Abstract.

Hydrologic modeling is an essential strategy for understanding and predicting natural flows, particularly where observations are lacking in either space or time, or where complex terrain leads to a disconnect in the characteristic time and space scales of overland and groundwater flow. However, significant difficulties remain for the development of efficient and extensible modeling systems that operate robustly across complex regions. This paper introduces the Simulator for Hydrologic Unstructured Domains (SHUD), an integrated, multi-process, multi-scale, flexible-timestep model, in which hydrologic processes are fully coupled using the Finite Volume Method. SHUD integrates overland flow, snow accumulation/melt, evapotranspiration, sub-surface flow, groundwater flow, and river routing, thus allowing physical processes in general watersheds to be realistically captured. SHUD incorporates one-dimensional unsaturated flow, two-dimensional groundwater flow, and a fully connected river channel network with hillslopes supporting overland flow and baseflow.

The paper introduces the design of SHUD, from the conceptual and mathematical description of hydrologic processes in a watershed to the model's computational structures. To demonstrate and validate the model performance, we employ three hydrologic experiments: the V-Catchment experiment, Vauclin's experiment, and a model study of the Cache Creek Watershed in northern California. Ongoing applications of the SHUD model include hydrologic analyses of hillslope to regional scales (1 m² to 10⁶ km²), water resource and stormwater management, and interdisciplinary research for questions in limnology, agriculture, geochemistry, geomorphology, water quality, ecology, climate and land-use change. The strength of SHUD is its flexibility as a scientific and resource evaluation tool where modeling and simulation are required.

1 Introduction

The complexity of today's environmental issues, the multidisciplinary nature of scientific and resource management questions, and the diversity and incompleteness of available observational data have all led to the need for models as a means of synthesis. When models are computationally efficient and physically consistent, they become important tools for extrapolation across observations and systems. They help us better understand the physical history of a given system and make decisions about

the future in light of socioeconomic, hydrologic, or climatological change. The datasets produced through modeling can assist with decisions for infrastructural planning, water resource management, flood protection, contamination mitigation, and other relevant concerns. Nonetheless, models of varying complexity are available, and the required model complexity (resolution, scale, coupled states/fluxes) for a given problem depends on the particular research or management purpose, the questions to be answered, and the data available.

Nonetheless, environmental managers, policymakers, and stakeholders have a growing demand for high-resolution and detailed information about hydrologic flows at fine temporal-spatial resolution across watersheds. This need reflects the ever-increasing importance of detailed long-term predictions and projections for ecological systems, agricultural development, and food security under future climate change. Global climate modeling, typically performed with a general circulation model, also requires information on soil moisture and groundwater fluctuations, which are related to streamflow and reservoir management (Hrachowitz and Clark, 2017; Blöschl et al., 2019).

In hydrology, lumped models (Hawkins et al., 1985; Fleming, 2010; Bergström, 1992) have proven to be fast and stable tools for estimating the streamflow in rivers, requiring simplified meteorological data and limited observed flow data. Lumped models disregard the spatial heterogeneity of terrestrial characteristics while including the basic watershed features (e.g., contributing area, overall relief, average landuse, soil conditions, etc.). Their purpose is input-output analysis without internal structure (Moradkhani and Sorooshian, 2008) and their parameters may lack precise physical meaning, which makes it challenging to interpret watershed characteristics or transfer parameters to other regions. On the other hand, distributed models (Beven, 2012; Lin et al., 2018; Gochis et al., 2015; Santhi et al., 2006; Liang et al., 1996; Vivoni et al., 2011; Refsgaard et al., 1998; Shen and Phanikumar, 2010) also have their limitations. One challenge for multi-process distributed models is addressing uncertainties in spatial parameters (soils, hydrogeology, land-surface processes, etc.) and limited predictive skill for large, high-resolution catchments, even if the estimated model parameters (e.g. soil properties, surface characteristics, aquifer properties) and atmospheric inputs have incommensurate resolutions. The latter is particularly important to watershed calibration and has led to a major source of uncertainty (Beven, 2012; Blöschl et al., 2019). Nonetheless, at the continental and global scale, progress has been made in higher resolution elevation data, refined soil surveys (Soil Survey Staff, 2015), satellite land cover (Homer and Fry, 2012) and much higher resolution atmospheric inputs. This has created new opportunities for the development of new hydrologic models that leverage advances in data and mathematical/computational strategies.

Communities have become more sophisticated about their choice of models (Beven, 2012) and tailoring models to explicit purpose or applications, with models ranging from the simplest lumped models (HEC-HMS (Fleming, 2010), HBV (Bergström, 1992)), to semi-distributed models (Beven, 1989; Beven and Germann, 1982; Beven and Kirkby, 1979), to complex distributed hydrologic models (WRF-Hydro (Lin et al., 2018; Gochis et al., 2015), PRMS (Leavesley et al., 1983), SWAT (Santhi et al., 2006), VIC (Liang et al., 1996), MIKE-SHE (Abbott and Refsgaard, 1996; Refsgaard et al., 1998), inHM (VanderKwaak, 1999), tRIBS (Vivoni et al., 2011, 2004, 2005) and PAWS (Shen and Phanikumar, 2010)), and even cutting-edge hydrologic models based on machine-learning methods (Rasouli et al., 2012; Petty and Dhingra, 2018; Shen et al., 2018). In each case the choice of model requires the assessment of factors related to prediction variables, performance, flexibility, and availability of data.

The Simulator for Hydrologic Unstructured Domains (SHUD) is a multi-process, multi-scale model where major hydrologic processes are fully coupled using the Finite Volume Method (FVM). SHUD encapsulates the strategy for the synthesis of multi-state distributed hydrologic models using the integral representation of the underlying physical process equations and state variables. As an intellectual descendant of Penn State Integrated Hydrologic Model (PIHM), the SHUD model is a continuation of 16 years of PIHM model development in hydrology and related fields since the release of its first PIHM version (Qu, 2004).

The conceptual structure of the *two-state integral-balance* model for soil moisture and groundwater dynamics was originally devised by (Duffy, 1996), in which the partial volumes occupied by unsaturated and saturated moisture storage were integrated directly into a local conservation equation. This two-state integral-balance structure simplified the hydrologic dynamics while preserving the natural spatial and temporal scales contributing to runoff response. Brandes et al. (1998) used FEMWATER to capture the inflow/outflow behavior within a hillslope-stream scheme. In 2004, Qu (2004) embedded evapotranspiration and river networks and released the Penn State Integrated Hydrologic Model (PIHM) v1.0, which was the most important milestone of the two-state integral-balance model. Since PIHM v1.0 (Qu, 2004), the PIHM has been a generic hydrologic model applicable to general watersheds or basins. After that, PIHM v2.0 (Kumar et al., 2009; Kumar and Duffy, 2009) enhanced PIHM's land surface modeling component. A GIS-tool, PIHMgis(Bhatt et al., 2014) and the Essential Terrestrial Variables Data Server (HydroTerre (Leonard and Duffy, 2013)) accelerated model deployment and motivated additional applications with PIHM. Because of the sophisticated hydrologic modeling capability and efficient spatial representation in PIHM, various model coupling projects were later initiated. For example, Flux-PIHM coupled the NOAH Land Surface Model into PIHM to provide a more detailed calculation of energy balance and evapotranspiration (Shi et al., 2015, 2014). Zhang et al. (2016) coupled landscaping evolution with PIHM (LE-PIHM). Bao (Bao, 2016; Bao et al., 2017) added a reaction-transport module to PIHM (RT-PIHM, RT-Flux-PIHM). Flux-PIHM-BGC (Shi et al., 2018) provided biogeochemistry into Flux-PIHM. The Multi-Module PIHM (MM-PIHM) project (<https://github.com/PSUmodeling/MM-PIHM>) was then devised to build a uniform repository for all coupled modules. Still, more PIHM coupling projects are ongoing, targeting sediments, lakes, crops, and other systems. Simultaneously, a Finite volume-based Integrated Hydrologic Modeling (FIHM) was also developed (Kumar et al., 2009), which used second-order accurate finite volumes and solved for both 2D unsteady overland flow and 3D subsurface flow. Figure 1 shows the family tree of PIHM and SHUD. Within this tree, essentially every revision/branch received cross-pollination from others, supporting the ever growing complexity of these systems. The PIHMgis (Bhatt et al., 2014) and SHUDtoolbox (Shu, 2020) are GIS, pre- and post-processing tools for PIHM and SHUD, respectively. Although PIHM and SHUD share the same fundamental conceptual two-state integral model, both the inputs and outputs are incompatible. Details of differences between them are summarised in section 4.1 of this paper.

SHUD's design is based on a concise representation of a watershed and river basin's hydrodynamics, which allows for interactions among major physical processes operating simultaneously, but with the flexibility to add or drop state-process-constitutive relations depending on the objectives of the numerical experiment.

