16 **Abstract**

17 Herein, we present the description of the Mechanism of Intermediate complexity for Modelling
18 Iron (MIMI). This iron processing module was developed for use within Earth system models and
19 has been updated within a modal aerosol framework from the original implementation in a bulk
20 aerosol model. MIMI simulates the emission and atmospheric processing of two main sources of
21 iron in aerosol prior to deposition: mineral dust and combustion processes. Atmospheric
22 dissolution of insoluble to soluble iron is parametrized by an acidic interstitial reaction and a
23 separate in-cloud reaction scheme based on observations of enhanced aerosol iron solubility in
24 the presence of oxalate. Updates include a more comprehensive treatment of combustion iron
25 emissions, improvements to the iron dissolution scheme, and an improved physical dust
26 mobilization scheme. An extensive dataset consisting predominantly of cruise-based
27 observations was compiled to compare to the model. The annual mean modelled concentration
28 of surface-level total iron compared well with observations, but less so in the soluble fraction
29 where observations are much more variable in space and time. Comparing model and
30 observational data is sensitive to the definition of the average and the temporal and spatial range
31 over which it is calculated. Through statistical analysis and examples, we show that a median or
32 log-normal distribution is preferred when comparing with soluble iron observations. We redefined
33 ocean deposition regions based on dominant iron emission sources and found that the daily
34 variability in soluble iron simulated by MIMI was larger than that of previous model simulations.
35 MIMI simulated a general increase in soluble iron deposition to Southern Hemisphere oceans by
36 a factor of two to four compared with the previous version, which has implications for our
37 understanding of the ocean biogeochemistry of these predominantly iron limited ocean regions.

38 1 Introduction

39 Iron is an essential micronutrient for ocean primary productivity (Martin et al., 1991; Martin, 1990).
40 Iron deficiency in oceans leads to high-nutrient low-chlorophyll (HNLC) conditions under which
41 the photosynthetic productivity of phytoplankton is iron limited (Boyd et al., 2007; Jickells et al.,
42 2005), and in other regions iron may be an important nutrient for nitrogen fixation by diazotrophs
43 (Capone et al., 1997; Moore et al., 2013, 2006). Atmospheric deposition of bioavailable iron (i.e.,
44 the fraction of the total iron deposited that is readily available for ocean biota uptake) contained
45 in aerosol is an important source of new iron for the remote open ocean (Duce and Tindale, 1991;
46 Fung et al., 2000); therefore, iron impacts the ability of oceans to act as a sink of atmospheric
47 carbon dioxide (Jickells et al., 2014; Moore et al., 2013).

48 Several definitions for bioavailable iron have been proposed. The solubility of iron is considered
49 to be a key factor modulating its bioavailability (Baker et al., 2006a, 2006b); therefore, we consider
50 bioavailable iron to be the dissolved (labile) iron in either a (II) or (III) oxidation state, and we
51 define this as the soluble iron concentration throughout the manuscript. However, since most
52 aerosol iron is insoluble at emission the processing of insoluble iron to a soluble form must occur
53 during atmospheric transport. The acidic processing of iron contained in aerosol is one pathway
54 under which soluble iron can be liberated from an insoluble form with decreasing pH (Duce and
55 Tindale, 1991; Solmon et al., 2009; Zhu et al., 1997). Organic ligands, in particular oxalate, also
56 increase iron solubility by weakening or cleaving the Fe–O bonds found in iron oxide minerals via
57 complexation (Li et al., 2018; Panias et al., 1996), and in nature this reaction proceeds most
58 rapidly in a slightly acidic aqueous medium, such as cloud droplets (Cornell and Schindler, 1987;
59 Paris et al., 2011; Xu and Gao, 2008). Organic ligand processing has been estimated to increase
60 soluble iron concentrations by up to 75% more than is achievable with acid processing alone (Ito,
61 2015; Johnson and Meskhidze, 2013; Myriokefalitakis et al., 2015; Scanza et al., 2018). However,
62 there is no single mechanism that describes the observed inverse relationship of higher iron
63 solubilities with decreasing iron concentrations (Sholkovitz et al., 2012). Rather, Mahowald et al.
64 (2018) used a 1–D plume model to demonstrate that the observed trend can be explained by
65 either the differences in iron solubility at emission or the atmospheric dissolution of insoluble iron.
66 Thus, there is no observational constraint to indicate which is more likely, unless spatial
67 distribution is also considered.

68 The recent increase in efforts to model iron solubility (Ito, 2015; Ito and Xu, 2014; Johnson and
69 Meskhidze, 2013; Luo et al., 2008; Meskhidze et al., 2005; Myriokefalitakis et al., 2015; Scanza
70 et al., 2018) reflects its importance for understanding biogeochemical cycles (Andreae and

71 Crutzen, 1997; Arimoto, 2001; Jickells et al., 2005; Mahowald, 2011) and how human activity may
72 be perturbing them (Mahowald et al., 2009, 2017). However, the multi-faceted nature of how iron
73 interacts within the Earth system results in many uncertainties regarding how best to represent
74 the atmospheric iron cycle within models, which are themselves of varying complexity
75 (Myriokefalitakis et al., 2018). To incorporate the processes currently thought to be the most
76 significant (Journet et al., 2008; Meskhidze et al., 2005; Paris et al., 2011; Shi et al., 2012) and
77 improve model-to-observation comparisons of the soluble iron fraction, particularly in remote
78 ocean regions (Baker et al., 2006b; Ito, 2015; Mahowald et al., 2018; Matsui et al., 2018;
79 Sholkovitz et al., 2012), model development has been focused on refining the atmospheric iron
80 emission sources and subsequent atmospheric processing (Ito, 2015; Ito and Xu, 2014; Johnson
81 and Meskhidze, 2013; Luo et al., 2008; Meskhidze et al., 2005; Myriokefalitakis et al., 2015;
82 Scanza et al., 2018).

83 A recent multi-model evaluation of four global atmospheric iron cycle models (Myriokefalitakis et
84 al., 2018) showed that total iron deposition is over-represented close to major dust source regions
85 and under-represented in remote regions compared with observations from all four models. This
86 is consistent with previous model intercomparisons studies that demonstrated the difficulty in
87 simultaneously simulating both atmospheric concentrations and deposition fluxes of desert dust
88 (Huneeus et al., 2011). Importantly, none of the atmospheric iron processing models can capture
89 the high (>10%) solubilities measured over the Southern Ocean; this is potentially owing to the
90 model processes associated with transport and aging of aerosol requiring further development
91 (Ito et al. 2019, *in review*). Conclusions from Myriokefalitakis et al. suggest that future model
92 improvements should focus on a more realistic aerosol size distribution and the representation of
93 mineral-to-combustion sources of iron. Most of the development of the Mechanism of Intermediate
94 Complexity for Modelling iron (MIMI), as described therein, focused on these points. First, we
95 transitioned from a bulk aerosol scheme to a two-moment modal aerosol scheme (Liu et al., 2012),
96 and second, we re-evaluated anthropogenic and fire combustion iron emissions. The modal
97 aerosol scheme was used to calculate both aerosol size and number at each time-step within an
98 updated global aerosol microphysics model, and the combustion emissions from Luo et al. (2008),
99 which are likely to be underestimated (Matsui et al., 2018), were improved upon.

100

101 Ocean observations of iron, and its soluble fraction, are limited both spatially and temporally owing
102 to the significant costs and logistical constraints associated with accumulating data from scientific
103 cruises. Thus, there is an inherent disparity in attempting to compare climatological means
104 calculated from temporally-chronological model results with observational means calculated from

105 temporally-limited and sporadic observations (e.g., Mahowald et al., 2008, 2009). This is
106 important because natural aerosol emissions are variable on seasonal, annual, and decadal
107 timescales, both in terms of primary natural iron emission sources (mineral dust and wildfires)
108 and the source of aerosol acidity. For example, sulphuric acid from the oxidation of dimethyl
109 sulphide and fire SO₂ (Bates et al., 1992; Chin and Jacob, 1996) have been observed to aid iron
110 dissolution when far from anthropogenic acid sources (Zhuang et al., 1992). Limitations
111 associated with the collection of continuous annual or inter-annual ship-based data across
112 multiple remote ocean regions are immutable at present, which hinders the required derivation of
113 basic statistical properties of such highly-variable data (Smith et al., 2017). Attention could
114 therefore be given to the methodologies under which such model-observation comparisons are
115 undertaken instead.

116 The present manuscript is presented in four parts. The first part (section 2) introduces updates
117 made to the Bulk Aerosol Module (BAM) iron scheme of Scanza et al. (2018) and its
118 implementation within the Modal Aerosol Module (MAM), with four modes (MAM4), within the
119 Community Earth System Model (CESM). In the second part (section 3), we compare iron
120 concentrations and the fractional solubility of iron with the observational data. Then the third part
121 (section 4) compares our updated version of the model with its predecessor. Finally, we suggest
122 further developments for atmospheric iron modelling and for comparing model results with
123 sporadic observations (section 5).

124

125

126 **2 Aerosol model**

127 The present study improves upon the previous atmospheric iron cycle module developed for the
128 Community Atmosphere Model (CAM) version 4 (CAM4) embedded in the CESM; we will refer to
129 this version as BAM-Fe (Scanza et al., 2015, 2018) therein. We incorporated the iron module
130 within the MAM framework (Liu et al., 2012, 2016) currently in the Department of Energy's Energy
131 Exascale Earth System Model (E3SM; Golaz et al. (2019)) and the CAM versions 5 and 6 (CESM-
132 CAM5/6; (Neale et al., 2010)); we refer to this new version of the iron model by its name (MIMI)
133 throughout the manuscript. Table 1 serves as a reference and summarizes the modifications made
134 for MIMI, which are discussed throughout the manuscript.

135 We use MAM4 with four simulated log-normal aerosol size modes: three modes (Aitken,
136 accumulation, and coarse) containing iron and a fourth primary carbonaceous mode. Table 2

137 details the new combustion iron modal aerosol properties, while those of mineral dust iron follow
 138 existing dust aerosol properties (Liu et al., 2012). Generally, the modelled density of iron is similar
 139 to size-resolved ambient aerosol densities measured in Eastern China (Hu et al., 2012), which
 140 has significant dust and combustion aerosol sources. MIMI was initially implemented and tested
 141 within a development branch of CAM 5.3, as per Wu et al. (2017) and Wu et al. (2018), using
 142 Cheyenne (Computational and Information Systems Laboratory, 2017) and closely resembles
 143 CESM version 1.2.2. We used a 2.5° x 1.9° horizontal (longitude by latitude) resolution and 56
 144 vertical layers up to 2 hPa. Stratiform microphysics followed a two-moment cloud microphysics
 145 scheme (Gettelman et al., 2010; Morrison and Gettelman, 2008). The other major aerosol species
 146 black carbon (BC), organic carbon, sea salt and sulphate (SO₄) were also simulated but are not
 147 explicitly examined here because we focused on the iron aerosol modelling. Fire emissions were
 148 vertically distributed between six injection height ranges: 0–0.1, 0.1–0.5, 0.5–1.0, 1.0–2.0, 2.0–
 149 3.0, and 3.0–6.0 km, as per AeroCom recommendations (Dentener et al., 2006). Fire emissions
 150 were uniformly distributed in model levels between height limits. Unless otherwise stated, aerosol
 151 and pre-cursor gas mass emissions were from the Climate Model Intercomparison Program
 152 (CMIP5) inventory (Lamarque et al., 2010). Major gas-phase oxidants (O₃, OH, NO₃ and HO₂)
 153 were supplied offline and were also from Lamarque et al. (2010). Meteorology (*U*, *V*, and *T*) was
 154 nudged to Modern-Era Retrospective analysis for Research and Applications (MERRA) data for
 155 2006–2011. Unless otherwise stated, the last five years were used for analysis.

156

157 **Table 1.** Short summary of major differences between BAM-Fe and MIMI.

