changes are directly proportional to leaf-level PAR, inversely proportional to LAI, and show no substantial relationship to leaf temperature. The forested and non-forested differences in Figure 9 can be explained further from the correlations shown in Figure 10. The forested areas with the largest decreases in
610 isoprene emissions tend to have high LAI values and lower canopy average leaf PAR, whereas the opposite is true for the non-forest locations. The relationships in Figure 10 support the interpretation that the leaf-level PAR and LAI effects are the largest drivers of change in biogenic isoprene emissions between the two model versions. Overall, these results indicate that the representation of canopy radiative physics is
615 more important than thermodynamically resolving the difference between air and leaf temperature for simulating biogenic emissions in the MEGAN framework.

620

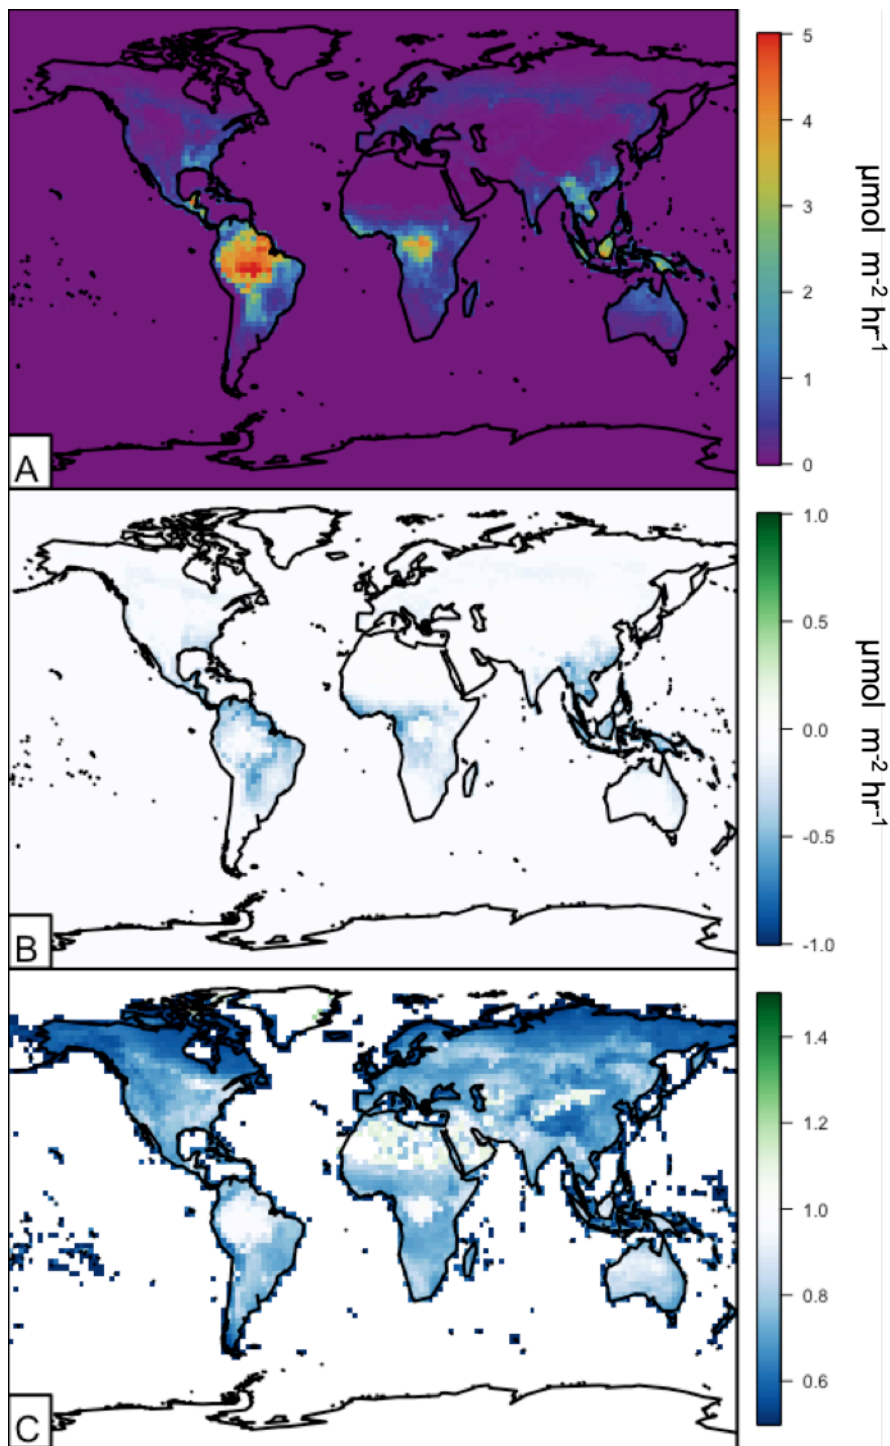

Figure 10. Difference in annual average isoprene emissions between the surrogate canopy model (MEGAN_{Canopy}) and the base simulation (MEGAN_{PCEEA}) (atoms C cm⁻² s⁻¹, see Figure 9B) as a function of LAI, Leaf Level PAR ($\mu\text{mol m}^{-2} \text{s}^{-1}$), and Leaf Temperature (K). Gridboxes dominated by water were filtered removed from these figures. The colorbar represents the number of observations in a given hex.

There are few spatial constraints on isoprene emissions that can act as independent validation data for the new model framework. However, recent work over the southeast United States (Kaiser et al., 2018; Travis et al., 2016; Yu et al., 2016) indicates that the base version of GEOS-Chem used here (v12.3.0), which uses MEGAN_{PCEEA}, overestimates isoprene emissions by 15-40%. The MEGAN_{Canopy} configuration reduces isoprene emissions in most locations in the Southeast United States by ~10%, and locally leads to reductions as large as ~20%, bringing the model into better agreement with these observational constraints.

