Abstract. We present a finite-element model of postseismic solid Earth deformation built in the software package ABAQUS (version 2018). The model is global and spherical, and includes self-gravitation and is built for the purpose of calculating postseismic deformation in the far-field (>~300km) of major earthquakes. An earthquake is simulated by prescribing slip on a fault plane in the mesh and the model relaxes under the resulting change in stress. Both linear Maxwell and biviscous (Burgers) rheological models have been implemented and the model can be easily adapted to include different rheological models and lateral variations in Earth structure, a particular advantage over existing models. We benchmark the model against an analytical coseismic solution and an existing open-source postseismic model, demonstrating good agreement for all fault geometries tested. Due to the inclusion of self-gravity the model has the potential for predicting deformation in response to multiple sources of stress change, for example, changing ice thickness in tectonically active regions.

1 Introduction

Earthquakes cause deformation at the Earth's surface from the immediate coseismic fault slip and, thereafter, from several processes. Afterslip on the fault on or near the rupture zone (e.g. Huang et al., 2014) and poroelastic relaxation due to changes in fluid pressure (e.g. Masterlark and Wang, 2002) result in deformation of near-field locations (typically <300km from the fault). As the Earth responds to stress changes associated with the earthquake, the lower crust and upper mantle undergo prolonged postseismic viscoelastic deformation. This is the dominant mode of displacement in the far-field and, for very large earthquakes (> magnitude 9), this can be observed geodetically over 1000 km from the earthquake source (Shao et al., 2016) and be sustained over decades. For example, deformation from the 1960 magnitude 9.5 Chile earthquake was still being observed ~40 years after the event (Khazaradze and Klotz, 2003). Postseismic deformation can be observed by increasingly dense networks of geodetic measurements such as GPS (e.g. Freed et al., 2012) and InSAR (e.g. Wang and Fialko, 2018) motivating the development of models to help interpret geodetically-observed deformation. The study of postseismic deformation can provide useful information about the Earth and can be used to place constraints on the likely Earth structure (Pollitz, 2005) or rheology (Freed et al., 2012). It is important to be able to accurately quantify postseismic deformation in

regions where deformation occurs as a result of multiple sources, for example in Alaska where the Earth is also deforming in response to a changing ice load (Suito and Freymueller, 2009).

Postseismic deformation has been studied using a variety of modelling techniques, from simple “flat-Earth” models to models that consider Earth’s sphericity and three-dimensional material properties. For studying the far-field effects of earthquakes consideration of sphericity is required (Pollitz, 1992). Pollitz (1997) developed a software (VISCO1D, freely available from the USGS at: <https://www.usgs.gov/software/visco1d>, which contains a link to download the software) to calculate postseismic deformation on a spherical layered Earth incorporating an Earth model that varies in the radial direction only. It uses viscoelastic normal mode theory and calculates deformation from spherical harmonic expansion of global modes of relaxation. Deformation can be calculated both with and without the effect of gravity, that is, the restoring forces within the Earth allowing it to regain gravitational equilibrium. The effect of including gravity is that deformation ceases once the Earth has adjusted to the change in stress, whereas without gravity, deformation continues. This model has been employed for a wide range of earthquake studies, such as constraining Earth properties and rheological behaviour in response to the magnitude 7.9 2002 Denali earthquake in Alaska (Pollitz, 2005), computing postseismic gravity change following the magnitude 9.1 2011 Tohoku-Oki earthquake gravity change (Han et al., 2014), and modelling postseismic deformation of Antarctica (King and Santamaría-Gómez, 2016). Furthermore, VISCO1D has been used to benchmark other codes of postseismic deformation calculation (Wang et al., 2006). Whilst VISCO1D is a powerful tool, it is limited to a one-dimensional Earth model which may not be appropriate for some studies where lateral variations in Earth structure may be required to fully explain geodetic observations (King and Santamaría-Gómez, 2016).

