Abstract. Extensive and rigorous model inter-comparison is of great importance before application due to the uncertainties in current land surface models (LSMs). Without considering the uncertainties of forcing data and model parameters, this study designed an ensemble of 55296 experiments to evaluate the Noah land surface model with multiparameterization (Noah-MP) for snow cover events (SCEs), soil temperature (ST) and soil liquid water (SLW) simulation, and investigated the sensitivity of parameterization schemes at a typical permafrost site on the Qinghai-Tibet Plateau. The results showed that Noah-MP systematically overestimates snow cover, which could be greatly resolved when adopting the sublimation from wind and semi-implicit snow/soil temperature time scheme. As a result of the overestimated snow, Noah-MP generally underestimates ST and ST is mostly influenced by the snow process. Systematic cold bias and large uncertainties of soil temperature remains after eliminating the effects of snow, particularly at the deep layers and during the cold season. The combination of roughness length for heat and under-canopy aerodynamic resistance contributes to resolve the cold bias of soil temperature. In addition, Noah-MP generally underestimates top SLW. The RUN process dominates the SLW simulation in comparison of the very limited impacts of all other physical processes. The analysis of the model structural uncertainties and characteristics of each scheme would be constructive to a better understanding of the land surface processes in the permafrost regions of the QTP and further model improvements towards soil hydrothermal regime modeling using the LSMs.

1 Introduction

The Qinghai-Tibet Plateau (QTP) is underlain by the world's largest high-altitude permafrost covering a contemporary area of 1.06 × 10⁶ km² (Zou et al., 2017). Under the background of climate warming and intensifying human activities, soil hydrothermal dynamics in the permafrost regions on the QTP has been widely suffering from soil warming (Wang et al., 2021), soil wetting (Zhao et al., 2019), and changes in soil freeze-thaw cycle (Luo et al., 2020). Such changes has not only induced the reduction of permafrost extent, disappearing of permafrost patches and thickening of active layer (Chen et al., 2020), but also resulted in alterations in hydrological cycles (Zhao et al., 2019; Woo, 2012), changes of ecosystem (Fountain et al., 2012; Yi et al., 2011) and damages to infrastructures (Hjort et al., 2018). Therefore, it is very important to monitor and simulate the soil hydrothermal regime to adapt to the changes taking place.

A number of monitoring sites have been established in the permafrost regions of the QTP (Cao et al., 2019). However, it is inadequate to construct the soil hydrothermal state by considering the spatial variability of the ground thermal regime and an uneven

A number of monitoring sites have been established in the permatrost regions of the QTP (Cao et al., 2019). However, it is inadequate to construct the soil hydrothermal state by considering the spatial variability of the ground thermal regime and an uneven distribution of these observations. In contrast, numerical models are competent alternatives. In recent years, land surface models (LSMs), which describe the exchanges of heat, water, and momentum between the land and atmosphere (Maheu et al., 2018), have received significant improvements in the representation of permafrost and frozen ground processes (Koven et al., 2013; Nicolsky et al., 2007; Melton et al., 2019). LSMs are capable of simulating the transient change of subsurface hydrothermal processes (e.g. soil temperature and moisture) with soil heat conduction (-diffusion) and water movement equations (Daniel et al., 2008). Moreover, they could be integrated with the numerical weather prediction system like WRF (Weather Research and Forecasting), making them as effective tools for comprehensive interactions between climate and permafrost (Nicolsky et al., 2007).

Some LSMs have been evaluated and applied in the permafrost regions of the QTP. Guo and Wang (2013) investigated near-surface permafrost and seasonally frozen

ground states as well as their changes using the Community Land Model, version 4 (CLM4). Hu et al. (2015) applied the coupled heat and mass transfer model to identify the hydrothermal characteristics of the permafrost active layer in the Qinghai-Tibet Plateau. Using an augmented Noah LSM, Wu et al. (2018) modeled the extent of permafrost, active layer thickness, mean annual ground temperature, depth of zero annual amplitude and ground ice content on the QTP in 2010s. Despite those achievements based on different models, LSMs are in many aspects insufficient in permafrost regions. For one thing, large uncertainties still exist in the state-of-the-art LSMs when simulating the soil hydrothermal regime on the QTP (Chen et al., 2019). For instance, 19 LSMs in CMIP5 overestimate snow depth over the QTP (Wei and Dong, 2015), which could result in the variations of the soil hydrothermal regime in the aspects of magnitude and vector (cooling or warming) (Zhang, 2005). Moreover, most of the existing LSMs are not originally developed for permafrost regions. Many of their soil processes are designed for shallow soil layers (Westermann et al., 2016), but permafrost would occur in the deep soil. And the soil column is often considered homogeneous, which cannot represent the stratified soil common on the QTP (Yang et al., 2005). Given the numerous LSMs and possible deficiencies, it is necessary to assess the parameterization schemes for permafrost modeling on the QTP, which is helpful to identify the influential sub-processes, enhance our understanding of model behavior, and guide the improvement of model physics (Zhang et al., 2016).