The MEGAN emissions framework calculates the emissions of other non-isoprene biogenic species as well, including monoterpenes. The influence of the canopy surrogate model on monoterpene emissions is shown in Figure 11. The annual total monoterpene emissions in 2012 from MEGAN_{Canopy} are ~95 Tg C yr⁻¹. These emissions are shown in Figure 11a and are highest over the densely vegetated regions of the world, in particular the tropics. Similar to isoprene emissions, monoterpene emissions in the northern latitude forests peak during summer months. The implementation of the canopy surrogate model reduces global annual total monoterpene emissions by approximately 20%. The annual average absolute and relative changes to monoterpene emissions due to the canopy surrogate model (MEGAN_{Canopy} - MEGAN_{PCEEA}) are shown in Figures 11b and 11c, respectively.

Simulated monoterpene emissions differ from isoprene emissions in that monoterpene emissions are more sensitive to temperature, with an additional influence of a light independent emission factor that varies with leaf temperature (Guenther et al., 2012). There is a fairly constant 20-30% decrease across regions

645 with lower LAI values, including the African savannahs and the Indian subcontinent.
The highest absolute changes are in transitional areas near high LAI forests, with
warmer temperatures (the tropics and subtropics). The high LAI areas of the
tropical and northern forests show smaller decreases of ~5%. These changes, while
substantial, are well within the stated uncertainty ranges in monoterpene emissions
650 of the MEGAN model (300-400%, Guenther et al., 2012).

655

Figure 11. Annual average (2012) monoterpene emissions simulated in GEOS-Chem driven by the surrogate model canopy physics. Panel A shows the annual average emissions. Panel B shows the difference between the surrogate model and base version of simulated emissions. Panel C shows the relative difference between the surrogate model and base version of simulated emissions (surrogate/base model).