BAM-Fe (CAM4)	MIMI (CAM5)
Externally mixed bulk aerosol tracers with 4 size bins (0.1–1.0, 1.0–2.5, 2.5–5.0, 5.0–10.0 μm)	Internally mixed 2-moment aerosol tracers with 3 aerosol iron modes (Aitken, accumulation, coarse)
Static soil erodibility from offline maps: DEAD (Zender et al., 2003) scheme	Time-varying soil erodibility calculated online: Kok et al. (2014a) scheme
8 dust minerals, 5 of which are iron bearing	No change
Static Luo et al. combustion iron emissions	Static Luo et al. combustion iron emissions x5
Static Luo et al. fire iron emissions	Time-varying Fe:BC fire iron emission ratio
Surface fire iron emissions	Vertically distributed fire iron emissions
Static aerosol pH across aerosol size	Aerosol pH size dependent
Assumed oxalate concentration based on primary organic carbon	Assumed oxalate concentration based on secondary organic carbon
In-cloud aerosol concentrations based on simulated cloud fraction	Separate in-cloud and interstitial aerosol tracers

158

159 The model used in this study performed well when compared to observations from a variety of
 160 different environments, and produced aerosol concentrations that were close to those of the multi-
 161 model mean of similarly complex aerosol models (Fanourgakis et al., 2019).

162

163 **Table 2.** Combustion iron aerosol size and number properties.

Mode	Number mode diameter, D_{gn} (μm)	Geometric standard deviation (σ)	Volume mean particle diameter, D_{emit} (μm) ¹	Density, ρ (kg/m^3)
Aitken	0.03 ^a	1.8 ^a	0.0504	1500 ^c
Accumulation	0.08 ^a	1.8 ^a	0.134	1500 ^c
Coarse	1.00 ^b	2.0 ^b	2.06	2600 ^c

164 1. $D_{emit} = D_{gn} \times \exp(1.5 \times (\ln(\sigma))^2)$

166 b. Dentener et al. (2006) and Liu et al. (2012)

167 c. Wang et al. (2015)

168

169

170 2.1 Dust modelling

171 Desert dust was modelled via the Dust Entrainment And Deposition model (DEAD; Zender et al.,
 172 2003), which was previously updated to include the brittle fragmentation theory of vertical dust
 173 flux (Kok, 2011) on mineral size fractions (Albani et al., 2014; Scanza et al., 2015). We further
 174 improved the emissions of dust in MAM to follow a physically-based vertical flux theory (Kok et
 175 al., 2014a), which has been shown to significantly improve dust emissions (Kok et al., 2014b).
 176 Notice that this method allowed for the removal of the soil erodibility map approach previously
 177 employed by the DEAD scheme (Table 1), and still provided more accurate simulations of regional
 178 dust emissions and concentration (Kok et al., 2014b). Dust aerosol optical depth (AOD) was
 179 calculated using mineralogy-based radiation interactions as described by Scanza et al. (2015).
 180 Dust emissions were tuned such that a global annual mean dust AOD of ~ 0.03 was attained, as
 181 recommended by Ridley et al. (2016) and matching values in Scanza et al. (2015) for a similar
 182 model configuration.

183 Dust mineralogy in MIMI is designed to be comprised of eight separate transported tracers: illite,
184 kaolinite, montmorillonite, hematite, quartz, calcite, feldspar and gypsum (Scanza et al., 2015).
185 Mineral soil distributions were supplied offline (Claquin et al., 1999) with the emission of each dust
186 mineral species further refined following the brittle fragmentation theory (Scanza et al., 2015).

187

188 2.2 Iron modelling

189 The simulated lifecycle of iron can be grouped into three main stages: (1) iron emission to
190 atmosphere, (2) physical-chemical iron processing during transport and (3) final iron deposition
191 and, thus, loss from the atmosphere. In the following sections, we describe the emissions and
192 subsequent atmospheric dissolution of iron (stages 1 and 2), while the effects of this on the
193 magnitude of oceanic soluble iron deposition (stage 3) in MIMI are examined and compared to
194 BAM-Fe in section 4.

195 Iron optical properties are currently considered to reflect those of hematite because this mineral
196 contains 97% of the iron mass fraction (see section 2.3.1).

197

198 2.3 Iron emissions

199 MIMI contains three major iron emission sources: mineral dust, fires (defined here as the sum of
200 wildfires and human-mediated biomass burning) and anthropogenic combustion (defined here as
201 the sum of industrial and domestic biofuel burning). In the BAM-Fe version of the model, fire and
202 anthropogenic combustion emissions were combined into a single static monthly mean value. In
203 MIMI, fire emissions of iron were updated to be distinct from other combustion iron sources and
204 were parametrized to track the BC emissions from fires using an Fe:BC ratio. Fire BC emissions
205 were simulated to be time varying on a monthly scale, resulting in a much more pronounced
206 seasonality to fire emissions (e.g., Giglio et al., 2013) compared to BAM-Fe where seasonality
207 was not imposed.

208 For all iron species in each mode, the aerosol number emissions ($Fe_{emit,num}$) were calculated from
209 the mass emissions within the same mode ($Fe_{emit,mass}$) using the properties in Table 2 following
210 Liu et al. (2012),

$$Fe_{emit,num} = \frac{Fe_{emit,mass}}{\left(\frac{\pi}{6}\right) \times \rho \times D_{emit}^3} \quad \text{Equation 1}$$

211 2.3.1 Iron emissions within mineral dust

212 Based on previous research by Journet et al. (2008) and Ito and Xu (2014), the iron fraction in
 213 each mineral species was prescribed at emission as follows: 57.5% in hematite, 11% in smectite,
 214 4% in illite, 0.24% in kaolinite, 0.34% in feldspar, and 0% in the remaining three mineral species
 215 (Table 3); which has been shown to improve the accuracy of the modelled total iron fraction
 216 estimated from dust (Scanza et al., 2018; Zhang et al., 2015). The mass of each of the eight
 217 mineral dust species advected at each model time step was the residual mineral mass (i.e., after
 218 the removal of the iron mass), such that the sum of all eight minerals and the total iron from
 219 mineral dust equalled unity, and hence, the original total singular dust mass emitted from the land
 220 surface.

221 Iron emissions from all eight mineral dust species were then partitioned into the four advected
 222 mineral-dust-bearing iron tracers (Table 3); iron tracers were defined as being (in)soluble and by
 223 the speed of the atmospheric reaction rate acting on them: slow or medium (Scanza et al., 2018).
 224 Note that, slow-soluble iron is only produced by atmospheric processing within the model.

225

226 **Table 3.** Mass fraction of iron in each simulated iron bearing mineral and allocation to each
 227 mineral iron tracer at emission.

Mineral	Mineral dust mass percent allocated to each dust iron tracer at emission				Total
	Med-soluble	Med-insoluble	Slow-soluble	Slow-insoluble	
Hematite	0.0%	0.0%	0.0%	57.5%	57.5%
Smectite	0.55%	10.45%	0.0%	0.0%	11.0%
Illite	0.11%	3.89%	0.0%	0.0%	4.0%
Kaolinite	0.01%	0.0%	0.0%	0.23%	0.24%
Feldspar	0.01%	0.0%	0.0%	0.33%	0.34%

228

229

230 2.3.2 Iron emissions from fires

231 Following Luo et al. (2008), we used observed Fe:BC mass ratios to estimate fine and coarse
 232 mode iron emissions from fires. An additional difference between BAM (CAM4) and MAM (CAM5)
 233 models is the emission dataset used to estimate global fire emissions of aerosol and trace gases.
 234 The BAM model uses adjusted AeroCom fire emissions (Dentener et al., 2006; Scanza et al.,

235 2018), while MAM uses CMIP5 fire emissions (Lamarque et al., 2010). Base fire BC emissions
 236 within the CMIP5 database are 2.55 Tg a⁻¹ BC; however, the scaling of emissions from fires has
 237 been shown to be necessary to improve model to observed (aerosol optical depth and particulate
 238 matter) BC ratios (Reddington et al., 2016; Ward et al., 2012). Therefore, we globally scaled the
 239 fire iron emissions by a uniform factor of two, which is comparable with the overall lower scaling
 240 factor from a review of the literature by Reddington et al. (2016: Table 2). Fine mode iron
 241 emissions from fires were then segregated to assign 10% of the fine mode mass to the Aitken
 242 mode, with the remaining 90% assigned to the accumulation mode.

243

244 **Table 4.** Measured iron (Fe) and black carbon (BC) values (various units; as only the Fe:BC ratio
 245 is required they are not included) and the Fe/BC ratio. Calculated with three decimal places, ratio
 246 reported to one significant figure to reflect high uncertainty.

Biome	Reference	Fe	BC	Fe/BC
Cerrado	Yamasoe et al. (2000)	0.08	12.6	0.006
	Yamasoe et al. (2000)	0.05	6.5	0.008
	Ward et al. (1991)	0.9	3.3	0.273
	Mean Fe/BC ratio = 0.1			
Temperate	Ward et al. (1991)	0.1	5.0	0.020
	Mean Fe/BC ratio = 0.02			
Tropical	Luo et al. (2008)	-	-	0.020
	Artaxo et al. (2013)	179	2801	0.639
	Artaxo et al. (2013)	27	405	0.067
	Artaxo et al. (2013)	20	98	0.204
	Artaxo et al. (2013)	12	235	0.051
	Ward et al. (1991)	0.9	10	0.090
	Yamasoe et al. (2000)	0.03	7.3	0.004
	Yamasoe et al. (2000)	0.05	3.9	0.013
Mean Fe/BC ratio = 0.06				
Global	Mean Fe/BC ratio = 0.06			

247

248

249 Luo et al. (2008) used a single Amazonian observational dataset in their study to determine the
 250 flux of iron from fires (Fe:BC). We extended this to incorporate other Amazonian fire (Fe:BC) data

251 and, importantly, non-Amazonian biome fire (Fe:BC) data, which are likely to have different
252 combustion properties, and hence iron emissions (e.g., Akagi et al., 2011). From Table 4, we
253 suggest that after adding 11 more data inventory values, Luo et al. likely under-represented the
254 global fine mode Fe:BC ratio at 0.02. We instead used the global mean Fe:BC ratio from the
255 additional data of 0.06. Conversely, Luo et al. likely over-represented the coarse mode Fe/BC
256 ratio at 1.4. By including additional observational information from Artaxo et al. (2013) we reduced
257 this to 1.0. Using size-segregated wet season (i.e., representing a locally-transported emission
258 source) observation data from Artaxo et al. (2013), we estimated that the amount of BC mass in
259 the coarse mode was 37% of fine mode mass. Overall this doubles the fractional contribution of
260 fine mode (BAM: 0.1–1 μ m size bin, MAM: sum of Aitken and accumulation modes) iron emissions
261 from fires (BAM-Fe: fine = 7% of total mass, MIMI: fine = 14% of total mass).

262 Using the soluble Fe:BC ratio of 0.02 reported in Luo et al. (2008) resulted in 33% solubility of
263 fine mode iron from fires at emission, which is lower than the 46% reported in Oakes et al. (2012)
264 and higher than the 12% reported in Ito (2013). As few data exist in the literature pertaining to
265 coarse mode BC, or more importantly its ratio to iron, we retained the 4% solubility of iron in the
266 coarse mode at emission, as suggested by Luo et al.

267 Total iron emissions from fires in MIMI were 2.2 Tg a⁻¹ Fe (Aitken: 0.02 Tg a⁻¹, accumulation: 0.28
268 Tg a⁻¹, coarse: 1.9 Tg a⁻¹), representing an approximate increase in iron emissions from fires of
269 around 25% compared with those from BAM-Fe, with most of the mass (86%) still in the coarse
270 mode. Aerosol number concentrations were then calculated using the physical properties listed
271 in Table 2. We adopted the methodology of Wang et al. (2015) by assuming that the density of
272 iron aerosol from fires (and anthropogenic combustion) in the Aitken and accumulation modes
273 matches that of BC, while in coarse mode matches mineral dust. The vertical distribution of iron
274 emissions from fires were also updated in MIMI (BAM-Fe emitted all iron from fires at the surface)
275 to account for pyro-convection, which lofts aerosol to higher altitudes at the point of emission
276 within the model (Rémy et al., 2017; Sofiev et al., 2012; Wagner et al., 2018).