Several finite-element models of postseismic deformation have also been developed (Freed et al., 2006; Masterlark et al., 2001; Takeuchi and Fialko, 2013), although the majority have been restricted to a flat-Earth geometry. Hu and Wang (2012) updated their flat-Earth finite-element model (Hu et al., 2004) to include spherical geometry and used it to study the 2004 magnitude 9.2 Sumatra earthquake, where a spherical geometry allowed for more realistic slab and fault geometry to be included, however they limited the spatial extent of the model to the case study region. Whilst limiting the spatial extent is computationally efficient and does not cause a problem for the estimation of postseismic deformation, to compute a fully self-gravitational solution using spherical harmonics a full global model is required. Self-gravitation takes account of the change in gravity field caused by deformation and the redistribution of mass within the Earth. The effect of self-gravitation due to earthquake-related deformation is likely to be small for the majority of earthquakes, and not on the same scale as that caused by glacial isostatic adjustment since the magnitude of deformation is much smaller, but including it allows consistent modelling of deformation due to multiple sources (e.g. glacial cycles). Furthermore, for large earthquakes, the change in gravity field resulting from deformation and redistribution of mass within the Earth could be significant, and, if the earthquake occurs under the ocean, redistribution of water also contributes to the change in gravity and hence affects sea levels (Broerse et al., 2011).

65 The purpose of the model presented in this paper is to estimate far-field postseismic deformation primarily from large earthquakes. The model is a global, spherical finite-element model constructed with the commercial software ABAQUS (<https://www.3ds.com/products-services/simulia/products/abaqus/>; Hibbitt et al., 2016). It is an improvement on existing models since it includes both global spherical geometry and the capability to use 3D variations in Earth properties and different rheological models. Furthermore, the model has the potential to simultaneously include different sources of Earth deformation, 70 for example postseismic deformation in a region undergoing, or which has previously undergone, surface-mass change (e.g., ice-mass change). This is needed, for instance, to separate present-day surface deformation signals observed by GPS.

This paper describes the model setup and the methods implemented to estimate coseismic and postseismic deformation (Sects. 2 and 3). Since afterslip and poroelastic relaxation are considered only to affect deformation in the near-field of the fault for all but the largest earthquakes (Peña et al., 2019) they are not included in our model. We benchmark model results for several 75 simple scenarios against existing codes (Sect. 4) and discuss the advantages and limitations of the model (Sect. 5). The input files are available to allow other users to replicate results and use the methods to set up their own postseismic deformation models.

80 2 Model Setup

2.1 Model Geometry and Mesh

The model is a global, spherical representation of the Earth, developed in ABAQUS version 2018, but is also compatible with older versions of the software as well. It is based on the finite-element model for computing glacial isostatic adjustment following the methods described by Wu (2004), whereby we use the same set up of a viscoelastic Earth relaxing in response 85 to a stress change, but instead of applying a changing ice-surface load we implement a fault and associated slip. We model a spherical Earth rather than taking a flat-Earth approach so more realistic geometry can be included and gravity perturbations due to deformation can be accounted for by means of a spherical harmonic expansion. The model has layers from the surface to the core-mantle boundary with computational feasibility being the only limit on the number of layers. Each layer is assigned material properties according to user requirements and would typically consist of an elastic outer layer representing the 90 uppermost lithosphere, with viscoelastic lower lithosphere and mantle layers below.

An earthquake is simulated in the model by movement on a fault plane within the mesh (see Sect. 3 for details) and in order to compute deformation to a sufficient accuracy a high-resolution mesh is required in the vicinity of the fault. To balance the need for a high-resolution mesh against a model with a computationally feasible number of elements, we take the approach of 95 constructing two separate parts (ABAQUS keyword *PART): one for the high-resolution fault region and one for the lower resolution surrounding earth (Fig. 1). The two parts are then tied together (ABAQUS keyword *Tie) using surface-to-surface

tie constraints which ensures that stress is transferred between the two meshes but that the two surfaces cannot penetrate each other. The size of the part containing the fault can be changed according to the requirements of the individual case study but should be large enough to contain the far-field area of interest, for example where geodetic observations may be located. The high-resolution mesh block extends to 670 km depth (i.e. the base of the upper mantle) so that any deformation that may be caused by the fault movement is within the block and hence there is minimal stress to transfer across the tied surfaces. The element type used is an 8-node linear brick element (C3D8 in ABAQUS).