Changes in simulated ozone dry deposition velocities in 2012 are summarized in Figure 12. Figure 12a shows the annual average spatial distribution of ozone dry
660 deposition velocities. The values vary from less than 0.1 cm s^{-1} over the global oceans, to above 0.5 cm s^{-1} in densely vegetated regions like the tropical rainforests.

The impact of the updated canopy model on ozone dry deposition velocities is in general quite small, with an average change of near zero ($\sim 0.004 \text{ cm s}^{-1}$). The annual average relative change is shown in Figure 12b, and the absolute difference in
665 Figure 12c, both in relation to the base version of GEOS-Chem v12.3.0. These changes are nearly all within $\pm 5\%$, or $\pm 0.01 \text{ cm s}^{-1}$, with a maximum change of 15%, (0.04 cm s^{-1}). Relative changes track most strongly with broadleaf and coniferous forested areas. This is consistent with those regions being most sensitive to stomatal deposition (Silva and Heald, 2018), as the canopy scheme implemented here
670 changes dry deposition only through the calculation of the stomatal resistance term.

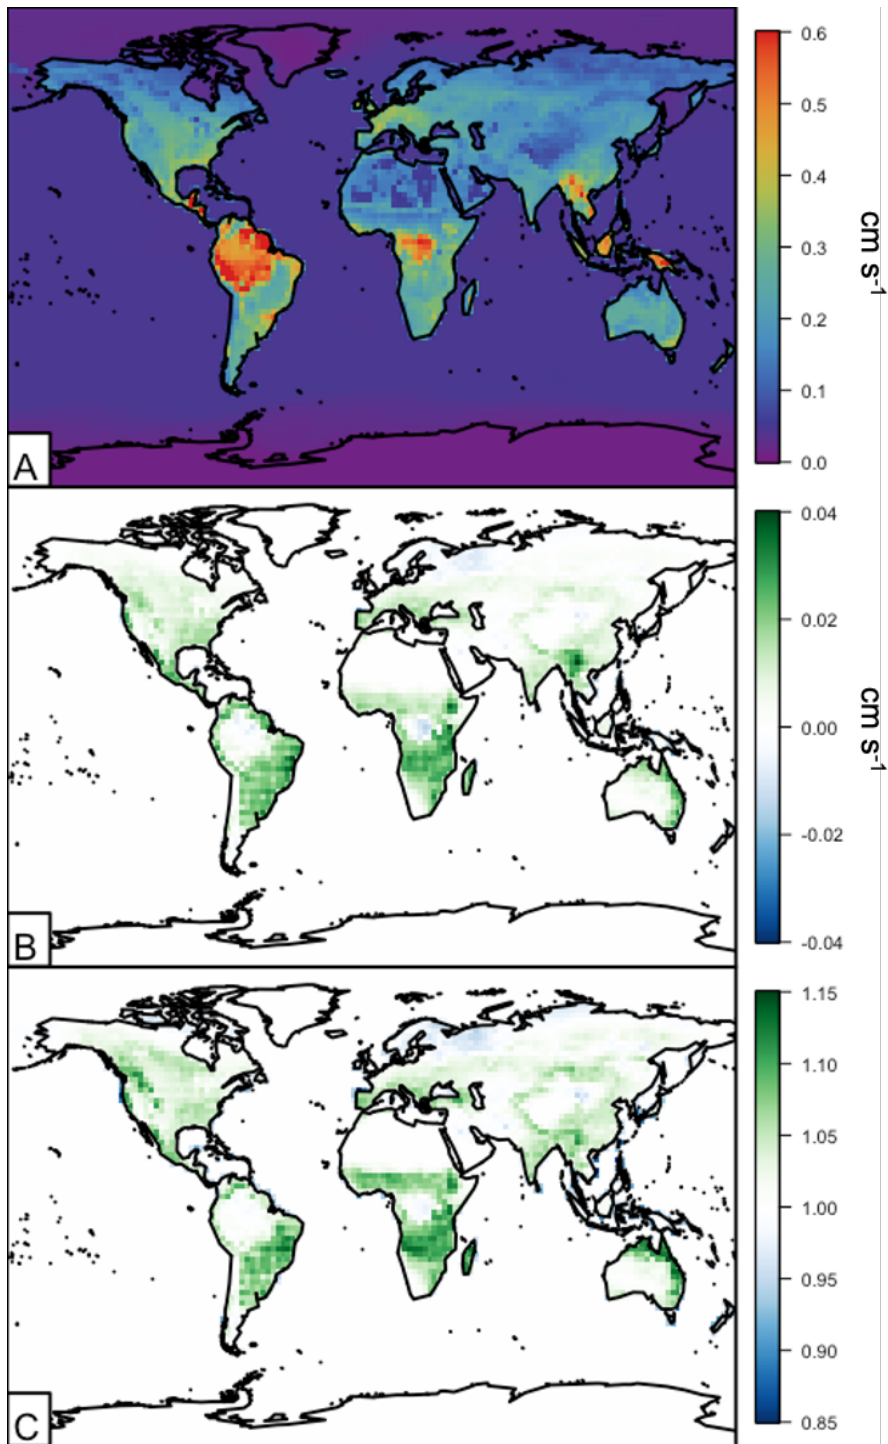

Figure 12. Annual average (2012) ozone dry deposition velocities simulated in GEOS-Chem when driven by the surrogate model canopy physics. Panel A shows the annual average dry deposition velocities (cm s^{-1}). Panel B shows the difference between the surrogate model and base version of simulated dry deposition velocities (cm s^{-1}). Panel C shows the relative difference between the surrogate model and base version of simulated dry deposition velocities (surrogate/base model).

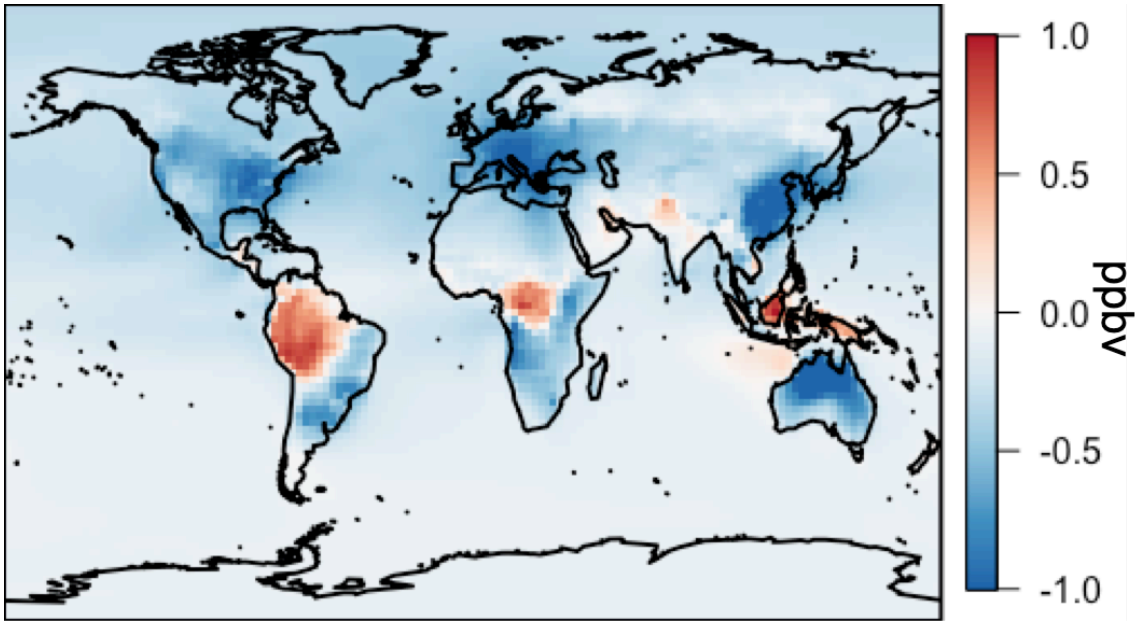

675

The small overall changes to surface-atmosphere exchange processes associated with the updated canopy scheme produce only a modest impact on simulated atmospheric composition. We describe the changes to surface ozone here, as an
680 illustrative example.