277

278 **2.3.3 Iron emissions from anthropogenic combustion sources**

279 Separate lines of evidence (Matsui et al., 2018, Ito et al. 2019 *in review*, Conway et al. 2019 *in*
280 *review*) have shown that anthropogenic industrial iron emissions are highly likely to be larger than
281 previously estimated (e.g., Ito, 2015; Luo et al., 2008; Myriokefalitakis et al., 2018a). Therefore,
282 anthropogenic combustion emissions of iron in MIMI were the same as those in BAM-Fe, as first

283 reported by Luo et al. (2008), uniformly multiplied by a factor of five to bring into closer agreement
284 with observations of industrial magnetite emissions in line with Matsui et al. (2018). Similar to fire
285 emissions, 10% of fine size emissions were partitioned into the Aiken mode at emission, while
286 the remainder was emitted into the accumulation mode. We retain the Luo et al. (2008) estimate
287 of 4% combustion iron solubility at emission (Chuang et al., 2005). Calculations of aerosol number
288 concentrations of combustion iron followed the same procedure as described for fire emissions in
289 the previous section 2.3.2.

290

291 **2.4 Atmospheric iron processing**

292 Once airborne, iron undergoes a series of physical and chemical processing steps within the
293 atmosphere, each working to alter the soluble iron fraction (i.e., its solubility). The MIMI
294 atmospheric iron dissolution scheme is summarized in Table 5, with a full description reported
295 previously by Scanza et al. (2018). Within each of the three iron-bearing aerosol size modes, six
296 tracers of iron were advected within the model: medium-insoluble and medium-soluble mineral
297 dust iron (containing both readily-released and medium-reactive mineral dust iron (Scanza et al.,
298 2018)), slow-insoluble and slow-soluble mineral dust iron, and insoluble and soluble combustion
299 iron (assumed to be medium reactive (Scanza et al., 2018)). Both proton and organic ligand
300 promoted iron dissolution mechanisms were modelled. The proton promoted dissolution scheme
301 was dependent upon an estimated $[H^+]$ and the simulated temperature. Organic ligand dissolution
302 was dependent upon the simulated organic carbon concentration as oxalate (the main reactant)
303 itself was not modelled. A structural model improvement was that MAM (CAM5) advected
304 separate tracers for interstitial and cloud-borne aerosol, and so the proton and organic ligand
305 promoted dissolution reactions were applied to each tracer, respectively.

306 Dust aerosol moving through areas containing acidic gases, with a pH 1–2, increases the solubility
307 of the iron contained within it (Ingall et al., 2018; Longo et al., 2016; Meskhidze et al., 2003;
308 Solmon et al., 2009); with mineralogy being a key factor determining the rate of dissolution at a
309 given pH (Journet et al., 2008; Scanza et al., 2018). Modelled aerosol pH in MIMI was
310 parametrised to depend only on the ratio of the calcium to sulphate aerosol concentration (Scanza
311 et al., 2018). At each time step, if $[SO_4] > [Calcite]$, then the aerosol was assumed to be acidic
312 with a low pH, while if $[SO_4] < [Calcite]$, then aerosol was assumed to be well buffered (Böke et
313 al., 1999) and the pH = 7.5. In MIMI, we updated the pH calculation from BAM-Fe two-fold: (1) In
314 BAM-Fe, pH was calculated as the mean across all four size bins (0.1–10 μm), while in MIMI, pH
315 was calculated separately for each interstitial aerosol size mode. (2) Aerosol measurements of

316 pH have shown that interstitial aerosol is likely to be more acidic than was assumed in BAM-Fe
317 (Longo et al., 2016; Weber et al., 2016), even when taking into account declining sulphate levels
318 (Weber et al., 2016); therefore, we have lowered pH to 1 (from 2) in both the Aitken and
319 accumulation modes where sulphate aerosol dominates. However, in the coarse mode, where
320 dust dominates, we retained the lower pH boundary of 2. Furthermore, MAM aerosol was
321 simulated as an internally mixed aerosol; therefore, the SO₄:Ca ratio included the mixing of these
322 aerosol components within each mode.

323 The in-cloud organic dissolution reaction only occurs where cloud-borne aerosol are present. An
324 assumed oxalate concentration in MIMI was estimated based on the modelled organic carbon
325 concentration and could not exceed a maximum concentration threshold of 15 µmol/L (Scanza et
326 al., 2018). In BAM-Fe, oxalate was derived from the sum of both the primary and secondary
327 organic carbon aerosol concentrations, while in MIMI this was updated to be dependent only upon
328 the secondary organic carbon source because oxalate is itself a product of the oxidation of volatile
329 organic carbon gases (Myriokefalitakis et al., 2011). An additional term was added to the reaction
330 mechanism to account for the small amount of organic ligand processing proceeding by species
331 other than oxalate (Scanza et al., 2018).

332

333 **2.5 Observation and model iron calculations**

334 **2.5.1 Spatially aggregating limited observations**

335 The observations of total iron concentrations and the fractional solubility of iron used in this study
336 are the joint totals (1524 records) of those reported in Mahowald et al. (2009) and Myriokefalitakis
337 et al. (2018). However, many of these observations represent averages of only one or a few days
338 of iron and soluble iron measurements, and thus can be difficult to compare against annual, or
339 longer, mean time periods calculated within the model. Furthermore, building empirical
340 distributions of iron properties from observations requires a larger sample size than currently
341 available in many regions. We therefore tested how aggregating the observations spatially,
342 sometimes termed 'super-obbing', altered our model evaluation. Our objective was to capture the
343 small regional scale properties of iron, and not those at a point source; therefore, we assume that
344 the benefits gained by aggregating in this way, to help produce a statically useful amount of
345 observations, outweighs any potential biases.

346

347 **Table 5.** Summary of atmospheric processing reaction equations from Scanza et al. (2018). Here
 348 / represents either medium or slow reacting iron aerosol (combustion iron is modelled as medium).
 349 The pH calculation is updated to be calculated within each mode and oxalate ($C_2O_4^{2-}$)
 350 concentrations are calculated based only on the secondary organic aerosol (SOA) concentrations.

	Reaction equation	Reaction rate constituents
Acid processing of interstitial aerosol		$RFe_{l,acid} = K_l(T) \times a(H^+)^{m_l} \times f(\nabla G_r) \times A_l \times MW_l$
	Equation 2: $\frac{d}{dt}[Fe_{soluble}] = RFe_{l,acid} \times [Fe_{insoluble}]$	$K_l(T)$ is the temperature dependent rate coefficient (moles $m^{-2} s^{-1}$) $a(H^+)$ is the proton concentration, with an empirical reaction order m_l If $[SO_4] > [Calcite]$ then $pH = 1$ in Aitken and accumulation modes or 2 in coarse. Else $pH = 7.5$.
	Equation 3: $\frac{d}{dt}[Fe_{insoluble}] = -\left(\frac{d}{dt}[Fe_{soluble}]\right)$	$f(\nabla G_r)$ accounts for dissolution rate change with variation from equilibrium (equals 1 for simplicity (Luo et al., 2008)) A_l is the specific surface area ($m^2 g^{-1}$) MW_l is the molecular weight ($g mol^{-1}$)
Organic ligand processing of in-cloud aerosol		$RFe_{l,oxal} = a_l \times [C_2O_4^{2-}] + b_l$
	Equation 4: $\frac{d}{dt}[Fe_{soluble}] = RFe_{l,oxal} \times [Fe_{insoluble}]$	If $l = \text{medium (or combustion) iron}$: $a = 2.3 \times 10^{-7} \mu M^{-1} s^{-1}$ $b = 4.8 \times 10^{-7} s^{-1}$ If $l = \text{slow iron}$: $a = 9.5 \times 10^{-9} \mu M^{-1} s^{-1}$ $b = 3.0 \times 10^{-8} s^{-1}$
	Equation 5: $\frac{d}{dt}[Fe_{insoluble}] = -\left(\frac{d}{dt}[Fe_{soluble}]\right)$	For longitude(i), latitude(j) and level(k): $[C_2O_4^{2-}]_{i,j,k} = 150 \times \frac{[SOA_{i,j,k}]}{\max[SOA]}$

352 2.5.2 Variations in model temporal averaging

353 The model was run at a 30-minute time resolution. At each 30-minute timestep, soluble iron, total
 354 iron, and the ratio of soluble to total iron (iron solubility) were computed. The model output was
 355 S_i , (daily mean soluble iron concentration on day i), T_i (daily mean total iron concentration on day
 356 i), and R_i (daily mean iron solubility on day i). Note that R_i is the daily mean of the calculated 30-
 357 minute solubilities and hence is not equal to S_i / T_i . We define online solubility as the average-of-
 358 ratios and was calculated as follows:

$$\left(\sum_{i=1}^n R_i \right) / n \quad \text{Equation 6}$$

359

360 where n represents the total number of records over which the average was calculated. Online
 361 solubility is reported throughout this study. In section 5.2, we then compare the average-of-ratios
 362 to the ratio-of-averages (defined as offline solubility), calculated as follows:

363

$$\frac{(\sum_{i=1}^n S_i) / n}{(\sum_{i=1}^n T_i) / n} = \frac{\bar{S}}{\bar{T}} \quad \text{Equation 7}$$

364

365 where \bar{S} and \bar{T} are the grid cell averages of soluble and total iron concentrations, respectively,
 366 over the total time period considered in this study (2007 to 2011). While equation 7 is common
 367 within the literature, this methodology can produce larger variability in iron solubility across grid
 368 cells because it is based on both soluble and total iron annual mean concentration. In the online
 369 method, variability is reduced as extreme values in soluble and total iron concentrations generally
 370 do not occur at the same time. We can define the occurrence of extreme values, with respect to
 371 the time frame considered, by analysing a relative Z-score metric, calculated as follows:

372

$$Z_{Fe,t} = \frac{(Fe_t - \overline{Fe}_t)}{\sigma Fe_t} \quad \text{or} \quad Z_{Fe,s} = \frac{(Fe_s - \overline{Fe}_s)}{\sigma Fe_s} \quad \text{Equation 8}$$

373

374 where Fe is either total (Fe_t) or soluble (Fe_s) iron. The relative normalized Z-score can then be
 375 calculated as follows:

$$\sum_{i=1}^n (z_{t,i} - z_{s,i}) / z_{t,i}$$

Equation 9

376

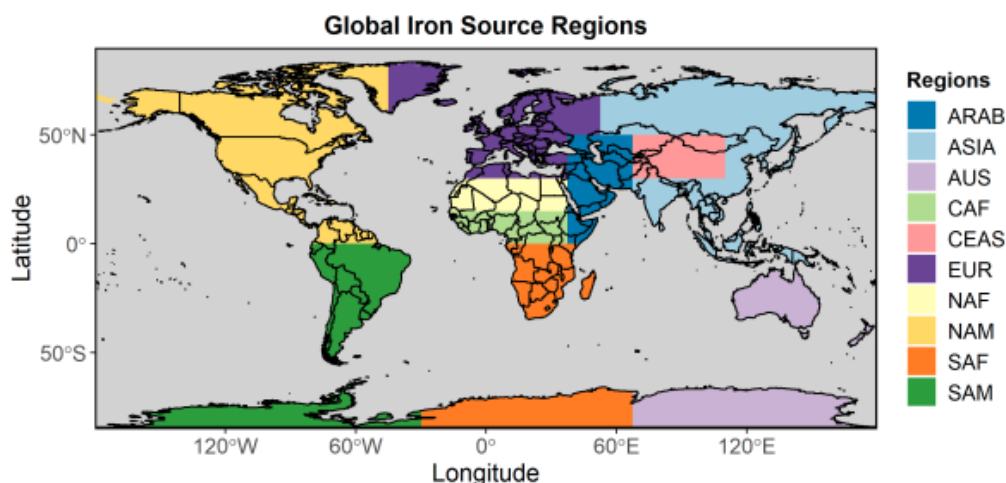

377 where $Z_{t,i}$ and $Z_{s,i}$ are the Z-scores of total and soluble iron concentrations, respectively, at each
378 grid cell for each time step i . The Z-score metric provides a relative direction and distance of an
379 instantaneous value with respect to its mean. The Z-score is reported in multiples of the standard
380 deviation (Equation 8); therefore, a Z-score of zero indicates that the data point value is identical
381 to the mean. To assess the relative difference in the variability, at a given time, between the
382 modelled total and soluble iron concentration and its mean we calculated the difference in Z-
383 scores between total and soluble iron concentrations and normalized it using the Z-score of total
384 iron concentration (Equation 9). Note that the Z-score of the soluble iron concentration could also
385 be used to normalise the difference. This method allows for the examination of how the
386 occurrence of extreme concentration values in total and soluble iron influences the method of
387 solubility calculation (Equation 6 vs. Equation 7).