2.2 Rheology and Earth Parameters

All layers within the model are assigned a density (ρ), Poisson's ratio (ν) and Young's Modulus (E) (ABAQUS key words *Density *Elastic). For viscoelastic layers below the purely elastic outer shell, a relaxation time is specified which is based on a Prony time series (ABAQUS key words *Viscoelastic). In this study we limit our benchmarking examples to a 1D linear viscoelastic rheology with one (Maxwell) or two (Burgers) relaxation times, however ABAQUS has the capability of using a variety of rheological models and variations of our model could be constructed using a 3D Earth structure (e.g. van der Wal et al., 2015).

2.3 Boundary Conditions

We follow the approach of Wu (2004) and apply elastic foundations (ABAQUS keyword *Foundation) to each layer boundary with a material density contrast occurring across it (including the surface and core-mantle-boundary). This takes care of the restoring forces of buoyancy neglected in a conventional finite-element model (Wu, 2004). The elastic foundations have a stiffness equal to the difference in density multiplied by gravitational acceleration. Schmidt et al. (2012) show that the use of foundations at surfaces not perpendicular to the direction of gravity produces errors in results, but we ensure that density contrasts occur only at spherical layer boundaries in our model which satisfies this requirement. The foundations could be also replaced by spring elements when an inclined density contrast is used (Schmidt et al., 2012).

2.4 Time Steps

Once the model has been set up with the geometry, rheology, Earth parameters, boundary conditions, and fault slip (see Sect. 3); time steps are created to run the model. The first step of the run is a static step to allow the fault to slip. In this step all material properties are treated as elastic and the fault displaces immediately, hence no actual time needs to be assigned. All subsequent steps are for the simulation of postseismic relaxation and consequently must have a time assigned to them. One full run of all the time steps is one iteration.

2.5 Self-Gravitation

Movement of mass due to deformation of the Earth perturbs the gravity field which in turn affects the Earth's deformation. The effect of changes in the gravity field needs to be taken into account to make the model self-gravitating. This is done

iteratively, first using a non-self-gravitating model and computing the resulting gravitational potential from the radial displacement using the equations presented by Wu (2004). Applying this as a new load at the interfaces of the model where a density contrast occurs across them, the displacement is recalculated (i.e. another iteration is run). Wu (2004) suggests running
130 the model for 4-5 iterations to achieve convergence of the solution.

2.6 Outputs

ABAQUS can compute many different output variables depending on the model setup. For our model the main output of interest is a global grid of deformation in the east, north and radial directions. It is also possible to output stress, strain, and perturbation to the geoid which could be used to correct satellite gravimetry data for the gravity change associated with very
135 large earthquakes (e.g. Han et al. 2014).

3 Implementation of an Earthquake

3.1 Fault Geometry and Slip

In our model an earthquake is simulated by prescribing slip on a fault plane. In order to implement this in a finite-element mesh we require two separate surfaces that can move relative to each other. We take the approach of Steffen et al. (2014),
140 whose model simulates fault slip due to changes in stress during glacial cycles, whereby the fault plane geometry is created prior to meshing and then once generated, the mesh is subsequently altered to produce two surfaces. This is accomplished by duplicating the nodes that lie on the fault surface and then reassigning the duplicated nodes to the elements on one side of the fault plane, thereby creating a “cut” in the mesh. Although the elements on each side of the fault are defined by different nodes, the node pairs initially have the same coordinates (Fig. 2).

145

The model of Steffen et al. (2014) incorporates a complex stress history comprising tectonic stresses and stresses relating to glacial cycles allowing faults to slip in response to the changing conditions. Our model differs from this approach because the amount of slip that occurs on the fault plane is prescribed. This negates the need to specify any fault surface parameters such as coefficient of friction or cohesion but does require detailed knowledge of the earthquake event. Prescribing an amount of
150 slip on the fault plane is a reasonable approach as fault properties, such as length, width, strike, dip, rake, and slip are often solved through independent means such as fault inversion studies (Hayes, 2017) and detailed fault slip information is not required when studying far-field deformation. Furthermore, we do not include any pre-stress in the model, that is, there is no tectonic or background stress applied before the fault slips. This has no effect for models that use Maxwell or Burgers rheology as they are independent of stress.