As a distributed hydrologic model, the computational domain of the SHUD model is discretized using an unstructured triangular irregular network (e.g., Delaunay triangles) generated with constraints (geometric and parametric). A local prismatic

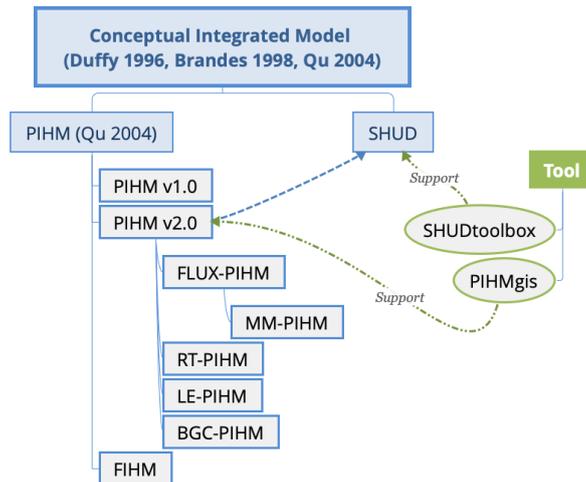

Figure 1. The family tree of PIHM and SHUD. PIHM and SHUD share the same fundamental conceptual model, but use different realization. The PIHMgis and SHUDtoolbox (Shu, 2020) are GIS-tools for pre- and post-processing.

control volume is formed by the vertical projection of the Delaunay triangles forming each layer of the model. Given a set of constraints (river network, watershed boundary, elevation, and hydraulic properties), an *optimized mesh* is generated. The *optimized mesh* allows the underlying coupled hydrologic processes for each finite volume to be calculated numerical efficiently and stability (Farthing and Ogden, 2017; Vanderstraeten and Keunings, 1995; Shewchuk, 1996). River volume cells are also prismatic, with trapezoidal or rectangular cross-section, and maintain the topological relation with the Delaunay triangles. The local control volumes encapsulate all equations to be solved and are herein referred to as the model kernel. The R package SHUDtoolbox (Shu, 2020) has been developed to help users generate these triangular domains.

The objective of this paper is to introduce the design of SHUD, from the fundamental conceptual model of hydrology to governing hydrologic equations in a watershed to computational structures describing hydrologic processes. Section 2 describes the conceptual design and equations used in the model. In section 3, we employ three hydrologic experiments to demonstrate the simulation and capacity of the model. The three applications presented here are (1) the V-Catchment experiment, (2) the Vauclin experiment (Vauclin et al., 1979), and (3) the Cache Creek Watershed (CCW), a headwater catchment in Northern California. Section 4 summarizes the differences between SHUD and PIHM, then proposes possible applications of the SHUD model.

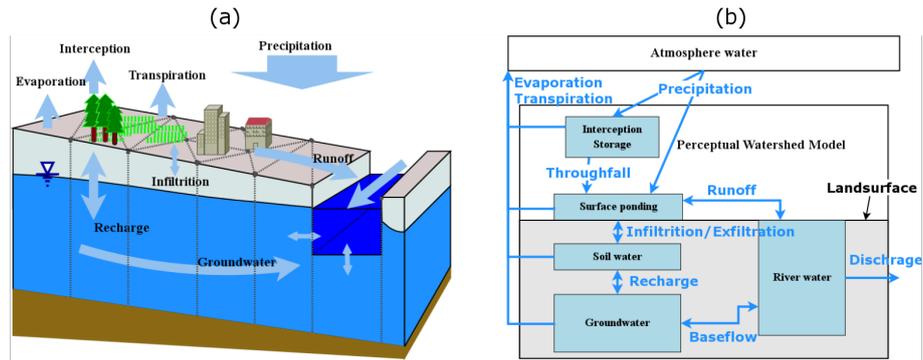

Figure 2. The conceptual schematic of hydrologic processes in the SHUD model.

2 Model design

2.1 Conceptual description of hydrologic system

We begin our introduction to the SHUD model with a conceptual description of water movement in a watershed. Figure 2 depicts processes that are incorporated in the model. Catchment hydrology is driven by atmospheric inputs, including rain-
 110 fall, snowfall and irrigation. The land surface hydrology first interacts with vegetation through plant-canopy interception and through-fall. When precipitation exceeds the interception capacity, through-fall or excess precipitation falls to the land surface. Snowfall accumulation and melting is an important land-surface process and a major source of soil moisture and recharge in many temperate or mountainous climate regions. SHUD captures the partitioning of excess precipitation into surface runoff and infiltration into the soil.

115 Vertically, the aquifer is divided into two coupled layers based on its saturation status: the top unsaturated layer (or vadose layer) is constrained to 1-D vertical flow and the saturated groundwater layer admits 2-D flow. These layers overlie an impermeable or low-permeable layer such as bedrock or an effective depth of circulation where deeper flows are small and unlikely to contribute to baseflow. The vertical fluxes within the unsaturated zone include infiltration and exfiltration. Deep percolation or recharge to groundwater is fully coupled to soil moisture dynamics. SHUD accounts for conditions when the groundwater
 120 table reaches or exceeds the land surface, decreasing infiltration, allowing exfiltration as local ponding and runoff. The model also accounts for upward capillary flow from a shallow water table depending on soil moisture and vegetation conditions. Lateral (2-D) groundwater flow represents the basic mechanism for baseflow to streams or rivers.

Surface runoff or overland flow is generated by excess rainfall and ponding and is represented as 2-D shallow water flow in SHUD. Surface runoff complements baseflow runoff as the dominant source of streams or rivers. SHUD also allows reversing
 125 flows from the channel to the hillslope as surface inundation or channel losses to groundwater. This may occur when the river stage rises above bankfull storage during flooding events or in an arid region where the river recharges the local groundwater.

Evaporation generally represents the largest water loss from the catchment with four components: evapotranspiration (ET) from interception storage, surface ponding, soil moisture and shallow groundwater. Transpiration occurs only when vegetation

is present and could draw from the saturated groundwater when the groundwater level is high enough. Direct evaporation
130 occurs from interception, ponding water, and soil moisture.

Following the above description, several assumptions and simplifications are made in the SHUD model:

- In the default configuration, the watershed boundary is generally handled as a closed domain, in which precipitation/evapotranspiration are the major vertical fluxes and river flow is the major lateral flow into and out of the domain. It is a common water balance assumption of $\Delta S = P - E - Q$, where ΔS , P , E , Q are total water storage, precipitation,
135 evapotranspiration and discharge, respectively. Modifications to these conditions can be applied to realize additional flows such as pumping wells, irrigation, basin diversions, and so forth. The model is able to further support boundary conditions as needed for various research questions.
- The hydraulic gradient is vertical within the soil column and is controlled by gravity and capillary potential. This assumption is invalid for microscale soil water movement but useful when the model grid spacing ranges from meters to
140 kilometers (Beven, 2012).
- The evaporative fluxes that occur due to ET from rivers are assumed to be small and can be approximated by the evapotranspiration from the riparian or hyporheic area of the model where the shallow water table and high soil moisture conditions exist.
- The hydrologic characteristics, including all physical parameters in soil, land-use, and terrain, are homogeneous within
145 each cell. This is a typical assumption in distributed models, as these models still need discretized domains.
- At present SHUD requires all geographic, topographic and hydraulic parameters do not change in time.
- Finally, SHUD uses a simplified representation of the geometry of the river networks due to the limitation of such data. This assumption is due to the inherent challenges in measuring the geometry of the river cross-section everywhere along with the stream network.

150 2.2 Mathematical structure

The notation used in this section is summarized in the list of symbols in the appendix.

Figure 3 depicts the geometric structure of the discrete cells in SHUD. The watershed domain is discretized using an irregular unstructured triangular network (Delaunay triangles) generated with imposed spatial constraints by Triangle (Shewchuk, 1996). Non-Delaunay triangulations are also permitted, so any GIS software and advanced programming language (R, Matlab and
155 Python) could potentially generate the triangular domain. A prismatic control volume is formed by the vertical extension of the Delaunay triangles to produce three layers: land surface layer, unsaturated zone, and groundwater layer. The modeler is responsible for defining the aquifer depth (from the land surface to the impervious bedrock) based on measurements or terrestrial characteristics. The thickness of the unsaturated zone (D_{us}) is determined by the difference between the land surface elevation (z_{sf}) and groundwater table (z_{gw}) above datum, i.e. $D_{us} = z_{sf} - z_{gw}$. When the groundwater table reaches the land
160 surface ($z_{gw} > z_{sf}$), the thickness of unsaturated zone $\rightarrow 0$.

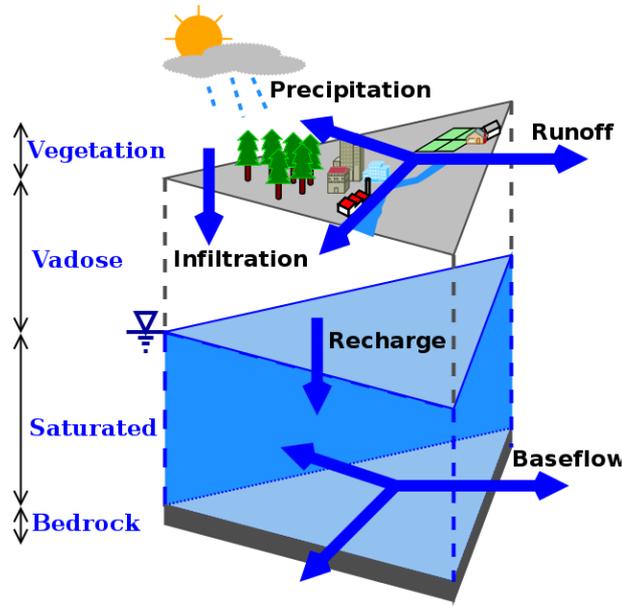

Figure 3. The three layers of the SHUD model and fluxes between layers.