388

389 2.6 Iron ocean deposition source apportionment

390 An ocean deposition source apportionment sub-study was designed to classify ocean deposition
391 regions according to the dominant atmospheric soluble iron sources, rather than ocean basins
392 defined from a more traditional physical oceanographic viewpoint (e.g., Gregg et al., 2003). By
393 incorporating recent model estimates for dust and the importance of combustion iron emissions
394 (Luo et al., 2008; Matsui et al., 2018) the seven large-scale source regions defined in Mahowald
395 et al. (2008) were modified slightly to separate the major dust iron source regions from combustion
396 iron source regions. This resulted in a total of 10 iron emission source regions (Fig. 1; see also
397 Table S1 for details).

398 Simulations in the source apportionment study used BAM-Fe, as described in Scanza et al. (2018)
399 with slight modification. Briefly, anthropogenic combustion emissions were increased by a uniform
400 factor of five, and iron from fires followed the updated Fe:BC ratio (Table 4) and seasonal
401 variability in the fire BC emissions; all as per MIMI. Aerosols were externally mixed in BAM, and
402 therefore altering the regional aerosol loading did not affect aerosol transport or deposition in the
403 more significant way it could in MAM, in which aerosol are internally mixed. This information was
404 then used in Section 4 to compare the differences in daily mean deposition of soluble iron between
405 the BAM-Fe and MIMI models within each defined ocean region.

406

407 **Figure 1.** Major iron emission source regions.

408

409 **3 Modelled dust and iron concentrations compared to observations**

410 In terms of Earth system modelling, and the biogeochemistry that connects the land–atmosphere–
411 ocean components, we are ultimately motivated here to improve the magnitude of the atmosphere
412 to ocean iron deposition flux and its fractional solubility (from which the soluble iron flux can be
413 derived). We compare the model results with a series of observations, and herein, highlight some
414 of the problems discovered when directly comparing with a sporadic (in both space and time)
415 observation dataset, as is currently common practice (Myriokefalitakis et al., 2018)

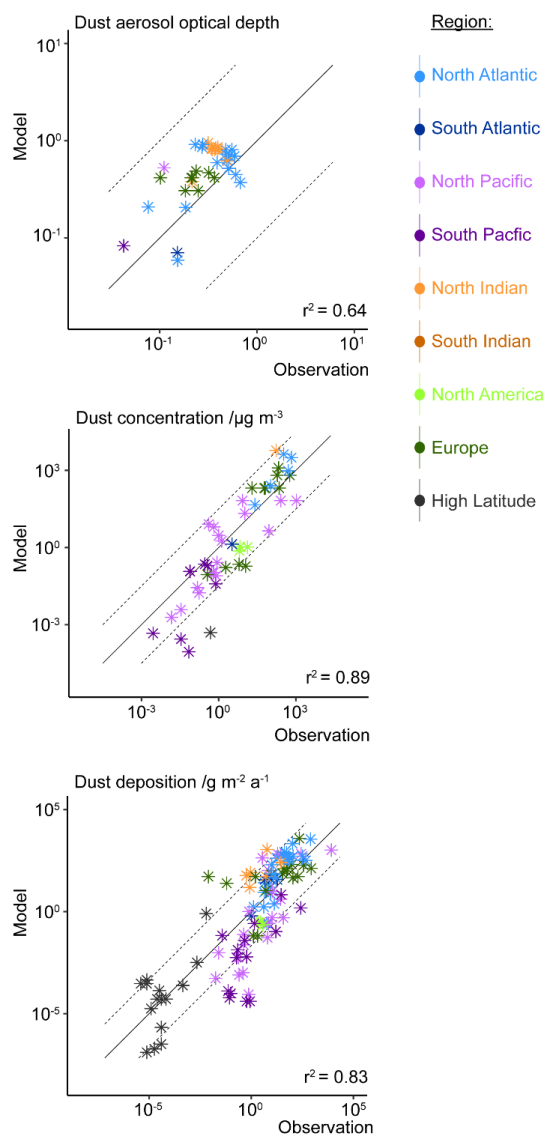

416

417 **3.1 Global dust comparisons**

418 Comparison of dust AOD with regional dust AOD observations (Fig. 2) from the AERONET
419 observational datasets (Holben et al., 2000), as subsampled in Albani et al. (2014), shows good
420 agreement (correlation: $r^2 = 0.64$). This results in MAM annual global mean emissions of $3250 \pm$
421 $77 \text{ Tg dust a}^{-1}$, which is at the higher end of literature estimates of $\sim 500\text{--}4000 \text{ Tg dust a}^{-1}$ (Bullard
422 et al., 2016; Huneus et al., 2011; Kok et al., 2017). Dust emissions in MAM are $84 \pm 4\%$ higher
423 than our previous mean of $1768 \text{ Tg dust a}^{-1}$ in BAM (Scanza et al., 2018), because dust lifetime
424 has proportionally decreased (Table S2). Both dust concentrations and deposition are simulated
425 well within MIMI, improving on previous dust modelling complications related to underestimating
426 dust deposition when tuned to dust concentration (Huneus et al., 2011).

427

428

429

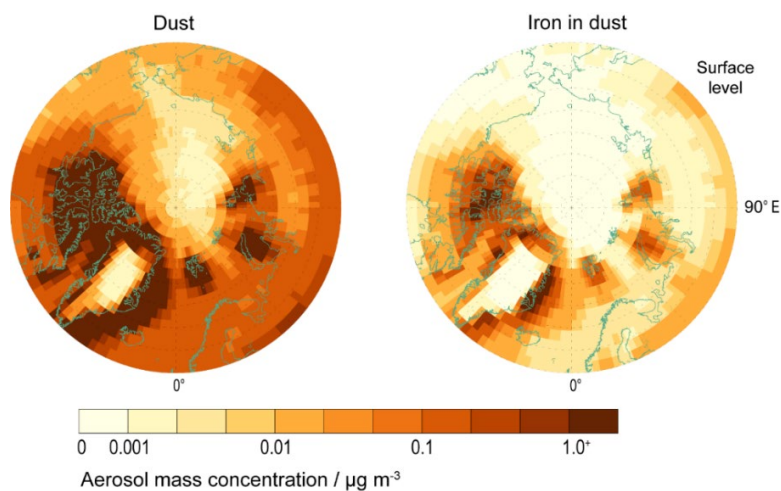

430 **Figure 2.** Dust aerosol optical depth, surface concentrations and deposition in modal aerosol
431 model and observations (Albani et al., 2014; Holben et al., 2000).

432

433 **3.2 High latitude dust and iron aerosol**

434

435

436

437 **Figure 3.** High latitude ($>60^{\circ}\text{N}$) dust (sum of eight mineral species and four dust-iron species)
438 and iron (sum of four dust-iron species) mass concentrations ($\mu\text{g m}^{-3}$) at the surface model level.

439

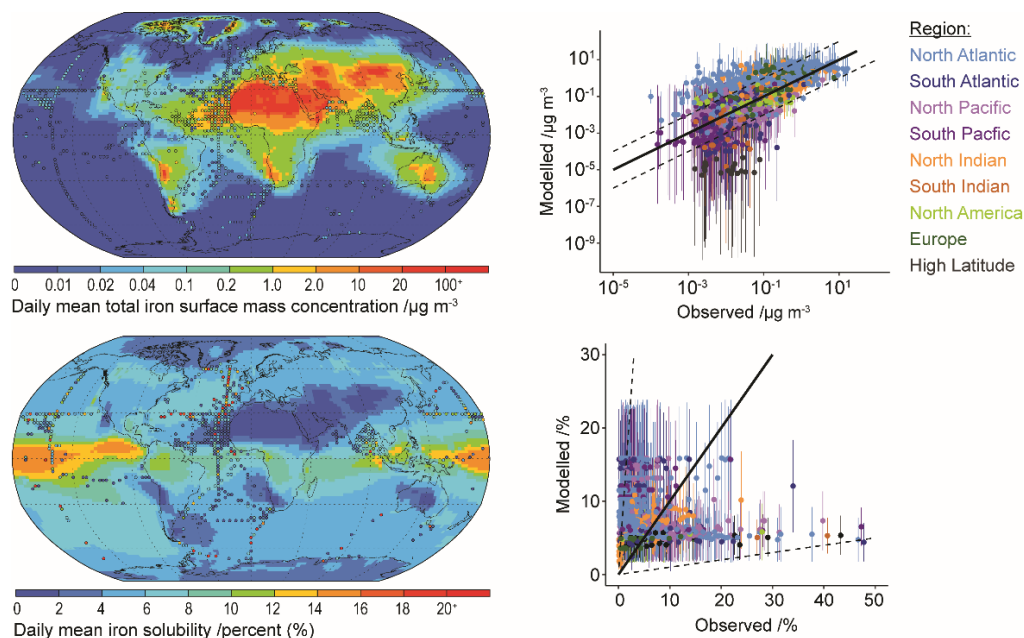

440 Including the parametrization of Kok et al. (2014a) removes the requirement of a soil erodibility
441 map (Table 1). In addition, in previous versions of the model, the high latitude dust sources were
442 zeroed, because there were no observations at that time for high latitude sources of dust (Albani
443 et al., 2014). However, more recent observations have suggested high latitude dust sources do
444 exist (Bullard et al., 2016; Crusius et al., 2011; Tobo et al., 2019), often related glacial processes
445 (Bullard, 2017) with a higher fraction of bioavailable iron relative to lower latitude dust sources
446 (Shoenfelt et al., 2017). Thus, for the new version of the model we have allowed for the inclusion
447 of high latitude dust sources (Fig. 3). In general, aerosol dust and iron concentrations peak closest
448 towards the coast lines and during summer. Emissions of dust from $>50^{\circ}\text{N}$ are $\sim 1.3 \pm 0.2\%$ of the
449 global dust total, which is half of the estimates derived from field and satellite data at 2–3% of the
450 global total (Bullard, 2017; Bullard et al., 2016). However, the resulting magnitude and seasonality
451 of dust concentrations has been shown in a recent study to be consistent with observed
452 measurements from Svalbard (Tobo et al., 2019).

453

454 **3.3 Global iron aerosol concentration and fractional solubility**

455

456

457

458 **Figure 4.** Daily mean model total iron concentration and solubility from 2007 to 2011.
459 Observations (circles) overlaid (at resolution of the model grid) as a mean from 1524 individual
460 records in Mahowald et al. (2009) and in Myriokefalitakis et al. (2018). Also shown are scatter
461 plots of the model mean and standard deviation compared to each available observation and
462 identified by oceanic region.

463

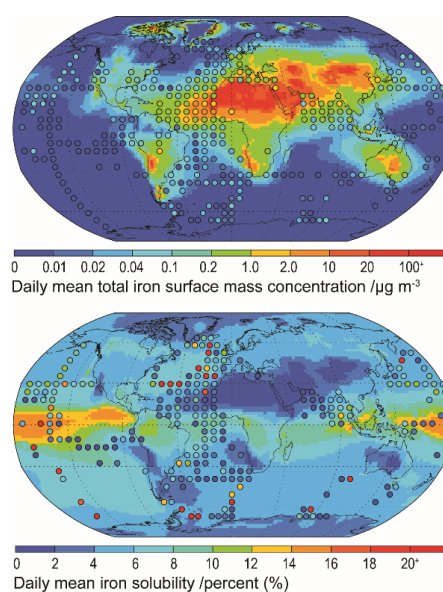

464 There are several propositions explaining the sources of soluble iron, and the inverse relationship
465 between total iron amount and iron solubility (Sholkovitz et al., 2012). While total iron mass
466 concentrations are dominated by desert dust sources, soluble iron can be a product of mineral
467 dust processed in the atmosphere or emitted from different sources (e.g., Chuang et al., 2005;
468 Guieu et al., 2005; Luo et al., 2008; Meskhidze et al., 2003; Schroth et al., 2009). Previous studies
469 have shown that either of these can explain the inverse relationship, and that the spatial
470 distribution of data is required to provide more information (Mahowald et al., 2018). Therefore, we
471 explored how to best use the spatial data to compare with the model results. The five-year (2007

472 to 2011) mean iron concentration from MIMI is compared to an extensive dataset of observations
473 of total iron and its fractional solubility (Fig. 4). Except for between 30 and 60°N in the North
474 Pacific (and near Hawaii) and a latitudinal band ~30°N in the North Atlantic, the model captures
475 the mean observational total iron concentration well.