155 3.2 Coseismic Slip

Once the finite-element mesh has been adjusted to accommodate the fault plane, coseismic displacement is prescribed following the approach of Masterlark (2003). For every node pair on the fault plane (i.e. nodes on either side of the fault that have the same coordinates), a third “dummy” node is created at the same location but not connected to any element in the mesh (Fig. 2). Dummy nodes are assigned a displacement boundary condition (ABAQUS keyword *Boundary) in the x and y
160 directions of a local coordinate system aligned with the fault plane (see Fig. 2) with the amount of displacement in each direction depending on the slip and rake. For example, using basic trigonometry, a slip of 5m at a rake of -60° would equate to slip of 2.5m in the X direction and 4.3m in the Y direction. Kinematic constraint equations (ABAQUS keyword *Equation) are then constructed for each node pair and its corresponding dummy node which specifies the relative displacement between the node pair in the X and Y direction. There is no relative displacement in the Z direction of the local coordinate system (i.e.
165 normal to the fault plane), as the fault is not allowed to open. Because the constraint equations are specified separately for each node, the fault plane can accommodate a spatially variable slip distribution. The first step of the model run is a static step (ABAQUS keyword *Static) in which the nodes (and hence the fault plane) displace according to the kinematic constraint equations. During the static step, all materials are treated as elastic.

3.3 Postseismic Deformation

170 Following the first step of the model run (i.e. the earthquake), the subsequent time steps simulate postseismic deformation (ABAQUS keyword *Visco) by allowing the mesh to deform under the stresses caused by the displacement on the fault plane. The kinematic constraint equations remain in place throughout the model run which means that there is no further relative displacement between the node pairs.

4 Benchmarking

175 In order to verify the model we benchmark the results against those produced with the Okada analytical solution for coseismic displacement (Okada, 1985) and the VISCO1D code (Version 3) for gravitational postseismic relaxation (Pollitz, 1997).

4.1 Test Setup

We perform three benchmarking tests: a strike-slip fault, a 30° dipping reverse fault, and a 45° dipping fault with rake of -60° , as summarised in Table 1. All faults outcrop at the surface of the model. In plan view, the ABAQUS mesh has 10 km elements
180 in the vicinity of the fault, increasing to 50 km at the edge of the fault region, with elements in the surrounding low-resolution part being 500 km (Fig. 1). The element size increases with depth as shown in Table 2. The model is run for 500 years in order to verify both the short and long term postseismic deformation, and for 4 iterations to ensure convergence of the self-gravitational solution. The ABAQUS input files for the benchmarking tests are included in the supplementary material (Nield, 2020). VISCO1D is run for the same time period and with maximum spherical harmonic degree of 2000, equivalent to ~ 10

185 km resolution. In all tests the same simple Earth structure is used (details for the ABAQUS model are in Table 2), which is based on the Earth structure used by Pollitz (1997) for the upper most 670 km, and we include a uniform lower mantle layer below. We found that the vertical deformation results for VISCO1D were sensitive to the number of layers in the input Earth structure and the presence of a lower mantle, so whilst the material properties are the same for both models, the VISCO1D Earth model contains more layers. We use a linear Maxwell rheology for all three benchmarking tests. We additionally verify
190 the implementation of Burgers rheology against VISCO1D for the third test, with the transient viscosity (η) given in Table 2. The input files for each test case and the Earth models used in the VISCO1D modelling for both Maxwell and Burgers rheology are given in the supplementary material (Nield, 2020). All output displacement is shown normalised to the fault slip, in other words as a percentage of fault slip. This is consistent with the presentation of results by Pollitz (1997) and provides a useful metric for comparison of results. Differences between the model results are given as the difference between the percentages
195 of fault slip.