Noah land surface model with multi-parameterization (Noah-MP) provides a unified framework in which a given physical process can be interpreted using multiple optional parameterization schemes (Niu et al., 2011). Due to the simplicity in selecting alternative schemes within one modeling framework, it has been attracting increasing attention in inter-comparison work among multiple parameterizations at point and watershed scales (Hong et al., 2014; Zheng et al., 2017; Gan et al., 2019; Zheng et al., 2019; Chang et al., 2020; You et al., 2020). For example, Gan et al. (2019) carried out an ensemble of 288 simulations from multi-parameterization schemes of six physical processes, assessed the uncertainties of parameterizations in Noah-MP, and further

revealed the best-performing schemes for latent heat, sensible heat and terrestrial water storage simulation over ten watersheds in China. You et al. (2020) assessed the performance of Noah-MP in simulating snow process at eight sites over distinct snow climates and identified the shared and specific sensitive parameterizations at all sites, finding that sensitive parameterizations contribute most of the uncertainties in the multi-parameterization ensemble simulations. Nevertheless, there is little research on the inter-comparison of soil hydrothermal processes in the permafrost regions. In this study, an ensemble experiment of totally 55296 scheme combinations was conducted at a typical permafrost monitoring site on the QTP. The simulated snow cover events (SCEs), soil temperature (ST) and soil liquid water (SLW) of Noah-MP model was assessed and the sensitivities of parameterization schemes at different depths were further investigated. This study could be expected to present a reference for soil hydrothermal simulation in the permafrost regions on the QTP.

This article is structured as follows: Section 2 introduces the study site, atmospheric forcing data, design of ensemble simulation experiments, and sensitivity analysis methods. Section 3 describes the ensemble simulation results of SCEs, ST and SLW, explores the sensitivity and interactions of parameterization schemes. Section 4 discusses the schemes in each physical process. Section 5 concludes the main findings.

2 Methods and materials

2.1 Site description and observation datasets

Tanggula observation station (TGL) lies in the continuous permafrost regions of Tanggula Mountain, central QTP (33.07°N, 91.93°E, Alt.: 5,100 m a.s.l; Fig. 1). This site a typical permafrost site on the plateau with sub-frigid and semiarid climate (Li et al., 2019), filmy and discontinuous snow cover (Che et al., 2019), sparse grassland (Yao et al., 2011), coarse soil (Wu and Nan, 2016; He et al., 2019), and thick active layer (Luo et al., 2016), which are common features in the permafrost regions of the plateau. According to the observations from 2010–2011, the annual mean air temperature of

TGL site was -4.4 °C. The annual precipitation was 375 mm, and of which 80% is concentrated between May and September. Alpine steppe with low height is the main land surface, whose coverage range is about 40% \sim 50% (Yao et al., 2011). The active layer thickness is about 3.15 m (Hu et al., 2017).

The atmospheric forcing data, including wind speed/direction, air temperature/relative humidity/pressure, downward shortwave/longwave radiation, and precipitation, were used to drive the model. These variables above were measured at a height of 2 m and covered the period from August 10, 2010 to August 10, 2012 (Beijing time) with a temporal resolution of 1 hour. Daily soil temperature and liquid moisture at depths of 5cm, 25cm, 70cm, 140cm, 220cm and 300cm from August 10, 2010 to August 9, 2011 (Beijing time) were utilized to validate the simulation results.

2.2 Ensemble experiments of Noah-MP

The offline Noah-MP LSM v1.1 was assessed in this study. The default Noah-MP consists of 12 physical processes that are interpreted by multiple optional

parameterization schemes. These sub-processes include vegetation model (VEG), canopy stomatal resistance (CRS), soil moisture factor for stomatal resistance (BTR), runoff and groundwater (RUN), surface layer drag coefficient (SFC), super-cooled liquid water (FRZ), frozen soil permeability (INF), canopy gap for radiation transfer (RAD), snow surface albedo (ALB), precipitation partition (SNF), lower boundary of soil temperature (TBOT) and snow/soil temperature time scheme (STC) (Table 1). Details about the processes and optional parameterizations can be found in Yang et al. (2011a).