476

477

478

479

480 **Figure 5.** Daily mean model total iron concentration and solubility from 2007 to 2011.
481 Observations (circles) overlaid (at resolution one-third of the model grid) as a mean from 1524
482 individual records in Mahowald et al. (2009) and in Myriokefalitakis et al. (2018).

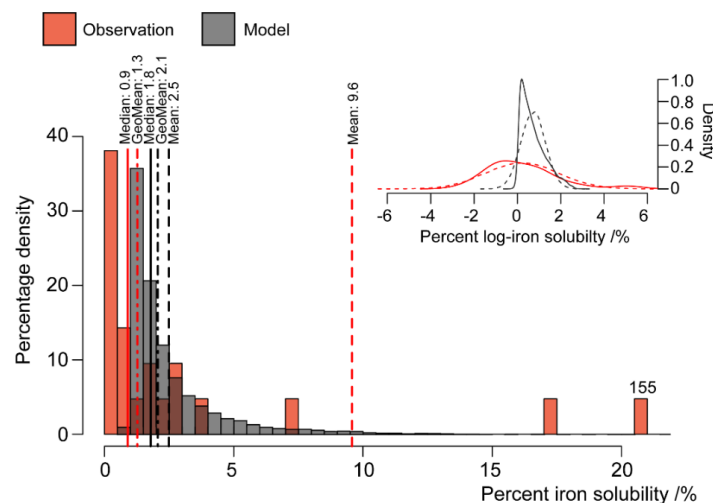

483

484 Aggregating observations onto a lower resolution grid (sometimes termed 'super-obbing')
485 compared with the model can help reduce the representation error when comparing with such
486 limited observations (Schutgens et al., 2017). Fig. 5 uses an observational resolution one-third
487 that of the model and the model-to-observation comparison of the mean state is thus improved.
488 Persistent observation-based features of the local environment become more obvious while,
489 conversely, less frequent ones diminish. At this observational resolution, the low total iron

490 concentrations in the North Atlantic ~30°N, as seen in Fig. 4, are perhaps not a common feature,
491 and the model much more precisely represents the climatological state here than Fig. 4 might
492 suggest. However, examining the North Pacific reveals that the model imprecisely represents the
493 mean state here. Potential missing iron sources in remote regions, such as the North Pacific,
494 include: (1) shipping emissions (Ito, 2013), which have a high iron content from oil combustion
495 (Schroth et al., 2009); (2) volcanic emissions, which provide a localized “fertilizer” to the surface
496 ocean owing to the macronutrients and trace metal nutrients contained within them (Achterberg
497 et al., 2013; Langmann et al., 2010; Rogan et al., 2016); and (3) low Asian and South American
498 aerosol concentrations, either through underrepresenting combustion emission sources (Matsui
499 et al., 2018) or in the transport and deposition of aerosol within these regions (Wu et al., 2018).
500 These are discussed in more detail in the discussion sections 5.1 and 5.2.

501

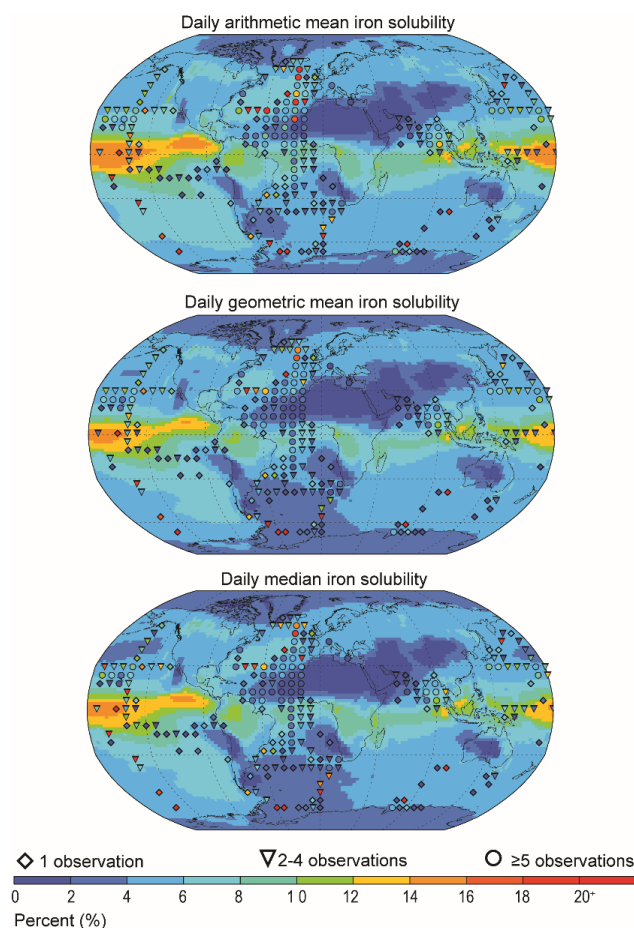

502

503

504 **Figure 6.** Histogram of observations ($n = 21$) and daily model results (2007 to 2011) of iron
505 solubility between 16 to 20°N and 27 to 32°W (one observation point and nine co-located model
506 grid cells in Fig. 4). Mean (dashed lines), geometric mean (dot-dash lines) and median (full line)
507 values shown above respective dataset colour line. Note that the single observation value of
508 155% is off the scale and placed as such with value given above. **Insert.** Log-plot for the same
509 data (solid lines) with projected log-normal distribution from mean and standard deviation of data
510 (dashed lines).

511

512

513 **Figure 7.** Daily arithmetic mean, geometric mean, and median model solubility (2007 to 2011).
514 Observations overlaid (at resolution one-third of the model grid) as either the arithmetic mean,
515 geometric mean or median, respective to the model averaging. Number of observations denoted
516 by symbol: lowest confidence (one observation, diamond); intermediate confidence (two to four
517 observations, triangle); highest confidence (\geq five observations, circle).

518

519 In terms of iron solubility (soluble iron concentration / total iron concentration), the model is not
520 capturing the observational mean state in many regions (Fig. 5). A detailed examination of the
521 observation point at 18°N and 330°E (anomalous green point surrounded by blue points in the
522 North African outflow plume in Fig. 4) and the nine model grid cells co-located with it in Fig. 6

523 shows how a single high observation (155% percent solubility) is causing a representation issue
524 (see also section 4.3.1 regarding soluble iron deposition). Both model and observation histogram
525 distributions are similar, as are the median and geometric mean values. However, the arithmetic
526 means are not similar and while a high observation value of 155% is likely to be an outlier, and
527 should be at most 100%, it still informs us about what is possible and simply discounting it (even
528 at an adjusted 100%) would require strong justification. It is therefore advisable to instead alter
529 the estimator of the average. Comparing model to observation differences calculated using the
530 median or geometric mean reveals that they are similar in magnitude, as one would expect for
531 log-normally distributed data (Fig. 6 insert). Although the median is robust with respect to outliers,
532 the model results may not exhibit a uniform Gaussian distribution (Fig. 6 insert; solid compared
533 to dashed lines) and often the amount of available observations is also low (Fig. 7) suggesting
534 that its use also requires careful consideration. An equivalent methodology to the geometric mean
535 in Fig. 7 would be to first log transform the data before calculating the arithmetic mean. Arguments
536 pertaining to the appropriate methodology for comparing model results to temporally limited
537 observations extend beyond the iron aerosol examination in this study to all aerosol comparisons
538 with limited observations.

539

540 **3.4 Calculating iron solubility**

541 It is interesting to note the effect that the order of operations (taking the average-of-ratios
542 compared to the ratio-of-averages) has when calculating iron solubility (Fig. 8). Throughout the
543 manuscript, percent iron solubility was calculated at each model time step (30 minutes) and then
544 the daily mean output analysed (online; Equation 6) at an annual or 5 year mean time resolution.
545 It is also acceptable to use the simulated soluble and total iron concentrations to generate the
546 annual or 5 year mean iron solubility in a postprocessing step (offline; Equation 7). The resulting
547 differences between methods is not insignificant however, with the offline method creating a
548 distribution in which, low iron solubility is generally lower and the highest (>18%) iron solubilities
549 are generally higher.

550

551

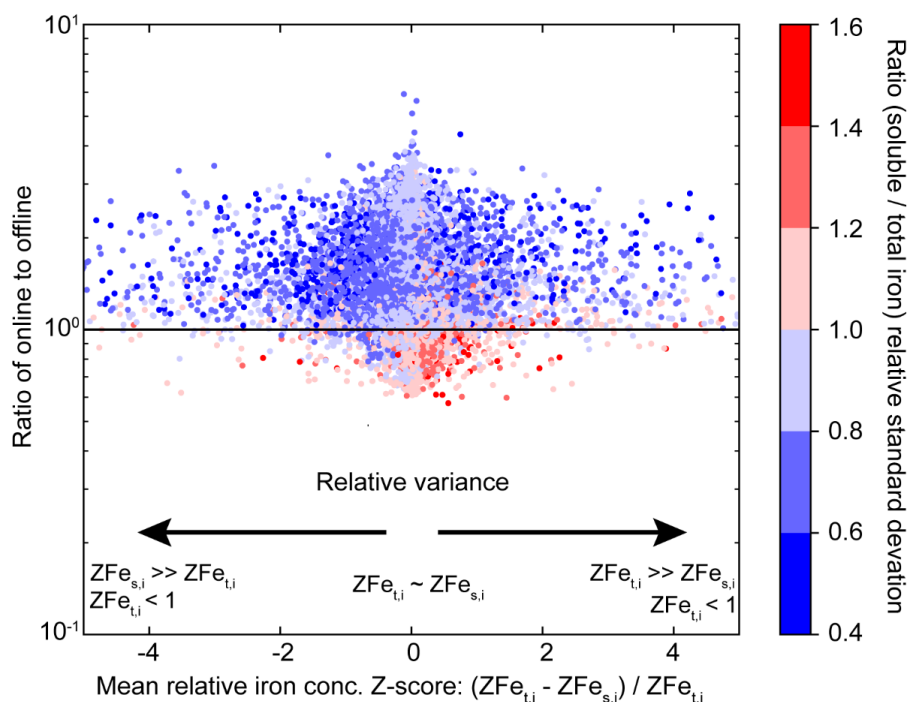

552

553 **Figure 8.** Mean solubility of iron when solubility is calculated at each 30 min model time step
554 ('online') and when it is calculated post processing from the daily mean soluble and total iron
555 concentration ('offline').

556

557 The average relative Z-score (Equations 8 and 9) is around zero for most model grid cells (Fig.
558 9) indicating that they mostly followed similar temporal and relative magnitude trends. However,
559 even if the average relative Z-scores are around zero and the ratio of relative standard deviations
560 is around one, the ratio of online:offline calculated iron solubility is most likely >1 . Temporal
561 differences in the soluble and total iron concentration might therefore be controlling the overall
562 solubility at each grid cell. We also find that the ratio of online and offline solubility is >1 for most
563 of the cases when the ratio of relative standard deviations of soluble and total iron is <1 (Fig. S1),
564 indicating that the differences in the both methods of solubility calculation are sensitive to the
565 differences in relative size of the tails of the distribution. That is, if soluble iron has narrower tails
566 compared to total iron at any grid cell, it is highly likely that a higher solubility will be obtained in
567 the online method compared to the offline. We also find that the ratio of online and offline solubility
568 is >1 for most of the cases when the ratio of relative standard deviations of soluble and total iron
569 is <1 (Fig. S1), indicating that the differences in the both methods of solubility calculation are
570 sensitive to the differences in relative size of the tails of the distribution. That is, if soluble iron has
571 narrower tails compared to total iron at any grid cell, it is highly likely that a higher solubility will
572 be obtained in the online method compared to the offline. The ratio of the tails of soluble and total
573 iron are generally found around regions with highest temporal variability in emissions and
574 modelled solubilization of insoluble iron (Fig S1).