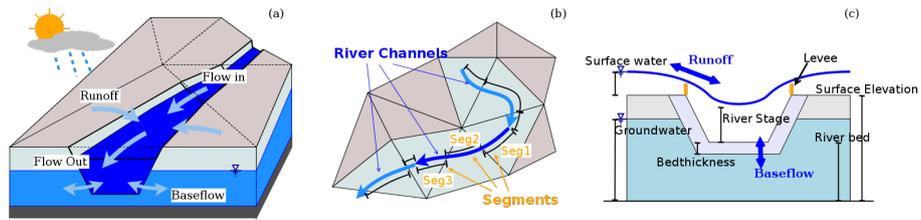

Figure 4. A depiction of the interaction between cells and the river network in the SHUD showing (a) water balance in river channels, (b) the topologic relationship between river channels and hillslope cells, and (c) water fluxes between river segments and hillslope cells.

Figure 4 depicts the exchange of water between the rivers and hillslope cells. Within each river channel, there are two longitudinal fluxes and two lateral fluxes: upstream (Q_{up}), downstream (Q_{dn}), overland (Q_{sf}) and groundwater (Q_{sub}).

The hydrologic model uses the Method of Moments to reduce the partial differential equations (PDEs) into ordinary differential equations (ODEs) and solve the ODE system using a globally implicit numerical solver. The state variables include water height on the land surface (Y_{sf}), soil moisture storage (Y_{us}), groundwater depth (Y_{gw}), and river stage (Y_{riv}). The initial value problem for these ODEs is formulated as

$$\frac{d\mathbf{Y}}{dt} = f(t, \mathbf{Y}), \quad \mathbf{Y}(t_0) = \mathbf{Y}_0,$$

Table 1. The governing equations in the SHUD model.

Physical process	Method	Governing equation	Reference equation
Interception	Bucket model	$\frac{dS_{ic}}{dt} = P - E_{ic} - P_{tf}$	1
Snow melt	Temperature Index Model	$\frac{dS_{sn}}{dt} = P - E_{sn} - q_{sm}$	9
Overland flow	Diffusive Wave	$\frac{\partial h}{\partial t} + \frac{\partial(uh)}{\partial x} + \frac{\partial(vh)}{\partial y} = q$	11
Unsaturated zone	Richards Equation	$C(\psi) \frac{\partial \psi}{\partial t} = \nabla - K(\psi) \cdot \nabla(\psi + Z)$	15
Groundwater flow	Richards Equation	$C(\psi) \frac{\partial \psi}{\partial t} = \nabla - K(\psi) \cdot \nabla(\psi + Z)$	18
River channel	St. Venant Equation (1D)	$\frac{\partial h}{\partial t} + \frac{\partial(uh)}{\partial x} = q$	25

where the discrete state vector is denoted by \mathbf{Y} ,

$$\mathbf{Y} = \begin{pmatrix} \mathbf{Y}_{sf} \\ \mathbf{Y}_{us} \\ \mathbf{Y}_{gw} \\ \mathbf{Y}_{riv} \end{pmatrix},$$

\mathbf{Y}_0 are the initial conditions and $f(t, \mathbf{Y})$ denotes the equations governing the hydrologic flow, which are described in this section.

165 The system of ODEs describing the hydrologic processes are fully coupled and solved simultaneously at each time step ($\Delta t = t_n - t_{n-1}$) using CVODE, a stiff solver based on Newton-Krylov iteration (Hindmarsh et al., 2019). In brief, the CVODE solver calculates $\mathbf{Y}(t_n)$, given $\mathbf{Y}(t_{n-1})$ and $\frac{d\mathbf{Y}}{dt}|_{t_{n-1}}$. The technical description of the CVODE solver can be found in the literature (Hindmarsh et al., 2019, 2005; Cohen and Hindmarsh, 1996). The governing equations in SHUD are provided in table 1.

170 Figure 5 depicts the workflow within the SHUD model. The explicit model time step (MTS) $\Delta t = t_n - t_{n-1}$ is user-specified, typically varying from one minute to one hour. Within the MTS, the relevant gradient law determines the fluxes, and hence all state values.

The fluxes of ET and interception change relatively slowly within short periods (such as one hour) so that full coupling of ET with soil water is not necessary for this model. Instead, the interception, ET and snow calculations are solved explicitly at 175 the MTS, while the calculation of \mathbf{Y}_{sf} , \mathbf{Y}_{us} , \mathbf{Y}_{gw} and \mathbf{Y}_{riv} use the implicit time step (ITS).

The CVODE solver determines the ITS automatically based on both the specified tolerances and the error function of \mathbf{Y} and $d\mathbf{Y}$. The initial ITS equates to the explicit MTS. Within the ITS, $d\mathbf{Y}$ s is calculated based on \mathbf{Y} from the last MTS. If the CVODE solver converges with the current value of the ITS, it returns the updated \mathbf{Y} . Otherwise, a convergence failure occurs that forces an ITS reduction.

180 The mathematical model underlying SHUD consists of five components: vegetation and evapotranspiration, land surface, unsaturated layer, saturated layer, and river channel. These are described in the following subsections.

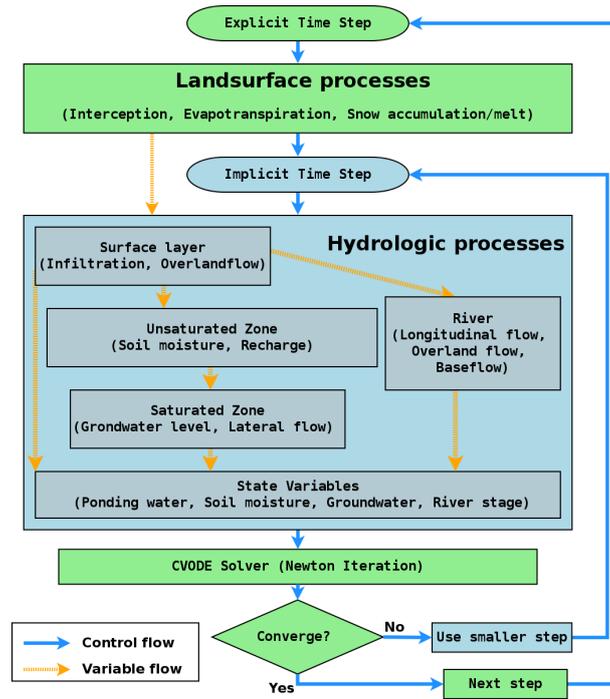

Figure 5. The flowchart demonstrates calculation of variables and time step control in the SHUD model. The hydrologic processes are simulated in each finite volume cell, then the state variables (Y) are passed to the CVODE solver.

2.2.1 Vegetation and evapotranspiration

Interception refers to the direct water loss of precipitation when vegetation cover exists, and is treated as a simple storage *bucket* — namely, precipitation cannot reach the land surface until the interception storage capacity is satisfied. The capacity of this storage is the maximum interception volume, which is a function of the vegetation Leaf Area Index (LAI) and satisfies equation 185 $S_{ic}^* = C_{ic}LAI$, where LAI represents the coverage of vegetation canopy over the land area (area of leaves over the area of land, m^2/m^2), and C_{ic} is interception coefficient [m]. The default C_{ic} is taken to be $0.2 \text{ kg}/m^2$ as suggested in Dickinson (1984).

The interception is equal to the deficit of interception – the difference between interception capacity (S_{ic}^*) and existing 190 interception storage (S_{ic}). If precipitation is less than the deficit, interception is equal to the precipitation rate (see Fig. 6).

$$\frac{dS_{ic}}{dt} = q_{ic} - E_{ic} \quad (1)$$

$$q_{ic} = \begin{cases} \min\left[\frac{S_{ic}^*}{\Delta t}, P\right] & S_{ic} \leq 0 \\ \min\left[\frac{(S_{ic}^* - S_{ic})}{\Delta t}, P\right] & 0 < S_{ic} < S_{ic}^* \\ 0 & S_{ic} \geq S_{ic}^* \end{cases} \quad (2)$$

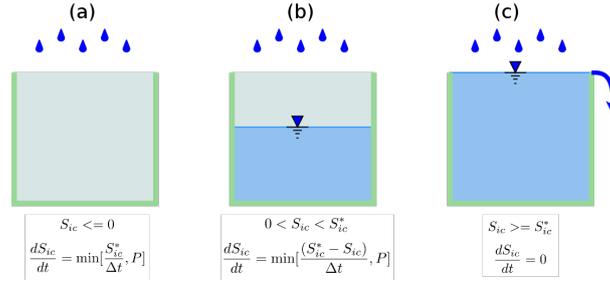

Figure 6. The three conditions for the interception calculation within the imaginary canopy *bucket*. The through-fall or excess precipitation after interception produces the water gain on the land surface.

Potential Evapotranspiration (PET) is the quantity of water that would evaporate and transpire from an ideal surface if extensive free water was available to meet the demand (Maidment, 1993; Kirkham, 2014). As such, PET is a practical and rapid estimation of water flux from land to atmosphere. The PET (E_0) is governed by Penman-Monteith equation (Penman, 1948):

$$E_0 = \frac{1}{\lambda} \frac{\Delta (R_n - G) + \rho_a c_p \frac{(e_s - e_a)}{r_a}}{\Delta + \gamma \left(1 + \frac{r_s}{r_a}\right)}. \quad (3)$$

Here we do not elaborate on this equation, as it is common among different hydrologic models (Allen, 1998; Maidment, 1993). At each ET step, the model calculates PET in terms of the prescribed forcing data. PET values are conditioned on the parameters from various land cover types, including factors for albedo, LAI, and roughness length.