The annual average spatial difference in surface ozone between a simulation using the canopy physics described here and the base version of GEOS-Chem is shown in Figure 13. These changes are all generally quite small; all are within 10% of the base simulated annual averages. The changes are generally within ± 1 ppbv, with the
685 largest absolute changes over regions with the largest changes in isoprene emissions. The distribution of differences largely follows well-known NO_x -VOC ozone formation patterns. The NO_x limited regions of the world, in particular the remote tropics, show an inverse relationship with isoprene emissions. This is consistent with ozone titration by isoprene in the presence of low NO_x . The largest
690 changes in ozone over the VOC limited regimes of India and China correspond directly to the changes in isoprene emissions changes, with enhanced isoprene emissions over the Indian subcontinent increasing ozone concentrations, and the decrease in isoprene emissions over China leading to a decline in ozone. The overall influence of the changes in ozone dry deposition velocity is fairly negligible. Even
695 the regions where the dry deposition velocity change is the largest (e.g. the Amazon) are dominated by the shift in isoprene emissions.

In total, the changes in surface ozone concentrations slightly ameliorate known biases. There is a persistent high bias (~ 10 ppbv) across chemical transport models

in simulating surface ozone concentrations over the continental mid-latitudes
700 (Travis et al., 2016). The addition of the new canopy physics parameterization very
modestly reduces this bias in GEOS-Chem (approximately 8 ppbv) by about 1 ppbv,
driving simulated ozone closer to observations.

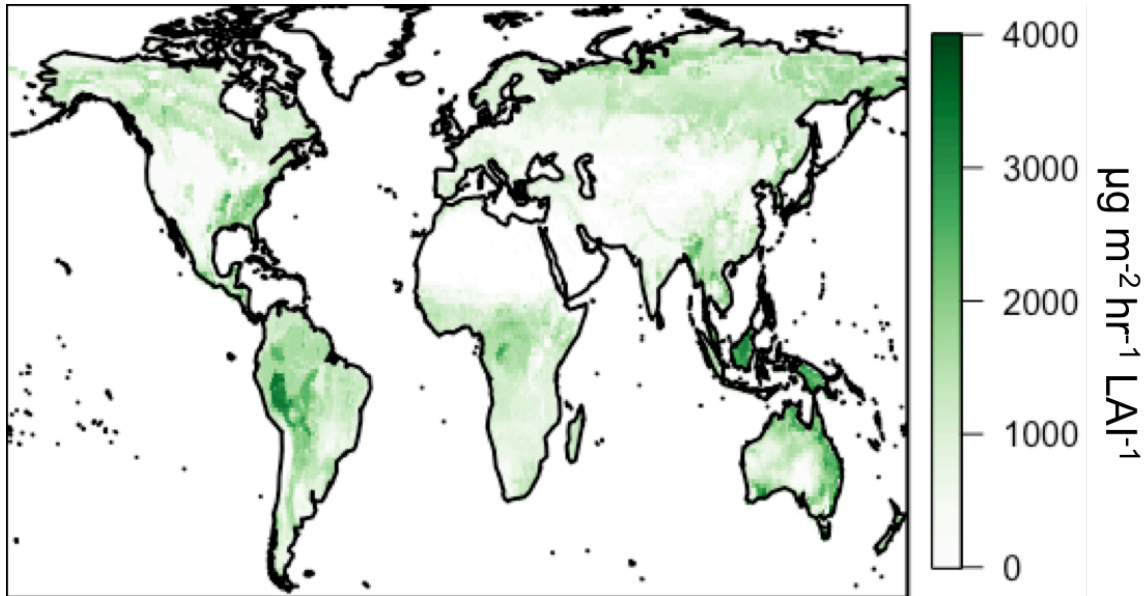

705 **Figure 13. Annual spatial average surface ozone difference (ppbv) between the updated model version with surrogate canopy physics and the base version of GEOS-Chem (surrogate-base).**