575

576

577 **Figure 9.** Relationship of online to offline derived iron solubility to the relative Z-score for total
 578 (ZFe_t) and soluble (ZFe_s) iron and the relative standard deviation ($\sigma_{Fe} / \overline{Fe}$) at each grid cell for
 579 the year 2007.

580

581 Field measurements have generally suggested an inverse relationship between total and soluble
 582 iron concentrations (Myriokefalitakis et al., 2018). This means that high total iron concentrations
 583 are generally accompanied by low soluble iron concentrations and vice versa. By assuming that
 584 the field measurements faithfully represented the actual average values of soluble and total iron
 585 concentration at those locations, we implicitly assume that all the measurements have a Z-score
 586 of zero. In Fig. 9 we show that this is not the case with the modelled results, and the two variables
 587 can be relatively farther from their respective means even when averaged over the modelled time
 588 period.

589 Sensitivity of a result to the order of operations extends beyond iron solubility to any variable that
 590 is calculated in a similar manner, and current multi-model inter-comparison project (MIP) protocols

591 do not explicitly account for this. However, the effects of outliers, in both online and offline
592 methods, can be reduced by employing the geometric mean and has been used in some MIP's
593 (e.g., Mann et al., 2014). It will be also be important to consider differences in the solubility of iron
594 induced by the choice of the order of operations as ocean biogeochemical models move away
595 from using offline results from global climate models to online results within Earth system models,
596 which are designed to couple the two components at each time step. For short term interactions
597 between deposited iron and ocean biota shorter term averaging may be more important (e.g.,
598 Guieu et al., 2014), but for long term period accumulation of iron that is (re-)cycling in the oceans,
599 the longer term average may be more appropriate (Moore et al., 2013). One should be aware,
600 however, that iron is readily removed from the ocean mixed layer, and thus, the lifetime of iron
601 may well be short enough for the 'online' calculation to be more appropriate much of the time
602 (Guieu et al., 2014).

603

604 **4.0 MIMI vs. BAM-Fe**

605 In this section, we discuss how the new modal aerosol mode version of MIMI compares to its
606 predecessor bulk aerosol model version (BAM-Fe) throughout all three stages of the atmospheric
607 iron life-cycle.

608

609 **4.1 Iron emission comparison**

610 Globally averaged emissions of dust are ~80% higher and the iron it contains ~120% higher in
611 MIMI compared to those in BAM-Fe (Table 6). Although both models are globally tuned to a similar
612 dust AOD, and based within the same host model (CESM), changing from a bulk aerosol to a
613 modal scheme (e.g., Albani et al., 2014; Scanza et al., 2015) reduces the aerosol lifetime
614 significantly (Liu et al., 2012 and Table S2). The spatial distribution of dust emissions is also
615 different following the move to the Kok et al. (2014a, 2014b) parameterization (Table 1), resulting
616 in the spatial distribution of dust AOD also altering (Fig. S2). Total combustion iron emissions
617 (sum of fires and anthropogenic combustion activity) in MIMI are also higher than previous
618 estimates by a factor of between two and three (Table 6), reflecting the recently growing evidence
619 indicating that they have been previously underestimated (Matsui et al., 2018, Ito et al. 2019 *in*
620 *review*, Conway et al. 2019 *in review*).

621

622 **Table 6.** Dust, fire, and combustion emissions of iron and relevant co-emitted aerosol emissions
 623 (to two significant figures). Multi-model emission range from the four global atmospheric iron
 624 models (including BAM-Fe) reported in Myriokefalitakis et al. (2018). Fine (sum of Aiken and
 625 accumulation modes) and coarse (coarse mode) mass emissions also given for fire and
 626 combustion iron.

627

	Annual mean emissions /Tg a ⁻¹			
	BAM-Fe	MIMI	Luo et al. (2008)	Multi model
Dust	1800	3200	1600	1200–5100
Dust iron	57	126	55	38–134
Fire&Comb. iron	1.9	5.5	1.7	1.8–2.7
Fire BC	4.1	2.6	3.6	
Total fire iron	1.2	2.2	1.1	
Fine, Coarse	0.08, 1.1	0.30, 1.90	0.07, 1.00	
Combustion BC	4.6	5.0	5.0	
Total comb. iron	0.66	3.3	0.66	
Fine, Coarse	0.10, 0.56	0.50, 2.80	0.10, 0.56	

628

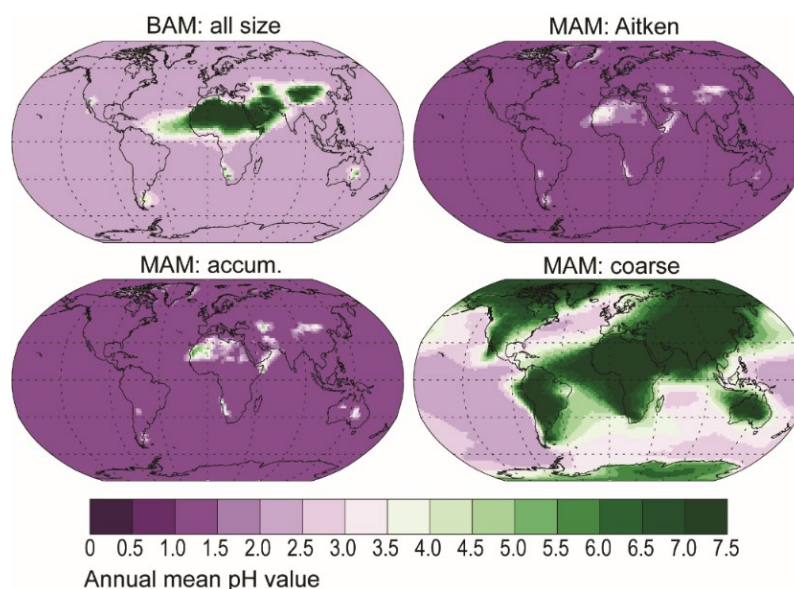

629

630 4.2 Iron atmospheric processing comparison

631 There is a much lower aerosol pH in the fine aerosol modes (Aiken and accumulation) in MIMI
 632 compared to that in BAM-Fe (Fig. 10). This is due to a combination of resolving pH in each aerosol
 633 size mode in MIMI and the subsequent lowering of the pH value (1) being applied in the two fine
 634 aerosol modes (Aitken and accumulation). Conversely, dust dominating the coarse aerosol mode
 635 provides more of an opportunity for [Calcite] > [SO₄] in this aerosol size fraction, resulting in most
 636 continental areas having a high coarse mode aerosol pH in MIMI compared with the higher pH
 637 being much more localized to the major desert regions in BAM-Fe. Acidic processing of iron in
 638 MIMI is therefore faster globally in the two finer aerosol modes compared to the BAM-Fe fine
 639 mode, but generally slower over continental regions in the coarse mode than in BAM-Fe.

640

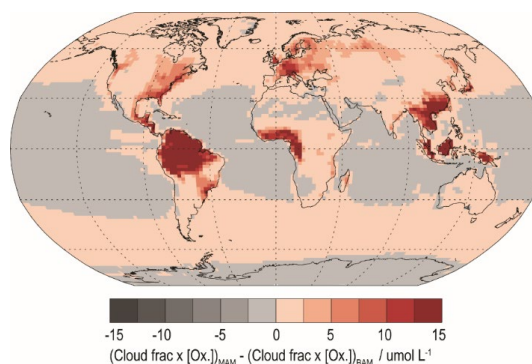

641

642 **Figure 10.** Surface level annual mean interstitial aerosol pH (see methods for pH calculation).

643

644 Model physics, and hence simulated cloud cover, is significantly different between CAM4 and
645 CAM5. Fig. 11 shows the relative model difference in the oxalate dissolution reaction between
646 MIMI, which also includes an increase in the tuning factor by an order of magnitude (from 15 to
647 150; Table 5), and BAM-Fe by normalising by the simulated cloud fraction in each model
648 respectively. The effect of oxalate on iron dissolution is larger in MIMI over extra-tropical ocean
649 regions, where iron models underrepresent solubility (Myriokefalitakis et al., 2018), and land
650 regions which are dense in tropical vegetation or industry (both centres of large aerosol pre-cursor
651 gas emissions).

652

653

654 **Figure 11.** Relative difference in organic ligand reaction on in-cloud iron aerosol dissolution
655 between MIMI and BAM-Fe versions of MIMI. Due to significant differences in simulated cloud
656 cover between CAM4 and CAM5 oxalate concentrations [Ox.] are multiplied by the model
657 simulated cloud fraction in this figure.

658

659 **4.3 Iron ocean deposition flux comparison**

660 Similar to the previous study by Scanza et al. (2018), we report the amount of total and soluble
661 iron deposited in each of the major ocean basins (Table 7) as defined by Gregg et al. (2003). We
662 find that, in MIMI the amount of total iron deposited in all ocean basins is approximately double
663 that estimated in BAM-Fe, while soluble iron deposition is similar. The larger mineral dust flux in
664 MIMI is driving most of the increases to total iron deposition because it is the primary iron source
665 (Table 6). In general, the magnitude of soluble iron deposition to the oceans is more evenly
666 distributed across hemispheres in MIMI owing to a major reduction (approximately one half) in
667 the equatorial North Central Atlantic basin flux and increases to Southern Hemisphere (SH) ocean
668 fluxes of a factor of two to four. There are significant increases in combustion iron deposition in
669 all equatorial and Northern Hemisphere (NH) ocean basins, driven by the 5-fold increase in
670 combustion emissions implemented in MIMI.

671

672

673

674

675 **Table 7.** Global and regional ocean basin deposition (Gg a^{-1}) of total and soluble iron in BAM-Fe
 676 (Scanza et al., 2018) and MIMI (this study). Deposition was multiplied by the ocean fraction of
 677 model grid cell and is reported at two significant figures. Percent contribution from combustion
 678 iron to deposition also given. Ocean basins are those defined by Gregg et al. (2003) and
 679 previously used by Scanza et al. (2018).

680

	Dust and comb. deposition / Gg a^{-1}				Percent from combustion /%			
	Total iron		Soluble iron		Total iron		Soluble iron	
	BAM-Fe	MIMI	BAM-Fe	MIMI	BAM-Fe	MIMI	BAM-Fe	MIMI
Global	12000	26000	500	530	3.3	5.0	7.6	23
N. Atlantic	1800	5300	46	86	1.9	2.9	4.8	11
N. Pacific	730	1200	35	36	10	19	15	43
NC. Atlantic	2900	5700	92	89	0.30	0.52	0.9	3.7
NC. Pacific	230	300	16	12	7.9	24	10	56

Antarctic	270	1300	12	37	20	12	48	44

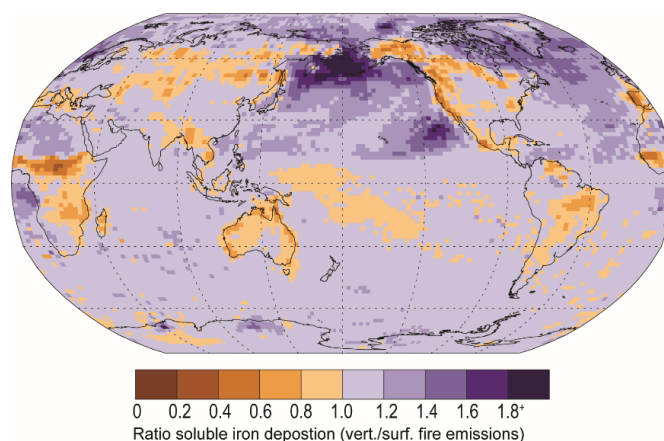

681

682

683 The fraction of fire aerosol which is injected above the boundary layer is crucial for determining
 684 its capacity for long range transport (e.g., Turquety et al., 2007). Vertically distributing fire iron
 685 emissions in MIMI, as compared to emitting all iron from fires at the surface as in BAM-Fe,
 686 increases the long-range transport of iron aerosol to remote ocean regions (Fig. 12). In general,
 687 vertically distributing fire emissions results in small increases in soluble iron deposition (between
 688 0 and 20%) in SH ocean regions and a larger increase (between 20 and 40%) to NH oceans, with
 689 converse lower land deposition close to the major regions of fire activity. The exception being in
 690 the sub-Arctic North Pacific, a HNLC region, where iron deposition from fires significantly
 691 increased until more than doubling that when surface fire emissions are used. The modelled ratio
 692 change in deposition between vertical/surface emissions will be sensitive to the vertical resolution
 693 of the model, where a higher resolution in the bottom layers will lead to increases in near-source
 694 deposition for surface emissions.