VEG(1) is adopted in the VEG process, in which the vegetation fraction is prescribed according to the NESDIS/NOAA 0.144 degree monthly 5-year climatology green vegetation fraction (https://www.emc.ncep.noaa.gov/mmb/gcip.html), and the monthly leaf area index (LAI) was derived from the Advanced Very High-Resolution Radiometer (AVHRR) (https://www.ncei.noaa.gov/data/, Claverie et al., 2016). Previous studies has confirmed that Noah-MP seriously overestimate the snow events and underestimate soil temperature and moisture on the QTP (Jiang et al., 2020; Li et al., 2020; Wang et al., 2020), which can be greatly resolved by considering the sublimation from wind (Gordon scheme) and a combination of roughness length for heat and under-canopy aerodynamic resistance (Y08-UCT) (Zeng et al., 2005; Yang et al., 2008; Li et al., 2020). For a more comprehensive assessment, we added two physical processes based on the default Noah-MP model, i.e. the snow sublimation from wind (SUB) and the combination scheme process (CMB) (Table 1). In the two processes, users can choose to turn on the Gordon and Y08-UCT scheme (described in the study of Li et al., 2020) or not. As a result, in total 55296 combinations are possible for the 13 processes and orthogonal experiments were carried out to evaluate their performance in soil hydrothermal dynamics and obtain the optimal combination.

The Noah-MP model was modified to consider the vertical heterogeneity in the soil profile by setting the corresponding soil parameters for each layer. The soil hydraulic parameters, including the porosity, saturated hydraulic conductivity, hydraulic potential, the Clapp-Hornberger parameter b, field capacity, wilt point, and

saturated soil water diffusivity, were determined using the pedotransfer functions proposed by Hillel (1980), Cosby et al. (1984), and Wetzel and Chang (1987) (Equations S1-S7), in which the sand and clay percentages were based on Hu et al., (2017) (Table S1). In addition, the simulation depth was extended to 8.0 m to cover the active layer thickness of the QTP. The soil column was discretized into 20 layers, whose depths follow the default scheme in CLM 5.0 (Table S1, Lawrence et al., 2018). Due to the inexact match between observed and simulated depths, the simulations at 4cm, 26cm, 80cm, 136cm, 208cm and 299cm were compared with the observations at 5cm, 25cm, 70cm, 140cm, 220cm and 300cm, respectively. A 30-year spin-up was conducted in every simulation to reach equilibrium soil states.

2.3 Methods for sensitivity analysis

The simulated snow cover events (SCEs) was quantitatively evaluated using the 187 188 overall accuracy index (OA) (Toure et al., 2016):

$$OA = \frac{a+d}{a+b+c+d}$$

where a is the positive hits, b represents the false alarm, c is the misses, and d represents the negtive hits. The value of OA range from 0 to 1. A higher OA signifies better performance. Ground albedo was used as an indicator for snow events due to a lack of snow depth observations. The days when the daily mean albedo is greater than the observed mean value of the warm and cold season (0.25 and 0.30, respectively) are identified as snow cover.

The root mean square error (RMSE) between the simulations and observations were adopted to evaluate the performance of Noah-MP in simulating soil hydrothermal dynamics.

To investigate the influence degrees of each physical process on SCEs, ST and SLW, we firstly calculated the mean OA (for SCE) and mean RMSE (for ST and SLW)

 (\bar{Y}_i^i) of the jth parameterization schemes (j = 1, 2, ...) in the ith process (i = 1, 2, ...). 201

Then, the maximum difference of \bar{Y}_i^i ($\Delta \overline{OA}$ or $\Delta \overline{RMSE}$) was defined to quantify the 202 sensitivity of the *i*th process (i = 1, 2, ...) (Li et al., 2015): 203

204
$$\Delta \overline{OA} \text{ or } \Delta \overline{RMSE} = \overline{Y}_{max}^i - \overline{Y}_{min}^i$$

where \overline{Y}_{max}^{i} and \overline{Y}_{min}^{i} are the largest and the smallest \overline{Y}_{j}^{i} in the *i*th process, respectively. For a given physical process, a high $\Delta \overline{OA}$ or $\Delta \overline{RMSE}$ signifies large difference between parameterizations, indicating high sensitiveness of the *i*th process for SCEs and ST/SLW simulation.

The sensitivities of physical processes were determined by quantifying the statistical distinction level of performance between parameterization schemes. The Independent-sample T-test (2-tailed) was adopted to identify whether the distinction level between two schemes is significant, and that between three or more schemes was tested using the Tukey's test. Tukey's test has been widely used for its simple computation and statistical features (Benjamini, 2010). The detailed descriptions about this method can be found in Zhang et al. (2016), Gan et al. (2019), and You et al. (2020). A process can be considered sensitive when the schemes show significant difference. Moreover, schemes with large mean OA and small mean RMSE were considered favorable for SCEs and ST/SLW simulation, respectively. We distinguished the differences of the parameterization schemes at 95% confidence level.