6. Implementation of MEGAN3 Emission Factors

In addition to improved process representation, the canopy surrogate model presented here allows for the direct application of new emission factors generated using the MEGAN3 Emission Factor Processor (<https://bai.ess.uci.edu/megan>),
710 which allows users to generate emission factors from various input datasets. While the focus of this work is on the impact of representing canopy physics, we include here a description of this full implementation of MEGAN3 in the GEOS-Chem model for completeness. We calculate landscape-average emission factor distributions

using the global growth form and ecotype distributions, the emission type
715 speciation, and the leaf level emission factor database available from the MEGAN3
Emission Factor Preprocessor. All MEGAN3 Emissions Factor Preprocessor options
are kept at their default values (i.e. confidence rating $J = 0$, and 20 total species
classes). The landcover and emissions data are the same as that used for MEGAN2.1
except that the landcover updates described by Yu et al. 2017 were used for the
720 contiguous US. The updated landcover is based on high resolution (30-m) PFT and
detailed vegetation types and is expected to more accurately represent the
landcover distributions in this region. The spatial distribution of the MEGAN3
activity factors is shown in Figure 14. It is important to note that these new
emission factors are input at the leaf level with units on a per LAI basis, as opposed
725 to the canopy-scale factors used in previous versions of MEGAN (applied earlier in
this manuscript), which makes direct comparisons of emission factor magnitudes
infeasible. This canopy to leaf level change ultimately has the consequence of
removing the need for the normalization factor in the activity factor calculation (see
Section 4.1). When these emission factors are scaled to the same units as in
730 MEGAN2.1 (i.e. the per LAI basis in the MEGAN3 emission factors is accounted for)
using the MODIS LAI product applied in this work, the resulting emission factors are
relatively similar (within $\pm 75\%$) though the MEGAN3 emission factors are lower
than those used with MEGAN2.1 in GEOS-Chem. Generally, more than half of all
changes are within $1000 \mu\text{g m}^{-2} \text{hr}^{-1}$, and 90% of all emission factors are within 3000
735 $\mu\text{g m}^{-2} \text{hr}^{-1}$. This comparison is not exact, due to the fact that the MODIS LAI product
used here is different from the input vegetation files used to create the original

MEGAN2.1 emission factors. Despite the differences in absolute magnitude, the spatial pattern in emission factors in Figure 14 are very similar to those used earlier in this work (Figure 8), with a spatial R^2 of 0.91.

740

Figure 14. MEGAN3 isoprene emission factors ($\mu\text{g m}^{-2} \text{hr}^{-1} \text{LAI}^{-1}$).

We implement the MEGAN3 emission factors in GEOS-Chem v12.3.0 using the canopy surrogate model activity factor formulation. For clarity, we refer to “MEGAN3_{Full}” as the emissions implementation in GEOS-Chem v12.3.0 using the

745 MEGAN3 leaf-level emission factors and MEGAN3 activity factors with canopy physics calculated following the canopy surrogate model described in Section 3. The annual isoprene emissions simulated using MEGAN3_{Full} are higher than using the MEGAN2.1 canopy-scale factors in GEOS-Chem (as in both MEGAN_{Canopy} and MEGAN_{PCEEAA}), but more in line with previous work (Guenther et al. 2012).