695

696

697

698 **Figure 12.** The ratio of soluble iron deposition from fires when emissions are emitted with a
699 vertical distribution to fires compared with when emission are only at the surface (i.e.,
700 vertical/surface). Single year (2007) comparison only.

701

702 4.3.1 Source region comparison

703 The eight regions in Fig. 13 are chosen based on 13 (one for each region in Fig. 1) simulations
704 undertaken using the modified version of BAM-Fe described in the methods section 2.6. The
705 emission region (Fig. 1) with the highest fractional contribution to the total soluble deposition flux
706 in each grid cell was examined and from this the boundaries of each region in Fig. 12 delineated.
707 The resulting eight ocean iron deposition regions are split equally into four in the NH and four in
708 the SH. Note, however, that the NH–SH divide sits at 15° S, and not the equator, which is due to
709 transport differences in each hemisphere and the position of the ITCZ. Of the four regions that
710 can be defined as being major dust deposition receptors (Fig. 11; bar chart) the North Indian
711 Ocean (#1), North Atlantic and Central Pacific (#4), and South America dust (#7) regions have a
712 single dominant source each, while the North Pacific (#3) region is more variable. These dust-
713 dominated iron deposition regions are similarly reproduced by other global iron models (Ito et al.
714 2019, *in review*). The regions of the Southern Hemisphere Oceans (#5) and Australian and South
715 Pacific (#6) receive similar amounts of mineral dust and combustion iron, suggesting that the iron
716 sources are spatially closer and, thus, share much more similar transport pathways than the South

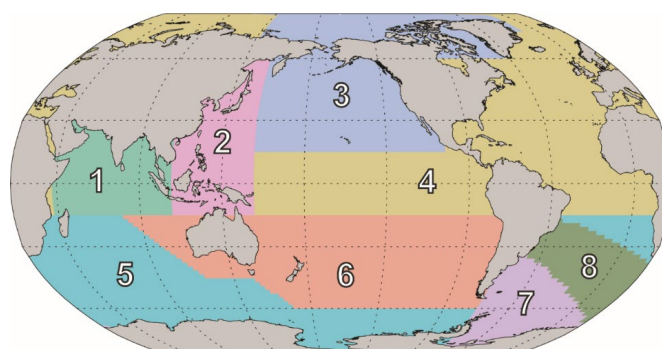

717 East Asian Ocean (#2) and South America Combustion (#8) regions, which have a much more
718 distinct combustion source signal. Deposition regions are more clearly defined when using this
719 methodology compared to those from a more traditional classification of ocean basins based on
720 physio-geographical oceanography (Fig. S3). This information can be used to assess which
721 ocean regions are most likely to be affected by anthropogenic perturbations to the magnitude of
722 iron sources within different regions, whether through land use land cover change or
723 industrialization.

724

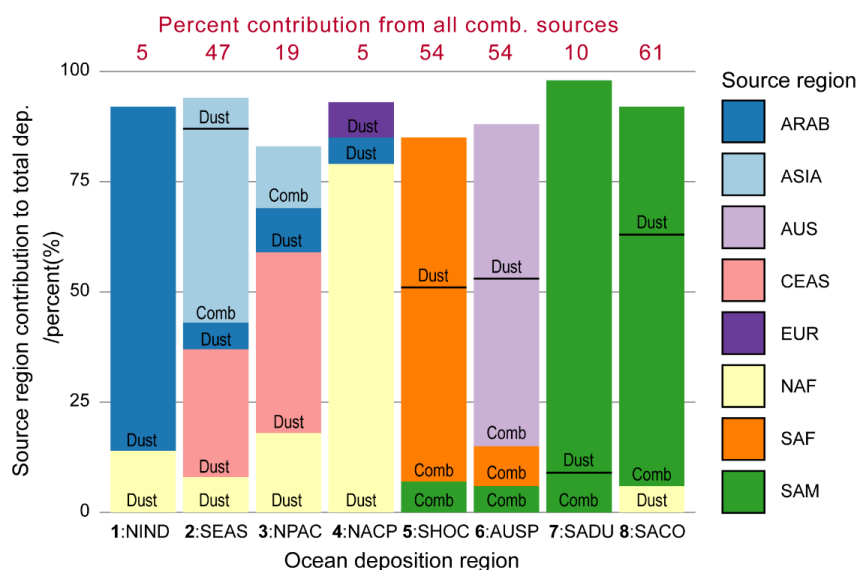

725 The variability in the daily soluble iron deposition flux to each of the eight ocean regions, as seen
726 in Fig. 13, is much larger in MIMI than it is in BAM-Fe (Fig. 14), reaching over 10 orders of
727 magnitude between the minimum and maximum flux in many regions. This is due in part to the
728 increased variability in fire emissions, which was improved in MIMI to track the BC emitted from
729 fires, and switching from the offline soil erodibility map used in BAM-Fe to the Kok et al. (2014a)
730 physical based emission parametrization used in MIMI. Anthropogenic combustion emissions are
731 temporally static in both model frameworks, and therefore do not affect the variability in this study
732 as much as fires and mineral dust but will in future if this is changed to represent a seasonal
733 emission cycle. We can see that each of the dust and fire updates in MIMI are having a large
734 impact by comparing the Patagonian dust dominated South America Dust (SADU) region and the
735 fire dominated South America Combustion (SACO) region. Most of the dust deposited (30 to 90%)
736 in the ocean occurs during large dust events that are on just 5% of the days (Mahowald et al.,
737 2009) resulting in large differences between median and mean deposition amounts in all regions,
738 as seen in Fig. 14. It is important to note that the mean is always above the inter-quartile range,
739 further supporting our previous arguments pertaining to the modelled mean not being an ideal
740 estimate of the average as it does not represent the log normal distribution of aerosol. Comparing
741 the mean:median ratio suggests that extreme dust events are also more pronounced in MIMI
742 (CAM5) than those in BAM-Fe (CAM4).

743

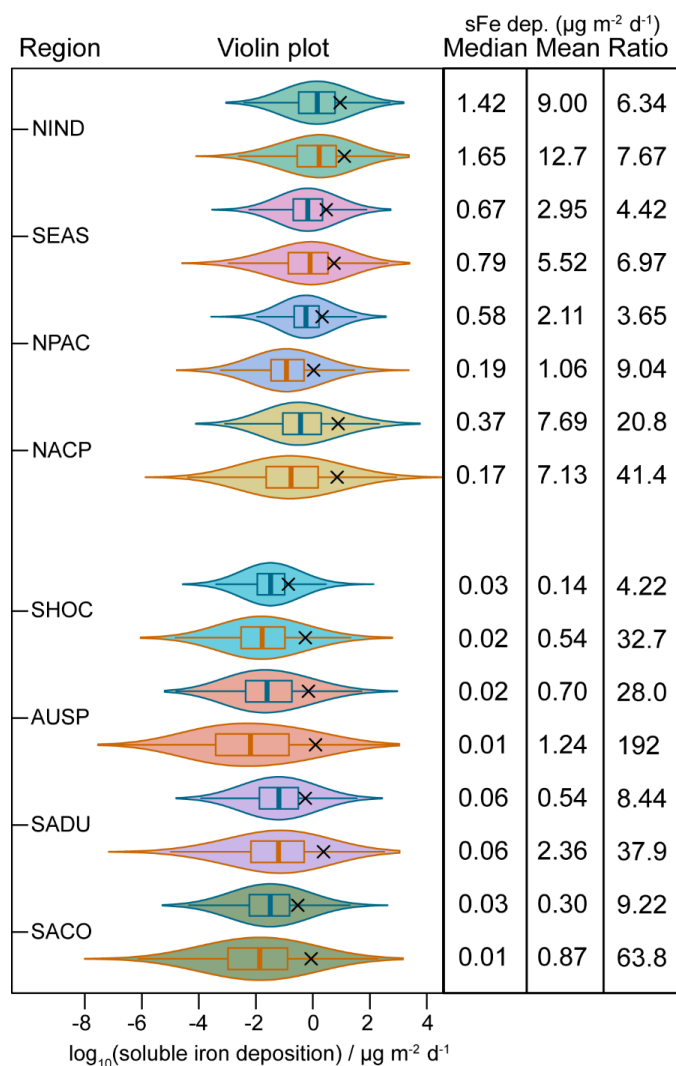

744

745

746 **Figure 13. Top.** Eight ocean soluble iron deposition regions defined by dominant source region
 747 apportionment. Region 1: North Indian Ocean (NIND). Region 2: South East Asian Ocean
 748 (SEAS). Region 3: North Pacific (NPAC). Region 4: North Atlantic and Central Pacific (NACP).
 749 Region 5: Southern Hemisphere Oceans (SHOC). 6: Australian and Southern Pacific (AUSP). 7:
 750 South America Dust (SADU). 8: South America Combustion (SACO). **Bottom.** Contribution of
 751 each emission source region (Fig. 1) to the total iron deposition across the region. Contribution of
 752 dust and combustion iron from source region also shown. Regions contributing <5% filtered out.
 753

754

755 **Figure 14.** Violin plots of five years of \log_{10} daily soluble iron deposition ($\mu\text{g m}^{-2} \text{d}^{-1}$) within each
 756 grid cell for the eight ocean regions defined in Fig. 13. Only grid cells where ocean fraction >0.5
 757 are included in analysis. Violin colour matches Fig. 1 region colour: North Indian Ocean (NIND);
 758 South East Asian Ocean (SEAS); North Pacific (NPAC); North Atlantic and Central Pacific
 759 (NACP); Southern Hemisphere Oceans (SHOC); Australian and Southern Pacific (AUSP);
 760 Southern American Dust (SADU); Southern American Combustion (SACO). Violin outline colours:
 761 blue lines = BAM results while orange lines = MAM results. Black cross = \log_{10} mean daily soluble
 762 iron deposition. Median, mean and ratio (mean/median) values for all five years of daily deposition
 763 amounts across each basin also given.

764 **5 Future directions**

765 The purpose of model to observation comparisons is to identify situations (regions, times, model
766 settings, or combinations thereof) in which the model output is inconsistent with observed realities;
767 with the goal being to further refine the model in the future. Each individual observation represents
768 a snapshot of the atmospheric state at a specific point in space and time and when an observation
769 falls outside of the distribution of model output values, from the same location and time, we can
770 view this as evidence of a model misspecification. For the example of iron modelling, constraining
771 current model-observation discrepancies would benefit from further exploring the model
772 sensitivity of simulated iron and its solubility to uncertainties in five major parameter sets: dust
773 iron emissions, combustion iron emissions, atmospheric iron dissolution chemistry, dry deposition
774 rates and wet deposition rates.

775 Here we discuss some of the model parameters which are likely important for improving modelled
776 iron emissions and deposition in MIMI, and ergo iron process models in general, in the future.

777

778 **5.1 Emissions**

779 Downwind of significant mineral dust sources iron models generally overestimate the observed
780 amount of total iron (Myriokefalitakis et al., 2018) and soluble iron comparisons are highly
781 sensitive to the assumed initial solubility of mineral dust iron at emissions (Conway et al. 2019, *in*
782 *review*). Conversely in remote ocean regions, improving the representation of combustion
783 emissions has been shown to be a necessary step towards more accurate representations of
784 observed high iron solubilities at low iron concentrations (Ito et al. 2019 *in review*).