4.2 Coseismic Results

The results of the benchmarking exercises are shown in Figs. 3-5. We show coseismic displacement in the east, north and vertical directions for a profile perpendicular to the fault strike for each of the benchmarking tests. The Okada analytical solution is shown by the dark green line with the equivalent ABAQUS coseismic output shown by the light green dots. The
200 difference between the models is shown in panel b) of Figs. 3-5. Overall, there is an excellent agreement between the ABAQUS model and the Okada analytical solution. Of the three cases, the strike-slip fault agrees most closely (Fig. 3), with differences peaking at 1% of the fault slip in the north direction (Fig. 3b). There are larger differences visible for the dipping fault cases (Figs. 4-5). Some of the near-field finer details of displacement in the east and vertical directions for the dipping faults (i.e. the directions with most displacement) are not perfectly captured by ABAQUS, for example at 50 km from the fault (see Fig. 4a,
205 vertical direction), most likely due to the mesh resolution and the distorted element shape that is required to mesh around a dipping fault. However, these differences are a maximum of 6% (Fig. 4b) and at distances greater than 300 km from the fault this decreases to less than 0.5%. Since the aim of our model is to predict far-field deformation these differences are acceptable.

4.3 Postseismic Results

Figs. 3-5 also show profiles of the postseismic displacement in the east, north and vertical directions for VISCO1D (light blue
210 line) and the ABAQUS model (dark blue dashed line). We show displacement as a percentage of fault slip at three times: 10, 50 and 100 years after the earthquake with corresponding differences between the models shown in panel b) of each figure. The ABAQUS predictions closely agree with VISCO1D for the strike-slip fault case (Fig. 3). Small differences can be observed for the dipping faults particularly in the vertical direction (Figs. 4b and 5b). It is likely that the mismatch in the coseismic displacement is the cause of mismatch for the postseismic displacement, i.e. less coseismic displacement from the ABAQUS
215 model would result in less stress and therefore less relaxation. However, the differences remain small and are concentrated within 100 km of the fault with a maximum difference of 5% of the fault slip after 100 years of relaxation (Fig. 4b) and less

than 0.5% at distances greater than 300 km from the fault. Therefore, we conclude that the model results are reliable for far-field postseismic deformation.

220 Figs. 6-7 shows displacement through time for the fault geometry in test 3 for two points at 100 km (Fig. 6) and 300 km (Fig. 7) from the fault using both a Maxwell and Burgers rheology. There is clear consistency in the evolution of postseismic relaxation between our model and VISCO1D, for both rheologies (compare solid with dashed lines on Figs. 6a and 7a). The insets in Figs. 6-7 show the results for the initial 30 years of the model run where a rapid displacement can be observed from the transient viscosity of the Burgers rheology (orange/red lines) before converging with the results from the Maxwell model (blue lines) after approximately 30 years. Over the 500-year period, differences between our ABAQUS model and VISCO1D for the Burgers rheology are less than 0.6% of the fault slip within 100 km of the fault (Fig. 6b), or less than 0.1% at distances of 300 km or more (Fig. 7b). For the Maxwell rheology, differences peak at 0.5% of the fault slip within 100 km, reducing to 0.2% at 300 km.

5 Discussion and Conclusions

230 We have presented a finite-element model constructed in ABAQUS for the purposes of modelling far-field coseismic and postseismic deformation. The model is global, spherical and self-gravitating, and allows for simple modification to include three-dimensional Earth structure, non-linear rheologies and alternative or multiple sources of stress change.

The model performs well when compared with the Okada coseismic analytical solution and predictions from the postseismic VISCO1D program for all three fault scenarios we have tested. For the coseismic displacement, differences are less than 6% of the fault slip, with the largest differences in the vertical direction and near to the fault; in the fault far-field the differences are negligible. For the postseismic displacement, differences are less than 5% of the fault slip and at distances of 300 km from the fault, i.e. the far-field which is the focus of our model, this reduces to differences of 0.5%. Furthermore, we have verified that the evolution through time is an excellent match with VISCO1D for both Maxwell and Burgers rheologies.

240 Inclusion of self-gravitation makes only a small difference to the displacement, peaking at 0.2 mm (less than 0.1% of the fault slip) for the reverse fault (test 2) in the vertical displacement and is negligible in the horizontal directions. This demonstrates that it is not necessary to include self-gravitation when modelling postseismic deformation in isolation, but it could become important when modelling postseismic deformation alongside other larger sources of deformation such as changes in ice loading.