The total Actual Evapotranspiration (AET) consists of three parts: evaporation from interception (E_c), transpiration from vegetation canopy (E_t) and direct evaporation of soil (E_s). The calculation of AET for these three components follows from the equations below:

$$E_c = \max[S_{ic}/\Delta t, E_0], \quad (4)$$

$$E_s = E_0 \beta_s (1 - \alpha_{imp})(1 - \alpha_{veg}), \quad (5)$$

$$E_t = E_0 \beta_s (1 - \alpha_{imp}) \alpha_{veg}, \quad (6)$$

$$\beta_s = \frac{\theta - \theta_r}{\theta_{fc} - \theta_r}. \quad (7)$$

Here, E_c is controlled by PET from interception storage. Both E_s and E_t are affected by soil water stress (β_s) and impervious area fraction (α_{imp}). Impervious area is also considered a barrier of evapotranspiration in the model. E_s is referred to as the demand water evaporation from soil, and emerges from two sources, namely the evaporation from ponding water (E_{sp}) and evaporation from soil moisture (E_{sm}), $E_s = E_{sp} + E_{sm}$. Ponded water has higher priority to evaporate and direct evaporation only uses the water in the surface when ponding water is able to meet the E_s demand, i.e. $y_{sf}/\Delta t > E_s$. When ponding water

is insufficient to meet E_s , soil water balances the difference between demand and available water in the surface; when ponding water does not exist, direct evaporation extracts water from the soil profile ($E_{sm} = E_s, E_{sp} = 0$):

$$215 \quad \begin{cases} E_{sp} = E_s, & E_{sm} = 0, & y_{sf} > E_s \times \Delta t, \\ E_{sp} = y_{sf}/dt, & E_{sm} = E_s - E_{sp}, & y_{sf} < E_s \times \Delta t, \\ E_{sp} = 0, & E_{sm} = E_s, & y_{sf} \leq 0. \end{cases} \quad (8)$$

Transpiration also has two potential sources: soil moisture and groundwater from the groundwater table and root depth for the land-use class. Once the groundwater table is higher than the root zone depth, vegetation uses groundwater, and soil moisture stress for transpiration is equal to zero ($\beta_s = 0$).

Water balance associated with snow accumulation is quantified via

$$220 \quad \frac{dS_{sn}}{dt} = P_{sn} - q_{sn}, \quad (9)$$

$$q_{sn} = (T - T_0) \times m_f, \quad (10)$$

225 Snow melt rate is determined by the snow melt factor (m_f), air temperature (T) and temperature threshold (T_0) at which snow melt occurs. This formulation is often referred to as the degree-day method, in which the values of the snow melt factor and temperature threshold are empirical (Maidment, 1993; Beven, 2012). The water from snow melt is considered as a direct water contribution to the land surface.

2.2.2 Water on the land surface

Water balance on the land surface is given by:

$$\frac{dy_{sf}}{dt} = P_n - E_{sp} - q_i - \sum_{j=1}^3 \frac{Q_s^j}{A_c}, \quad (11)$$

$$P_n = P - S_{ic} + q_{sn}, \quad (12)$$

$$230 \quad Q_s^j = \frac{L_j}{n} \overline{y_{sf}}^{\frac{5}{3}} s_0^{\frac{1}{2}}, \quad (13)$$

The water balance of net precipitation (P_n), infiltration (q_i), evaporation from the ponding layer (E_{sp}) and horizontal overland flow (Q_j) determine the storage of water on the land surface. Net precipitation (P_n) is the total residual water after adjusting for rainfall/snow interception and snowmelt. The overland flow Q_s^j in direction j is calculated with Manning's equation (13). Here $\overline{y_{sf}}$ is effective water height, determined by the gradient between two cells,

$$235 \quad \overline{y_{sf}} = \begin{cases} y_{sf} & z_{sf} + y_{sf} \geq z_{sf}^j + y_{sf}^j \\ y_{sf}^j & z_{sf} + y_{sf} < z_{sf}^j + y_{sf}^j \end{cases} \quad (14)$$

Infiltration is estimated using Richards equation:

$$q_i = K_{ei}(\Theta) \left(1 + \frac{y_s}{D_{inf}} \right)$$

$$K_{ei}(\Theta) = \begin{cases} K_r(\Theta)k_x(1 - \alpha_h) + \alpha_h k_m \Theta & y_s/\Delta t \geq K_{max} \\ K_r(\Theta)k_x(1 - \alpha_h) & y_s/\Delta t < K_{max} \end{cases}$$

$$K_r(\Theta) = \Theta^{\frac{1}{2}} \left(-1 + \left(1 - \Theta^{\frac{\beta}{\beta-1}} \right)^{\frac{\beta-1}{\beta}} \right)^2$$

$$240 \quad K_{max} = k_x(1 - \alpha_h) + \alpha_h k_m.$$

The infiltration rate is a function of soil saturation ratio (Θ), soil properties (k_x , k_m , α , β and α_h) and ponding water height (existing ponding water plus precipitation/irrigation). Infiltration occurs in the top soil layer (D_{inf}), and the infiltration rate results from the ponding water height and soil moisture. The default value of D_{inf} is 10 cm, which is adjustable in calibration files. The application rate $y_s/\Delta t$ combines ponding water, irrigation and precipitation together, and that determines the hydraulic gradient applied on the top soil layer. Finally, K_{max} is the infiltration capacity determined by both soil matrix and macropore characteristics. When application rate is less than the maximum infiltration capacity, the infiltration is controlled by soil matrix flow; when application rate is larger than K_{max} , effective conductivity is a function of the soil matrix and macropores (Chen and Wagenet, 1992). The infiltration equation takes the macropore effect into account, so the algorithm allows faster infiltration under heavy rainfall events and enables the soil to hold water for vegetation under dry conditions.

250 2.2.3 Unsaturated zone

As discussed above, the horizontal flow in the vadose zone is neglected compared to the dominant vertical flow. There are three processes controlling the water in vadose zone: infiltration (q_i), ET in soil moisture (E_{sm}) and recharge to groundwater (q_r). The calculation of infiltration and ET is explained in the previous subsection. Recharge to groundwater is calculated with equation (16). The soil moisture content to field capacity controls the recharge rate.

$$255 \quad s_y \frac{dy_{us}}{dt} = q_i - q_r - E_{sm}, \quad (15)$$

$$q_r = K_{er} \left(\frac{\theta - \theta_r}{\theta_{fc} - \theta_r} \right) \quad (16)$$

$$K_{er} = \frac{D_{us} + y_{gw}}{D_{us}/k_x + y_{gw}/k_v}, \quad (17)$$

Because of the simplifications required for the two-layer description of the vertical aquifer profile, SHUD uses the relationship between soil moisture and field capacity as the gradient to drive the recharge instead of the hydraulic gradient. K_{er} is the effective conductivity for recharge and is equal to the arithmetic mean of the conductivity of the unsaturated zone and saturated zone.

When the bottom of the vegetation root zone is below the groundwater table, then $E_{tg} > 0$ and vegetation extracts water from the saturated zone. Otherwise $E_{tg} = 0$, meaning that transpiration uses soil moisture. When ponding water exists on the

land surface, direct evaporation extracts water from ponding water first; when ponding water is depleted via evaporation, then
 265 the remainder of evaporation (E_{sm}) uses water from soil moisture based on the water stress.

2.2.4 Groundwater

The water balance of groundwater is controlled by the equation 18.

$$s_y \frac{dy_{gw}}{dt} = q_r - E_{tg} - \sum_{j=1}^3 \frac{Q_g^j}{A_c}, \quad (18)$$

$$Q_g^j = \bar{K} \cdot \frac{(y_{gw} + z_b) - (y_{gw}^j + z_b^j)}{d_j} \cdot (L_j \overline{y_{gw}}), \quad (19)$$

$$270 \quad \bar{K} = (K_{eg} + K_{cg}^j) * 0.5. \quad (20)$$

The calculation of horizontal groundwater flow uses the Boussinesq equation. When the bottom of the root zone is lower than the groundwater table, then $E_t > 0$, otherwise, $E_t = 0$.

The horizontal groundwater flux Q_g^j is determined by the Darcy equation and Dupuit-Forchheimer assumption. Above z_b is the elevation of impervious bedrock, z_b^j is the bedrock elevation of its j th neighbor cell and d_j is distance between the centroids
 275 of two adjacent cells, so the gradient between the two cells is $\left[(y_{gw} + z_b) - (y_{gw}^j + z_b^j) \right] d_j^{-1}$. The effective conductivity for the groundwater flow is the mean value of the effective horizontal conductivity over the two cells. The cross-sectional area along the groundwater flux is equal to $L_j \times \overline{y_{gw}}$.

In equation 20, the effective horizontal conductivity (K_{eg}) is a function of the groundwater table and characteristics of the macropores. The calculation of effective horizontal conductivity of each cell is given by

$$280 \quad K_{eg} = \begin{cases} k_g, & z_m > z_{gw}, \\ \frac{z_{gw} - z_m}{y_{gw}} (k_m \alpha_v + (1 - \alpha_v) k_g) + k_g, & z_m < z_{gw}, \end{cases} \quad (21)$$

$$z_{gw} = y_{gw} + z_{cb}, \quad (22)$$

where k_g and k_m are the saturated hydraulic conductivity of soil matrix and macropores, z_m , z_{gw} and z_{cb} are elevations of macropore, groundwater table and bedrock, and α_v is the vertical areal macropore fraction [m^2/m^2].