785

786 **5.1.1 Mineral dust iron emissions**

787 In Fig. 4 the high model estimates of total iron, compared to observations, downwind of North
788 African mineral dust sources could be due to uncertainties in the magnitude of hematite emissions
789 within the model. Hematite contains by far the largest fraction of iron of any mineral in MIMI
790 (Table 3) with a major source in the Sahel (Fig. S4). The Sahel is a borderline dust source and
791 emissions from this region have been shown to be sensitive to different model dynamics, even
792 when forced with reanalysis winds, for example between CAM4 and CAM5 (Scanza et al., 2015).
793 Other studies have shown a large sensitivity of dust generation to the details of the soil erodibility
794 map (e.g., Cakmur et al., 2006). For CAM5 with the DEAD emissions scheme Scanza et al. (2015)

795 showed that improvements in estimating the direct radiative forcing of mineral dust could be
796 achieved by assuming that hematite is only emitted from clay minerals and not silt, an effective
797 reduction of ~30% from the coarse mode emission of hematite. Although MIMI has employed an
798 updated dust emission scheme (Table 1; Kok et al., 2014a) the model is still sensitive to
799 assumptions within the offline mineralogy maps and applications of the brittle fragmentation
800 theory therein. For instance, the single scattering albedo, which is a critical parameter in
801 estimating the direct radiative forcing (e.g., Di Biagio et al., 2009), becomes more comparable to
802 observations (Kim et al., 2011) if the same assumption as Scanza et al. (2015) is applied (Fig.
803 S5). Quantifying the uncertainty on the climate response to different assumptions in mineralogy
804 and dust emissions, and any reanalysis meteorology driving them, is therefore an important task.

805

806 **5.1.2 Combustion iron emissions**

807 Matsui et al. (2018) recently showed that combustion emissions have been underestimated in
808 current models. One possible reason for this underestimate is that combustion iron emissions
809 from Luo et al. (2008) are for 1996. Taking steelmaking and coal consumption (which are also
810 linked to iron emissions) as a proxy for economic development (Ghosh, 2006; Lee and Chang,
811 2008) shows that growth in these sectors boomed exponentially post 2000, particularly in Asia
812 and India (Ghosh, 2006; Lee and Chang, 2008). Therefore 1996 emissions are not capturing
813 recent industrial developments and updating the combustion emission inventory for use in the 21st
814 Century is a critical next step.

815 During a fire, the iron contained in leaves and wood (Price, 1968) will be released to the
816 atmosphere along with iron contained in the surrounding soil, whether entrained from the ground
817 due to pyro-convective updrafts (Wagner et al., 2018) or a remobilization of terrigenous particles
818 which have previously been deposited onto vegetation (Gaudichet et al., 1995; Paris et al., 2010).
819 All sources are subsequently internally mixed within the smoke plume before any downwind
820 observation occurs. Differentiating the iron contribution from the biomass which is burnt to that
821 from the entrained dust was not considered in any of the studies in Table 4 but would be required
822 to define the correct mineralogy and solubility of iron from fires. If we assume that biomass
823 contains low concentrations of iron relative to the surrounding soils then we could expect a
824 difference in observed Fe:BC ratios between a cerrado (savannah) environment, where
825 surrounding soils are dry and dust easily mobilized, compared to a tropical environment, where
826 soils are wet, and dust not as easily mobilized. But we do not see this in Table 4, and both regions

827 have a similar range which spans around two orders of magnitude from low to high. However, no
828 concrete conclusions can be drawn from such a limited dataset and so more observations are
829 needed to distinguish which source (biomass or dust) is contributing most to the iron measured
830 downwind of fires.

831 The physical, chemical, and biological properties of the underlying soil are also impacted by fires
832 (Certini, 2005) and it can be years after the fire has occurred before returning to a pre-fire state
833 is achieved. For example, the removal of vegetation and the surface crust by fires from dune
834 regions will create a new opportunity for dust mobilization (Strong et al., 2010) and higher intensity
835 fires can also increase the erodibility of soils and availability of fine particles through breaking
836 down the soil structure (Levin et al., 2012). Furthermore, under high temperatures the fire can
837 transform the underlying soil mineralogy, with decreases to iron in clay minerals and increases in
838 magnetic iron oxides minerals (Crockford and Willett, 2001; Ketterings et al., 2000; Ulery and
839 Graham, 1993). The amount of dust emitted from post-fire landscapes is potentially very
840 significant with Wagenbrenner et al. (2017) estimating an extra 12-352 Tg of dust as PM₁₀ (40%
841 of which was estimated to be PM_{2.5}) was emitted to the atmosphere in 2012 from post-fire
842 landscapes in the western U.S. alone. The impact of fires on total and soluble iron emissions in
843 dust from within post-burn regions is also likely to be different but requires further study, although
844 likely depends on the fire regime and the time since the fire occurred.

845 The most advanced iron processing models currently consider industrial, domestic, wildfires and
846 shipping combustion emissions (Myriokefalitakis et al., 2018). An emerging discussion is the
847 importance of volcanic ash, and the iron it contains, on ocean biogeochemistry (Langmann, 2013).
848 Figs. 4 through 7 showed that MIMI underrepresents both total iron and its solubility in the remote
849 extra-tropical Pacific where volcanic emissions may be an important missing iron source. Future
850 understanding in volcanic iron sources are potentially important as once deposited to the ocean,
851 particularly in those regions that are iron limited or seasonally iron limited, volcanic inputs have
852 been shown to alter satellite chlorophyll (Hamme et al., 2010; Rogan et al., 2016) and the
853 drawdown of macronutrients (Lindenthal et al., 2013). The volume of metals released by a volcano
854 is subject to many uncertainties, including both the nature of the volcano and its eruption type and
855 strength; leading to estimates which can vary by many orders of magnitude (Mather et al., 2006,
856 2012). To date most studies have focused on ocean inputs from shorter term explosive eruptions,
857 rather than continuous inputs from quiescent passive degassing volcanoes which are likely to be
858 most important only for the central Pacific region downwind of volcanoes located within the “ring
859 of fire” (Olgun et al., 2011).

860 **5.2 Aerosol deposition**

861 Examination of aerosol dry deposition in CAM5 by Wu et al (2018) showed that the deposition
862 velocity for Aitken and accumulation sized BC particles is potentially an order of magnitude too
863 high. It is highly likely that this will also be the case for dust. As the largest discrepancies between
864 model and observations are in remote ocean regions improving the models long-range transport
865 of iron by investigating deposition rates is an important constraint to be applied to the model.

866

867 **6. Conclusion**

868 It is important to accurately model the atmospheric iron cycle because of the impacts of iron on
869 human health, ocean biogeochemistry and climate. Atmospheric iron process modelling suitable
870 for use in global climate and Earth system modelling is a new model development area, and as
871 such currently undergoing rapid development. Here we have detailed the development of the
872 Mechanism of Intermediate complexity for Modelling Iron (MIMI), such that it now represents iron
873 emissions, atmospheric processing and deposition within a global modal aerosol microphysics
874 framework.

875 The solubility of iron depends on the underlying aerosol iron properties, such as dust mineralogy
876 and combustion fuel type, and the degree to which dissolution from an insoluble to soluble iron
877 form has occurred in the atmosphere. Which of these is the dominant factor for describing the
878 observed inverse relationship between the solubility of iron to the total iron mass is currently
879 unknown (Mahowald et al., 2018). Updating the mineral dust emission scheme to a physical
880 based parametrisation however has improved model performance by increasing total iron close
881 to mineral dust sources, where solubility is observed to be low (Figs. 4 through 7). Updating
882 combustion emissions from fires increases the long range transport of soluble iron to remote
883 ocean regions, where observed solubility is higher (Figs. 4 through 7), while increasing
884 combustion iron emissions by a factor of five brings the total in line with more recent evaluations
885 of their magnitude (Matsui et al., 2018, Conway et al. 2019 *in review*, Rathod et al, *in prep*).
886 Emission updates have also increased the variability in soluble iron deposition (Fig. 14).
887 Improvements to the atmospheric iron processing scheme in MIMI also increase iron dissolution
888 in more remote regions relative to mineral dust sources, again in line with observations.

889 Comparison with observations (Figs. 4 through 7) show that in general MIMI simulates total iron
890 concentrations well. However, comparison of modelled iron solubility to observation reveals that

891 while the model captures many regional features, some are missed. It is unclear, however,
892 whether this problem arises from the model or observational representation of the system owing
893 to the insufficient numbers of observations available to build a robust observational result for such
894 a highly variable quantity in the Earth system, even when aggregating over small regional scales.
895 There are significant differences in calculating iron solubility based on the order of the averaging
896 operation and the mean is shown to not be an accurate representation of the average atmospheric
897 state, due to the non-Gaussian distribution of aerosol concentrations. In many regions however
898 there are just a few (less than five) observations, and often only one, and so while the use of the
899 median is robust with respect to extreme values, a limited observational dataset cannot truly
900 discriminate if extreme values are outliers or, rather, the norm. Use of the mean also significantly
901 overestimates the average atmospheric soluble iron deposition to the ocean and is always larger
902 than the upper quartile of the distribution in daily deposition. However, this bias may be tempered
903 due to ocean biogeochemistry processes likely being relevant over timescales which are longer
904 than those in the atmosphere. Future work will need to consider how best to compare model to
905 sporadic observations, potentially making use of distributions rather than a more limited absolute
906 average.

907 The main sources of soluble iron deposition vary both between and within ocean basin. The
908 redefinition of ocean basins based on the dominant iron deposition source, rather than a
909 traditional physio-geographical ocean basin, can therefore aid in determining where continental
910 anthropogenic activity will have the greatest impact on ocean biogeochemistry and which source
911 region is linked to where model-observation comparisons are poor. For example, modelling of
912 total iron and its solubility in the South Atlantic could be improved by further improving our
913 understanding of industrial combustion and fires within South America. Furthermore, soluble iron
914 deposition to Southern Hemisphere oceans in MIMI, where combustion and fire emissions have
915 a significant impact, is between a factor of two to four higher compared to BAM-Fe, itself the
916 model simulating the largest atmospheric fluxes to the ocean of the comparable models studied
917 in Myriokefalitakis et al. (2018). As integrated Earth system models develop in the future taking a
918 holistic view to understanding how dust and fires are coupled, in terms of feedbacks on iron
919 emissions, is an important step for predicting how future changes in climate will alter the climate
920 and Earth system response to human perturbations of the natural system.

921

922 **Code and data availability**

923 Code is available immediately from the corresponding author upon request and will be
924 incorporated in a future E3SM model release. Model data is available from the corresponding
925 author upon request. Observational data is available from Mahowald et al. (2009) and
926 Myriokefalitakis et al. (2018).

927

928 **Author contributions**

929 D.S.H. developed MIMI which incorporates model code previously developed by R.A.S., Y.F.,
930 J.F.K., X.L., and M.W. D.S.H. undertook all model simulations and wrote the manuscript with
931 support from N.M.M., J.G., and S.D.R.. D.S.H. prepared all Figures and Tables apart from Fig. 1
932 and Table S1 (J.S.W.), Figs. S2 and S5 (L.L.), and Fig. 9 and S1 (S.D.R.). All authors edited
933 manuscript text.

934

935 **Acknowledgements**

936 This work was supported by Department of Energy (DE) and National Science Foundation (NSF)
937 grants for atmospheric deposition impacts on ocean biogeochemistry (DE-Sc0016362; NSF
938 1049033; CCF-1522054). D.S.H. and N.M.M. were also supported by the Atkinson Center for a
939 Sustainable Future. J.F.K. acknowledges support from NSF grant 1552519. S.D.R. would like to
940 thank the Collaborative Proposal Fire Dust Air and Water Improving Aerosol Biogeochemistry
941 Interactions in ACME (DE-Sc0016321) in supporting his Masters. X.L. and M.W. would like to
942 thank the support of NASA CloudSat and CALIPSO Science Program (grant NNX16AO94G). We
943 would like to acknowledge high-performance computing support from Cheyenne
944 ([doi:10.5065/D6RX99HX](https://doi.org/10.5065/D6RX99HX)) provided by NCAR's Computational and Information Systems
945 Laboratory, sponsored by the National Science Foundation.