The main limitation of the model is that the geometry is restricted to a single fault plane within the mesh and it cannot have multiple segments of a fault plane with different strike or dip. This is due to the difficulties of constructing a valid mesh in

250 ABAQUS with elements that conform to verification checks. For the same reason, including more than one earthquake in the same model would be problematic. In the case of a fault inversion that suggests multiple fault segments (e.g. Ye et al., 2014), an approximation of all the fault planes into a single geometry would be required and, if constrained using near-field coseismic observations, could still provide a realistic far-field estimate of postseismic deformation. The model can, however, account for varying slip and rake along the single fault plane by specifying individual values at each node pair.

255 We have demonstrated the validity of this model for far-field coseismic and postseismic deformations. It is an improvement on existing models as it includes global spherical geometry, self-gravitation, and can be adapted to include 3D Earth structure. It will prove particularly useful for investigating earthquakes in regions that may have large lateral variations in Earth properties where a 1D Earth model cannot reproduce geodetic observations. Furthermore, the capability of ABAQUS to model surface loading such as a changing ice load has already been established (e.g. van der Wal et al., 2010; Wu, 2004), and could
260 easily be incorporated into this model.

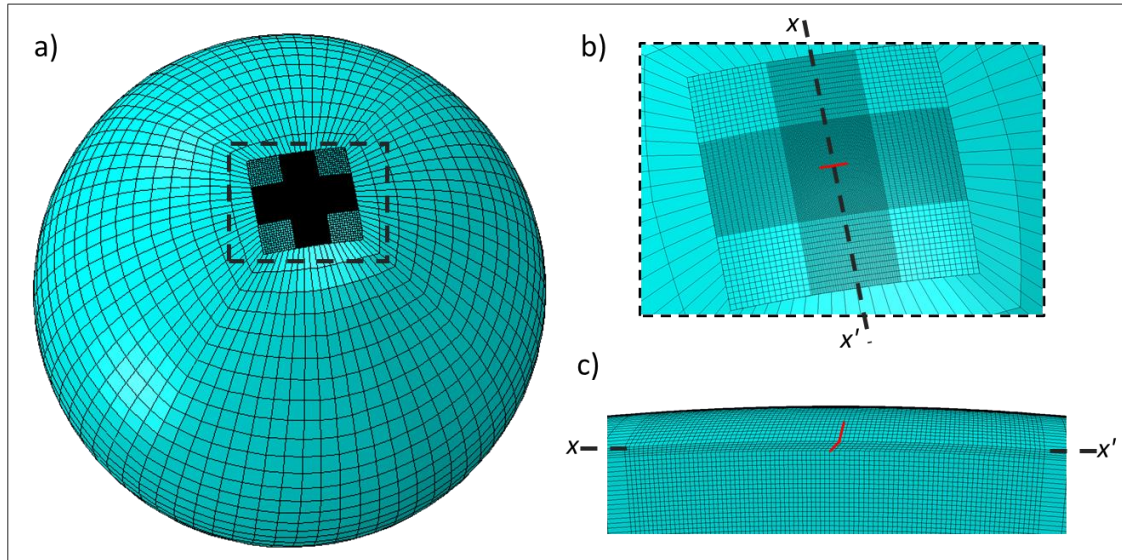

Code Availability. ABAQUS is a commercial software and can be purchased from the developer (<https://www.3ds.com/products-services/simulia/products/abaqus/>), we have used version 2018 in this study, but the methods
265 and functionality used are available in older versions of the software as well. ABAQUS input files for all four models presented in this paper are available at https://github.com/ganield/ABAQUS_Postseismic_model/releases/tag/v1.1, and archived on Zenodo: <https://doi.org/10.5281/zenodo.3891444> (Nield, 2020). Instructions on how to run the files are also available at this link. VISCO1D version 3 is available for download at: <https://www.usgs.gov/software/visco1d>. The VISCO1D input files and earth model files used in the experiments presented in this paper are included in the github repository, along with some
270 instructions on how to run the code.

Author Contributions. GN developed the model. MK conceived the study and consulted in the model implementation. RS contributed meshing code for ABAQUS and consulted in the model development. BB contributed the self-gravitational part of the code. All authors contributed to the manuscript.