The effective horizontal conductivity captures the effect of spatially varying conductivity on the saturated flow when the
 285 groundwater level rises (Jiang et al., 2009; Bobo et al., 2012; Chen et al., 2018; Cheema, 2015; Taylor, 1960; Lin et al., 2007). Figure 7 reveals the effective horizontal conductivity changes along with different groundwater levels. When the groundwater table is below the level of the macropores, K_{eg} is equal to the saturated conductivity. When the groundwater level is above the macropore level, the effective conductivity increases with the groundwater level, taking into consideration the conductivity and area fraction of macropores in the soil profile. The effective conductivity reaches its maximum value once the groundwater
 290 table level reaches the land surface.

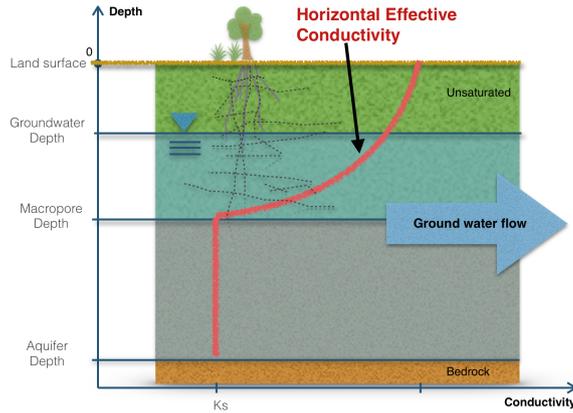

Figure 7. Effective conductivity for horizontal groundwater flow changes along the changing groundwater level. When the groundwater level is higher than macropore depth, groundwater flow increases due to the contribution of horizontal macropores.

2.2.5 Water in streams

The water balance in river channels is described by

$$\frac{dy_{riv}}{dt} = \frac{1}{A_r} \left(\sum_{j=1}^{j=N_c} Q_{sr}^j + \sum_{j=1}^{j=N_c} Q_{gr}^j + \sum_{j=1}^{j=N_u} Q_{up}^j + Q_{dn} \right). \quad (23)$$

The mass balance in each river channel consists of four parts: Q_s^j , the overland flow from cells (1 to N_c cells) that intersect with the river channel; Q_g^j , the lateral groundwater flux from intersection with the j th cell; Q_{up}^j , the longitudinal flow from upstream channels; and Q_{dn} , the flux to the downstream channel. N_u is the number of upstream channels; in the model, the number of upstream channels is nonnegative, but only one downstream channel is permitted. SHUD assumes river channels can converge to a single downstream channel. The convergence rule does not affect the topological relationship between river channels and cells.

The topological relationship between cells and river channels is shown in Fig. 4(b). As depicted, the river consists of a series of river reaches which intersect prismatic elements. A single reach is a sorted collection of multiple river segments, while each segment lies within hillslope cells. Surface and groundwater exchanges occur between each segment and the underlying cell. The sum of overland flow from multiple cells contributes to the net storage in a river reach.

The downstream channel flux Q_{dn} is based on the one-dimensional diffusive wave equation that is simplified as Manning's equation for open channel:

$$Q_{dn} = \frac{A_{cs}}{n} \left(\frac{A_{cs}}{P} \right)^{\frac{2}{3}} \bar{s}_0^{\frac{1}{2}}, \quad (24)$$

where A_{cs} is the cross-section area of the river reach, and \bar{P} and \bar{s}_0 are average wet perimeter and average slope of a river reach and its downstream reach.

The upstream flux Q_{up} is equal to the sum of Q_{dn} from the multiple upstream reaches. The water balance equation in the
 310 river channel neglects evaporation and precipitation because the area of open water in the watershed is relatively small, and
 the area of open water is already included in pre-computation for the cells. Therefore, the channel routing represents the water
 exchange between the river and hillslope and takes the overland flow and baseflow into account.

The overland flow between river segment and associated hillslope cell (Q_{sr}) is calculated as follows:

$$Q_{sr} = L_s C_w b_s \sqrt{2g|b_s|}, \quad (25)$$

$$315 \quad H_{riv} = y_{riv} + z_{rb}, \quad (26)$$

$$H_{csf} = y_{sf} + z_{cs}, \quad (27)$$

$$b_s = \begin{cases} H_{riv} - H_{csf}, & H_{riv} > z_{bank} \text{ and } H_{csf} > z_{bank}, \\ H_{riv} - z_{bank}, & H_{riv} > z_{bank} \text{ and } H_{csf} < z_{bank}, \\ H_{csf} - z_{bank}, & H_{riv} < z_{bank} \text{ and } H_{csf} > z_{bank}. \end{cases} \quad (28)$$

Here z_{bank} is the elevation of riverbank or levee, implying that the relative height of the land surface or river stage controls the
 direction of water exchange between the land surface and river segment.

320 The groundwater exchange between river segment and hillslope cell is described by Q_{gr} , which is calculated as

$$Q_{gr} = L_s b_g K_{gr} \frac{H_{riv} - H_{cgw}}{d_{rb}}, \quad (29)$$

$$H_{cgw} = y_{gw} + z_{cb}, \quad (30)$$

$$b_g = \begin{cases} y_{riv}, & H_{cgw} < z_{rb}, \\ \frac{1}{2}(y_{riv} + H_{cgw} - z_{rb}), & H_{cgw} > z_{rb}, \end{cases} \quad (31)$$

$$K_{gr} = \frac{1}{2}(k_{rb} + K_{eg}). \quad (32)$$

325 3 Applications

In this section, we present the results of using SHUD for three applications: first, we use the V-catchment experiment (Shu,
 2019e) to validate the calculation of overland flow and river routing in an idealized catchment; second, we use Vauclin's
 experiment (Vauclin et al., 1979) to assess the calculation of infiltration, unsaturated flow in the vadose zone and horizontal
 saturated flow; finally, we apply the model to a hydrologic simulation in the Cache Creek Watershed (Shu, 2019a), a headwater
 330 catchment in Sacramento Watershed of Northern California.

3.1 V-Catchment

The V-Catchment (VC) experiment is a standard test case for numerical hydrologic models to validate their performance for
 overland flow along a hillslope and in the presence of a river channel (Shen and Phanikumar, 2010). The VC domain consists
 of two inclined planes draining into a sloping channel (Fig. 8). Both hillslopes are 800×1000 m with Manning's roughness

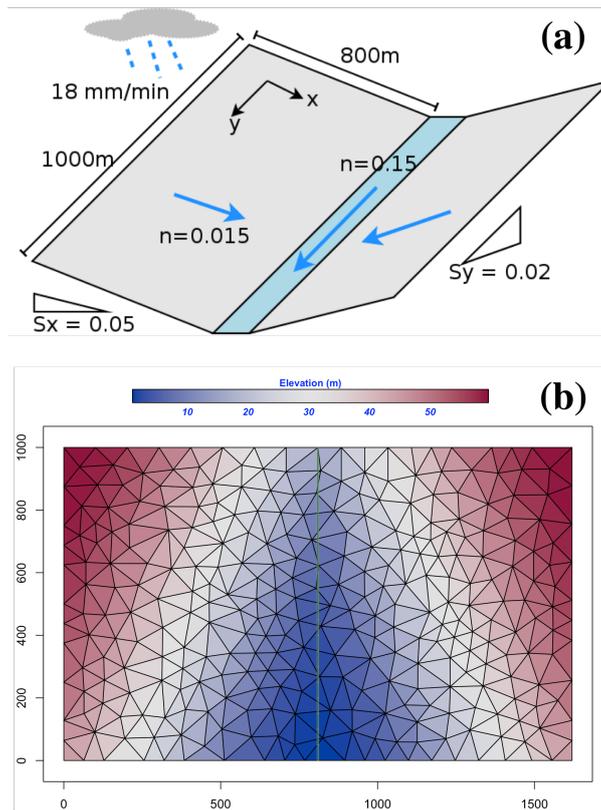

Figure 8. The tilted V-Catchment: (a) Basic structure of V-catchment, (b) the SHUD mesh used for the V-Catchment with elevation colored.

335 $n = 0.015$. The river channel between the hillslopes is 20 m wide and 1000 m in length with $n = 0.15$. The slope from the
 ridge to the river channel is 0.05 (in the x direction), and the longitudinal slope (in the y direction) is 0.02.

Rainfall in the VC begins at time zero at a constant rate of 18 mm/hr and stops after 90 min, producing 27 mm of accumulated
 precipitation. Since this experiment excludes the evaporation and infiltration, the total outflow from lateral boundaries and the
 river outlet must be the same as the total precipitation (following conservation of mass).