750 Specifically, annual total isoprene emissions for 2012 are $\sim 570 \text{ Tg C yr}^{-1}$ in MEGAN3_{Full} which is a factor of 1.6 larger than those configurations discussed

earlier in this manuscript. The largest contribution to these differences is not the differences in emission factor maps, but is instead the removal of the normalization factor of 0.21, which additionally removes the need for the somewhat arbitrary choice of “standard conditions” for emissions (see Section 4.1). This 570 Tg yr⁻¹ emissions total is much more similar to the magnitude of global emissions from versions of MEGAN2.1 implemented outside of the GEOS-Chem model (535-578 Tg yr⁻¹) given by Guenther et al. (2012), and within the stated uncertainty range for MEGAN isoprene emissions (Guenther et al., 2012). These annual average isoprene emissions using MEGAN3_{Full} are shown in Figure 15 below. In general the spatial pattern in the emissions in Figure 15 matches those from the MEGAN_{Canopy} configuration (Figure 9), with an R² of ~0.8.

765 **Figure 15. Annual average (2012) isoprene emissions simulated in GEOS-Chem driven by the surrogate model canopy physics and the MEGAN3 emission and activity factors.**

Since the isoprene emissions calculated using the MEGAN3_{Full} algorithm are so much larger than those used in previous versions of GEOS-Chem, they alter the

composition of the atmosphere significantly. For example, annual average surface ozone concentrations in the Southeast U.S. increase by nearly 5 ppbv relative to the base version of GEOS-Chem v12.3.0 (which uses MEGAN_{PCEE}), exacerbating the existing model bias further (Travis et al., 2016). However, MEGAN3_{Full} represents a more up-to-date and physical characterization of biogenic emissions. Future work reconciling the differences between these bottom up isoprene emissions estimates and top down constraints from measurements of composition (e.g. Kaiser et al., 2018) is needed.

7. Conclusions

We describe a novel method for simulating canopy physics relevant to atmospheric chemistry at very low computational cost. Our surrogate canopy model is based on the detailed canopy model in the MEGAN3 codebase, and simplified using a statistical learning technique for the determination of variable importance. This updated scheme allows for improved physical process representation of biosphere-atmosphere interactions, including a full implementation of the MEGAN3 emissions scheme activity factors and a more direct implementation of the light and LAI dependence of dry deposition.

When implemented into a chemical transport model, this canopy scheme impacts the spatial distribution of isoprene emissions, but maintains the global total to within 5%. Consistent with prior work (Kaiser et al., 2018), isoprene emissions are reduced over the Southeast United States, with local absolute changes that can exceed 30%. This difference in surface-atmosphere exchange ultimately has a

790 modest impact on surface ozone, with absolute annual average changes generally
less than 1ppbv, though it does drive ozone concentrations closer to observed
values. The surrogate model additionally allows for integrating new leaf level
emission factor maps into GEOS-Chem, which we show leads to substantial changes
in biogenic emissions.

795 In a rapidly changing earth system, it is critical to represent chemical, biological, and
physical processes with as high fidelity as possible. Surrogate models that allow for
rapid implementation of computationally expensive processes can play a key role in
representing these processes. The work presented in this manuscript represents a
step toward further explicit descriptions of biosphere-atmosphere interactions in
800 models of atmospheric chemistry. Future work should include more detailed
observational constraints and characterization of in-canopy chemical reactions,
turbulent exchange, and biological processes, and their resulting impacts on
abundances of trace gases in the atmosphere.

Author Contributions

805 CLH and SJS designed the study. SJS developed and implemented the surrogate
model and performed simulations and analysis. ABG developed MEGAN3 model
code. All authors contributed to the manuscript preparation.

Code Availability

The MEGAN3 and GEOS-Chem model code are available at:

810 <https://bai.ess.uci.edu/megan/data-and-code>, and

<https://zenodo.org/record/2620535>, respectively. The updated GEOS-Chem code containing the canopy model changes is available at:

<https://zenodo.org/record/3614062>.