340 Figure 9 illustrates the discharge from the side-plane to the river channel and at the river outlet. The specific discharge
 (the volume discharge divided by the total area of the catchment) increases with precipitation until it reaches the maximum
 discharge rate, which is equal to the precipitation rate. Discharges along lateral boundaries and from the river outlet reach the
 maximum discharge rate, but at different times; namely, the discharge rate from the side-plane reaches the maximum value
 earlier than in the river outlet. The dots are discharge digitalized from Shen and Phanikumar (2010) with WebPlotDigitizer
 345 (<https://automeris.io/WebPlotDigitizer/>). The results suggest SHUD can correctly capture the processes in overland flow and
 channel routing, although flow from the river outlet occurs earlier than the prediction in Shen and Phanikumar (2010). Both
 the fluxes from side-plane and outlet meet the maximum flow rate, which is the same magnitude of precipitation after a short

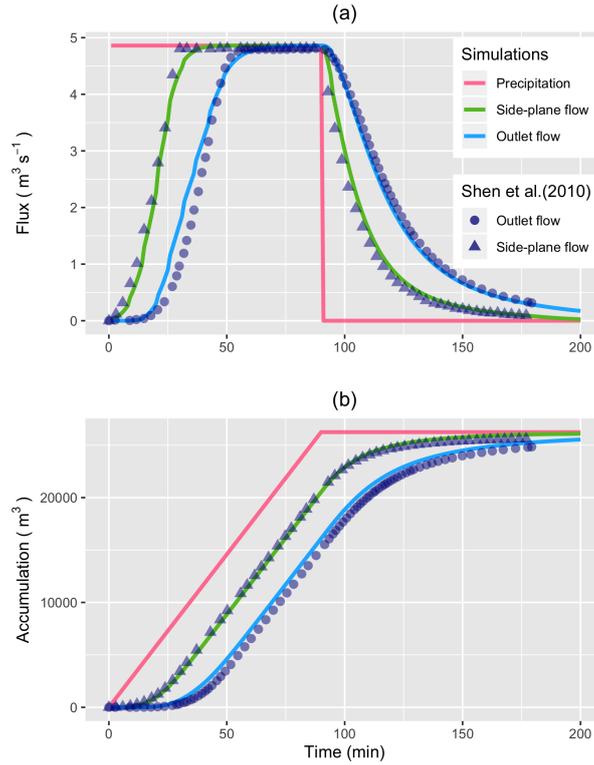

Figure 9. Comparison of overland flow and outflow at the outlet of the V-Catchment from the SHUD modeling versus Shen and Phanikumar (2010). (a) is volume fluxes, while (b) is accumulated water volume.

period of rainfall. The flux rates start decreasing after precipitation stops. The accumulated volume of flux confirms the correct mass-balance of both fluxes.

350 To verify correct performance of the numerical method, we calculate the bias of mass-balance in the model and assess the differences among input, output and storage change in the system (equation 35). For this simulation the bias ends up being $\sim 0.2\%$:

$$\Delta S = P - Q - E \quad (33)$$

$$\hat{\Delta S} = \Delta S_{ic} + \Delta y_{sf} + \Delta y_{us} + \Delta y_{gw} + \Delta y_{riv} \quad (34)$$

$$355 \text{ Bias} = \frac{|\hat{\Delta S} - \Delta S|}{\Delta S} \times 100\% \quad (35)$$

3.2 Vauclin's experiment

Vauclin's laboratory experiment (Vauclin et al., 1979) is to assess groundwater table change and soil moisture in the unsaturated layer under precipitation or irrigation. The experiment was conducted in a sandbox with dimension 3 m long \times 2 m deep \times 0.05

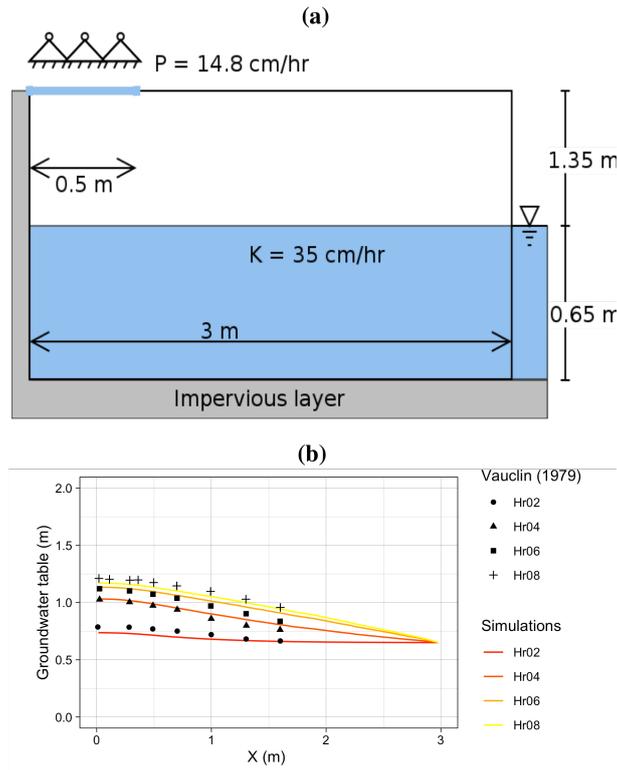

Figure 10. A schematic of (a) Vauclin’s experiment and (b) a comparison of Vauclin’s measurements versus simulated groundwater table change with SHUD.

m wide (see Fig. 10). The box was full of uniform sand particles with measured hydraulic parameters: the saturated hydraulic conductivity was 35 cm/hr, and porosity was $0.33 \text{ m}^3/\text{m}^3$. The left and bottom of the sandbox were impervious layers, and the top and the right side were open. The hydraulic head was 0.65 m constantly on the right boundary. Constant irrigation (1.48 cm/hr) was applied over the first 50 cm of the top-left of the sandbox while the rest of the top was covered to avoid water loss via evaporation.

The experiment’s initial condition is an equilibrium water table with a uniform hydraulic head. Irrigation was initiated at $t = 0$. The groundwater table was then measured at 2, 4, 6, and 8 hours at several locations along the length of the box. (Vauclin et al., 1979) also uses a 2-D (vertical and horizontal) numeric model to simulate the soil moisture and groundwater table. The maximum bias between measurement and simulation was 0.52 m, according to the digitalized value of Vauclin et al., 1979, Fig. 10.

Besides the parameters specified in (Vauclin et al., 1979), additional information is needed in the SHUD model, including the α and β in the van Genuchten equation and residual water content (θ_r). Therefore, we use a calibration tool to estimate the representative values of these parameters. The use of calibration in this simulation is reasonable because the model, inevitably, simplifies the real hydraulic processes. The calibration thus nudges the parameters to *representative* values that approach or

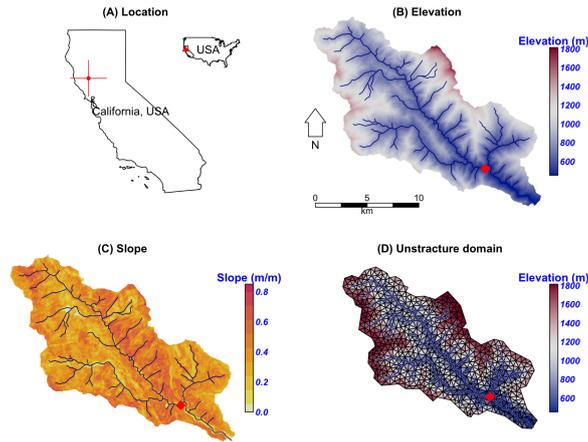

Figure 11. The location, terrestrial and hydrologic description of the Cache Creek in California. The red diamond in the map is the USGS gage station (11451100) used for calibration and validation.

fit the *true* natural processes. The calibrated values are $\theta_r = 0.001\text{m}^3/\text{m}^3$, $\alpha = 0.3$ and $\beta = 5.2$. The simulated results in our modeling and literature (Vauclin et al., 1979; Shen and Phanikumar, 2010) show a modest error between the simulations and measurements.

This error is likely due to (1) the need for a detailed aquifer layer description of soil layers or (2) possible invalidity of the vertical and horizontal flow assumptions in the SHUD model.

SHUD simulated the groundwater table at all four measurement points (see Fig. 10(b)). The maximum bias between simulation and Vauclin’s observations is 5.5 cm, with $R^2 = 0.99$, which is comparable to the bias 5.2 cm of numerical simulation in (Vauclin et al., 1979). By adding more layers to the structure, the bias in the simulation decreased to 3 cm. Indeed, as discussed earlier, the simplifications employed by SHUD for the unsaturated and saturated zone mainly benefits computational efficiency while limiting applicability where fine-scale soil profile information is required.

These simulations, compared against Vauclin’s experiment, generally validate the algorithm for infiltration, recharge, and lateral groundwater flow. A more reliable vertical flow within the unsaturated layer requires multiple layers, which is planned in the next version of SHUD.

3.3 Cache Creek Watershed

The Cache Creek Watershed (CCW)(Shu, 2019a) is a headwater catchment with area 196.4 km^2 in the Sacramento Watershed in Northern California (Figures 11 (a), (b) and (c)). The elevation ranges from 450 m to 1800 m, with a 0.38 m/m average slope, where the steep implies a particular challenge for numeric models.

Based on NLDAS-2 from 2000 to 2017, the mean temperature and precipitation were $12.8\text{ }^\circ\text{C}$ and $\sim 817\text{ mm}$, respectively, in this catchment. Precipitation varies seasonally; winter and spring are the primary wet seasons (Fig. 12).

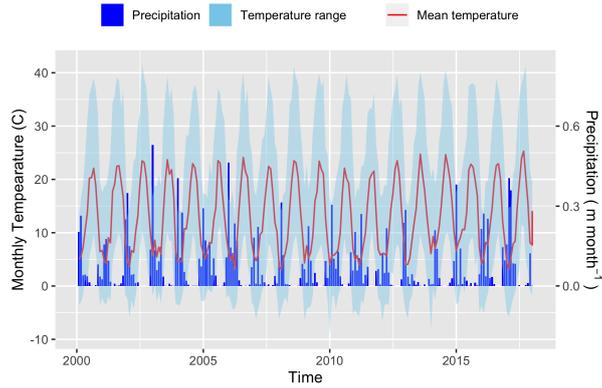

Figure 12. The monthly precipitation and temperature in Cache Creek based on NLDAS-2 data from 2000 to 2018. The blue ribbon is monthly precipitation in m/month; the red line is monthly mean temperature while the blue shaded region depicts the minimum and maximum temperature.

Data	Data Source	Type	Resolution
Hydrology	NHD plus(McKay et al., 2012)	Vector	-
Elevation	NED(U.S. Geological Survey, 2016)	Raster	30 m
Soil	gSSURGO(Soil Survey Staff, 2015)	Vector	-
Land-use	NLCD2006(Homer and Fry, 2012)	Raster	30 m
Climate	NLDAS-2 FORA(Xia et al., 2012)	Raster	1/8 deg

Table 2. The basic data sources used to build the model domain of the Cache Creek Watershed.

Table 2 lists the geospatial and forcing data supporting hydrologic modeling in the CCW. The DEM is 30-meter resolution raster data from National Elevation Dataset(NED)(U.S. Geological Survey, 2016). Forcing data, including precipitation, temperature, relative humidity, wind speed, and net radiation, is from NLDAS-2 ((Xia et al., 2012) <https://ldas.gsfc.nasa.gov/nldas/v2/forcing>). Our simulation in the CCW (Shu, 2019a) covers the period from 2000 to 2007. Because of the Mediterranean climate in this region, the simulation starts in summer to ensure adequate time before the October start to the water year. In our experiment, the first year (2000-06-01 to 2001-06-30) is the spin-up period, the following two years (2001-07-01 to 2003-06-30) are the calibration period, and the period from 2003-07-01 to 2007-07-01 is for validation.

The unstructured domain of the CCW (Fig. 11 (d)) is built with SHUDtoolbox (Shu, 2020). The domain consists of 1147 triangular cells, with a mean area of 0.17 km². The total length of the river network is 126.5 km and consists of 103 river reaches in which the highest order of stream is 4. With a calibrated parameter set, the SHUD model (Shu, 2019a) took 5 hours to simulate 18 years (2000-2017) in the CCW, with a non-parallel configuration (OpenMP is disabled on Mac Pro 2013 Xeon 2.7GHz, 32GB RAM).

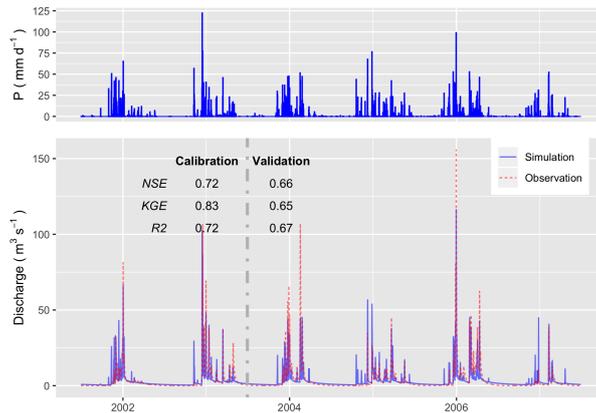

Figure 13. The hydrograph in Cache Creek (simulation versus observation) in the calibration (2001-07-01 to 2003-06-30) and validation periods (2003-07-01 to 2007-06-30).

Figure 13 reveals the comparison of simulated discharge against the observed discharge at the gage station of USGS 11451100 (https://waterdata.usgs.gov/ca/nwis/uv/?site_no=11451100). The calibration procedure exploits the Covariance Matrix Adaptation – Evolution Strategy (CMA-ES) to calibrate automatically (Hansen, 2016). The calibration program assigns 72 children in each generation and keeps the best child as the seed for next-generation, with limited perturbations. The perturbation for the next generation is generated from the covariance matrix of the previous generation. After 23 generations, the calibration tool identifies a locally optimal parameter set.

Within the calibration period, Nash-Sutcliffe efficiency (NSE Nash and Sutcliffe (1970)), Kling-Gupta Efficiency (KGE, Gupta et al. (2009)) and R^2 are 0.72, 0.83 and 0.72 respectively (Fig. 13). The goodness-of-fit in the validation period is less than calibration period (as expected), with NSE = 0.66, KGE = 0.67 and $R^2 = 0.65$. Although the SHUD model captures the flood peaks after rainfall events, the magnitude of high flow in the hydrograph is less than the gage data. There are two potential causes of this bias: (1) underestimated precipitation intensity from NLDAS-2 data, or (2) over-fitting in the calibration, as the NSE tends to capture the mean value of the observational data rather than the extremes.

Figure 14 represents the monthly water balance in CCW, in which the PET is three times the annual precipitation, but the actual evapotranspiration (AET) is only 27% of the precipitation. This result emerges because the summer is the peak of PET, while winter is the peak of precipitation and water availability. The AET is subjected to PET and water availability, so the maximum of AET occurs in early summer. The runoff ratio is about 73%.

We use the groundwater distribution (Fig. 15) to demonstrate the spatial distribution of hydrologic metrics calculated from the SHUD model. Figure 15 illustrates the annual mean groundwater table in the validation period. Because the model fixes a 30 m aquifer, the results represent the groundwater within this 30-meter aquifer only. The groundwater table and elevation along the green line on the map are extracted and plotted in the bottom figure. The gray ribbon is the 30-meter aquifer, and the blue line is the location where groundwater storage is larger than zero. The light blue polygons (with the right axis for

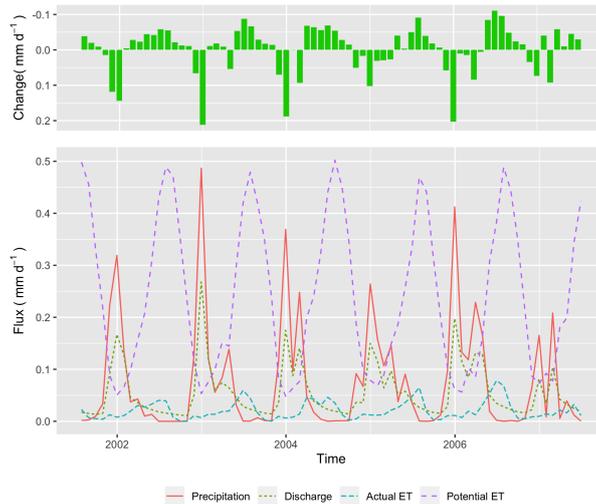

Figure 14. The monthly water balance trends in Cache Creek Watershed from 2001-07-01 to 2007-06-30. Top: net change of water storage; Bottom: fluxes of precipitation, actual evapotranspiration, potential evapotranspiration and discharge at the outlet.

425 scale) are the groundwater storage along the cross-section. The groundwater levels tend to follow the terrain, with groundwater accumulated in the valley or along relatively flat flood plains. In the CCW, groundwater does not stay on steep slopes suggesting the high conductivity of upland slopes.

4 Summary of SHUD features and differences from PIHM

The features of the SHUD model are as follows:

- 430
- SHUD is a physically-based process spatially distributed catchment model. The model applies national geospatial data resources to simulate surface and subsurface flow in gaged or ungaged catchments. SHUD represents the spatial heterogeneity that influences the hydrology of the region based on national soil data and superficial geology. Several other groups have used PIHM, a SHUD ancestor to couple processes from biochemistry, reaction transport, landscape, geomorphology, limnology, and other related research areas.
- 435
- SHUD is a fully-coupled hydrologic model, where the conservative hydrologic fluxes are calculated within the same time step. The state variables are the height of ponding water on the land surface, soil moisture, groundwater level, and river stage, while fluxes are infiltration, overland flow, groundwater recharge, lateral groundwater flow, river discharge, and exchange between river and hillslope cells.
- 440
- The global ODE system in SHUD is solved with a state-of-the-art parallel ODE solver, known as CVODE (Hindmarsh et al., 2005) developed at Lawrence Livermore National Laboratory.

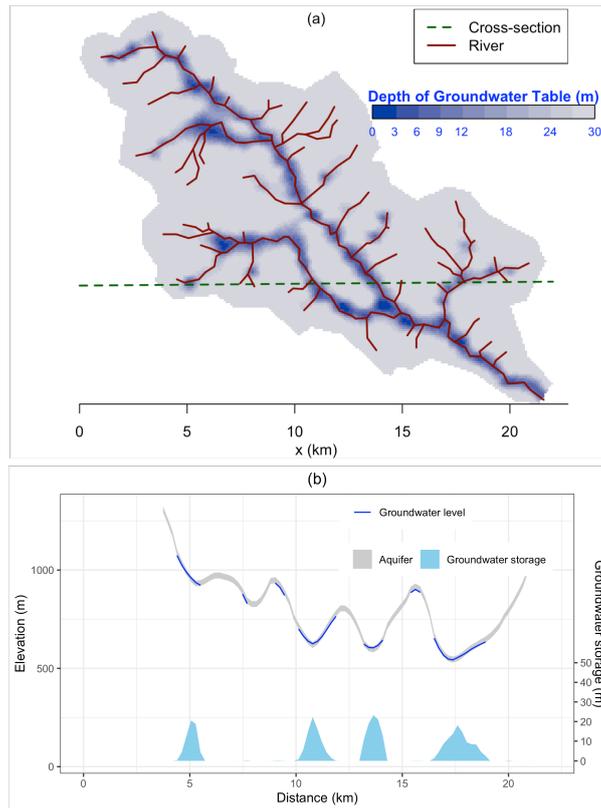

Figure 15. groundwater table (top) and the storage of groundwater (bottom) in 30 m depth aquifer. The groundwater table and elevation along the green dashed line on the top map are extracted and plotted in the bottom figure. The gray ribbon is the 30-meter aquifer, and the blue line is the groundwater table, only at the location where groundwater storage is larger than zero. The light blue polygons with the right axis are the groundwater storage along the cross-section.

- SHUD permits adaptable temporal and spatial resolution. The spatial resolution of the model varies from centimeters to kilometers based on modeling requirements computing resources. The internal time step of the iteration is adjustable and adaptive; it can export the status of a catchment at time-intervals from minutes to days. The flexible spatial and temporal resolution of the model makes it valuable for coupling with other systems.

445 – SHUD can estimate either a long-term hydrologic yield or a single-event flood.

- SHUD is an open-source model, available on GitHub (Shu, 2019b).

4.1 Differences from PIHM

As a descendant of PIHM, SHUD inherits many fundamental ideas and the conceptual structure from PIHM, including the solution of hydrologic variables using CVODE. The code has been completely rewritten in a new programming language, with

450 a new discretization and corresponding improvements to the underlying algorithms, adapting new mathematical schemes and flexible input/output data formats. Although SHUD is forked from PIHM, SHUD still inherits the use of CVODE for solving the ODE system but modernizes and extends PIHM's technical and scientific capabilities. The major differences are as follows:

1. SHUD is written in C++, an object-oriented programming language with functionality to avoid memory leaks from C. Most of the functions in SHUD do not exist in PIHM, which are newly defined because of the brand-new design of the SHUD model. Only a few functions related to physical equations, such as Manning's Equation and van Genuchten's Equation, are shared in SHUD and PIHM. So although SHUD and PIHM follow a similar fundamental perceptual model, they follow different mathematical and computational strategies.
2. SHUD implements a re-design of the calculation of water exchange between hillslope and river. The PIHM defines the river channel as adjacent to bank cells – namely, the river channel shares the edges with bank cells. This design leads to sink problems in cells that share one node with a starting river channel that can reduce simulation performance.
3. Although the mathematical equations underlying SHUD are generally the same as PIHM, the numerical formulation of processes, the coupling strategy and input/output structures have been greatly enhanced. Common computations in different functions within various processes are extracted and defined as shared inline functions, maintaining calculation consistency and facilitating code updates. The elimination of redundant variables and functions also advances consistency and efficiency.
4. SHUD adds mass-balance control within the calculation of each layer of cells and river channels, important for accurate and efficient long-term and micro-scale hydrologic modeling.
5. The internal data structure and external input/output formats have been redesigned for efficiency and user-friendly formats supporting ASCII and Binary. The binary format is particularly important for efficient writing and post-processing over numerous model domains.

We now briefly summarize the technical model improvements and technical capabilities of the model compared to PIHM. This elaboration of the relevant technical features aims to assist future developers and advanced users with model coupling. Compared with PIHM, SHUD (Shu, 2019b)...

- supports compatibility with the implicit Sundial/CVODE solver version 5.0 (the most recent version at the time of writing) and above,
- supports OpenMP parallel computation,
- utilizes object-oriented programming (C++),
- supports human-readable input/output files and filenames,
- exposes unified functions to handle the Time-Series Data (TSD) (in a standardized spreadsheet format), including forcing, leaf area index, roughness length, boundary conditions and melt factor,

- exports model initial condition at specific intervals that facilitate warm starts of continuous simulation,
- automatically checks the range of physical parameters and forcing data,
- adds a debug mode that monitors potential errors in parameters and memory operations.
- includes a series of R codes for pre- and post-processing data, visualization, and data analysis (that will be discussed in
485 future work).

5 Conclusions

The Simulator for Hydrologic Unstructured Domains (SHUD) is a multi-process, multi-scale and multi-temporal model that integrates major hydrologic processes and solves the physical equations with the Finite Volume Method. The governing equations are solved within an unstructured mesh domain consisting of triangular cells. The variables used for the surface, vadose
490 layer, groundwater and river routing are fully coupled together with a fine time-step. The SHUD uses the one-dimensional unsaturated flow and two-dimensional groundwater flow. River channels connect with hillslope via overland flow and baseflow. The model, while using distributed terrestrial characteristics (from climate, land use, soil, and geology) and preserving their heterogeneity, supports efficient performance through parallel computation.

SHUD is a robust integrated modeling system that has the potential for providing scientists with new insights into their
495 domains of interest and will benefit the development of coupling approaches and architectures that can incorporate scientific principles. The SHUD modeling system can be used for applications in (1) hydrologic studies from hillslope scale to regional scale; area of the model domain ranges from 1 m² to 10⁶km² (2) water resource and stormwater management, (3) coupling research with related fields, such as limnology, agriculture, geochemistry, geomorphology, water quality, and ecology, (4) climate change, and (5) land-use change. In summary, SHUD is a valuable scientific tool for any modeling task associating
500 with hydrologic responses.

Code and data availability. The source code of SHUD model (Shu, 2019b) is kept updating at <https://github.com/SHUD-System/SHUD>. The code and data used for this page is archived at ZENODO: SHUD model (Shu, 2019b) , User manual (Shu, 2019c), SHUDtoolbox (Shu, 2020), V-catchment: (Shu, 2019e), Vauclin(1979) experiment (Shu, 2019d), Cache Creek Watershed (Shu, 2019a).

555	k_m	Saturated conductivity of soil macropore [ms^{-1}]

	$K_r(\Theta)$	Relative conductivity, which is a function of saturation ratio [-]
	k_x	Saturated conductivity of the top soil [ms^{-1}]
	K_{eg}	Effective horizontal conductivity [ms^{-1}]
	$K_{ei}(\Theta)$	Effective infiltration conductivity [ms^{-1}]
560	K_{er}	Effective recharge conductivity [ms^{-1}]
	k_g	Saturated horizontal conductivity [ms^{-1}]
	k_{rb}	Saturated conductivity of the river bed [-]
	k_v	Saturated vertical conductivity of saturated layer [ms^{-1}]
	L_j	Length of edge j of a cell [m]
565	L_s	Length of river segment that overlay with a cell [m]
	LAI	Leaf Area Index [m^2m^{-2}]
	m_f	Snow melting factor [$ms^{-1}C^{-1}$]
	n	Manning's roughness [$sm^{-1/3}$]
	N_c	Number of cells overlaying a river reach [-]
570	N_u	Number of upstream reaches flowing to a river reach [-]
	P	Atmospheric precipitation or irrigation [ms^{-1}]
	P_n	Net precipitation [ms^{-1}]
	P_{sn}	Snowfall [ms^{-1}]
	Q_{dn}	Volume flux to the downstream river channel [m^3s^{-1}]
575	Q_{gr}	Volume flux between river and cells via groundwater flow [m^3s^{-1}]
	Q_g	Groundwater flow between two cells [m^3s^{-1}]
	q_i	Infiltration rate, positive is downward [ms^{-1}]
	q_r	Recharge rate, positive is downward [ms^{-1}]
	q_{sn}	Snow melting rate [ms^{-1}]

580	Q_{sr}	Volume flux between river and hillslope cells via overland flow [m^3s^{-1}]
	Q_s	The overland flow between two cells [m^3s^{-1}]
	Q_{up}	Volume flux from upstream river reaches [m^3s^{-1}]
	s_y	Specific yield [mm^{-1}]
	s_0	The slope of land surface [mm^{-1}]
585	S_{ic}	Water storage of interception layer (canopy) [m]
	S_{ic}^*	Maximum interception capacity [m]
	S_{sn}	Snow storage [m]
	T	Air temperature [C]
	T_0	Temperature threshold for snowmelt to occur [C]
590	y_{gw}	Groundwater head (above impervious bedrock) of a cell [m]
	y_{riv}	River stage in a river channel [m]
	y_{sf}	Surface water storage in a cell [m]
	y_{us}	Unsaturated storage equivalence of a cell [m]
	z_{bank}	Elevation of the riverbank from the datum [m]
595	z_b	Elevation of impervious bedrock from the datum [m]
	z_{gw}	Elevation of groundwater table from the datum [m]
	z_m	Elevation of macropore from the datum [m]
	z_{sf}	Elevation of land surface from the datum [m]

Variables used in CVODE

600	\bar{Y}_0	The initial conditions to start the simulation. [m]
	\bar{Y}_{gw}	Vector of cell groundwater head (above impervious bedrock) [m]
	\bar{Y}_{riv}	Vector of river stage in all river channels [m]
	\bar{Y}_{sf}	Vector of surface water storage of all cells [m]

Y_{us} Vector of unsaturated storage equivalence of all cells [m]
605 Y Vector of conserved state variables in CVODE [m]
 t Time [s]
 t_n Current time [s]
 t_{n-1} Previous time [s]

Author contributions. Lele Shu – Conceptualization, Investigation, Methodology, Software, Validation, Visualization, Writing original draft
610 and editing
Paul Ullrich – Supervision, Investigation, Writing original draft and editing
Christopher Duffy – Supervision, Investigation, Writing original draft and editing

Competing interests. Paul Ullrich is a member of the editorial board of the journal

Acknowledgements. Authors Shu was supported by the California Energy Commission grant “Advanced Statistical-Dynamical Downscaling
615 Methods and Products for California Electrical System” project (award no. EPC-16-063). Co-author Ullrich was supported by the U.S.
Department of Energy Regional and Global Climate Modeling Program (RGCM) “An Integrated Evaluation of the Simulated Hydroclimate
System of the Continental US” project (award no. DE-SC0016605) and the National Institute of Food and Agriculture, U.S. Department of
Agriculture, California Agricultural Experiment Station hatch project accession no. 1016611.