3 Results

3.1 General performance of the ensemble simulation

The performance of Noah-MP for snow simulation was firstly tested by conducting an ensemble of 55296 experiments. Due to a lack of snow depth measurements, ground albedo was used as an indicator for snow cover. Figure 2 shows the monthly variations of observed ground albedo and the simulations produced by the ensemble simulations. The ground albedo was extremely overestimated with large uncertainties when considering the snow options in Noah-MP, indicating the overestimation of snow depth and duration. Such overestimation continued till July.

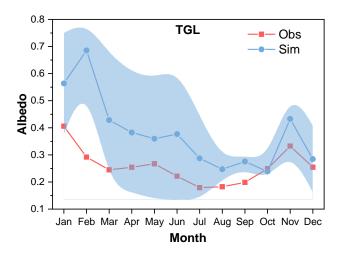

Figure 2. Monthly variations of ground albedo at TGL site for observation (Obs), and the ensemble simulation (Sim). The light blue shadow represents the standard deviation of the ensemble simulation.

Figure 3 illustrates the ensemble simulated and observed annual cycle of ST and SLW at TGL site. The ensemble experiments basically captured the seasonal variability of ST, whose magnitude decreased with soil depth. In addition, the simulated ST in the snow-affected season (October-July) showed relatively wide uncertainty ranges, particularly at the shallow layers. This indicates that the selected schemes perform much differently for snow simulation, resulting in large uncertainties of shallow STs. The simulated ST were generally smaller than the observations with relatively large gaps during the snow-affected season. It indicates that the Noah-MP model generally underestimates the ST, especially during the snow-affected months.

Since the observation equipment can only record the liquid water, soil liquid water (SLW) was evaluated against simulations from the ensemble experiments (Fig. 3). The Noah-MP model generally underestimated surface (5cm and 25cm) and deep (220cm and 300cm) SLW (Fig. 3g, 3h, 3k, 3l). However, Noah-MP tended to overestimate the SLW at the middle layers of 70cm and 140cm. Moreover, the simulated SLW exhibited relatively wide uncertainty ranges, particularly during the warm season (Fig. 3).

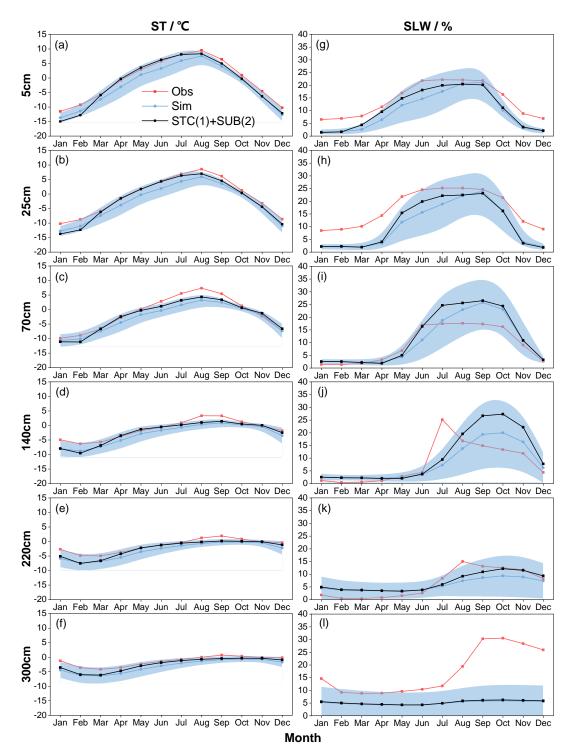

Figure 3. Monthly soil temperature (ST in °C) and soil liquid water (SLW in %) at (a, g) 5 cm, (b, h) 25 cm, (c, i) 70 cm, (d, j) 140 cm, (e, k) 220 cm, (f, l) 300 cm at TGL site. The light blue shadow represents the standard deviation of the ensemble simulation. The black line-symbol represents the ensemble mean of simulations with STC(1) and SUB(2).

3.2 Sensitivity of physical processes

3.2.1 Influence degrees of physical processes

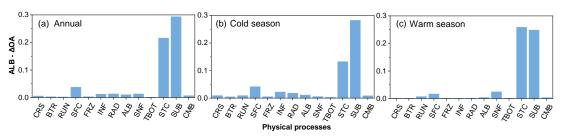

Figure 4. The maximum difference of the mean overall accuracy (OA) for albedo (ALB- ΔOA) in each physical process during the (a) annual, (b) cold season, and (c) warm season at TGL site.

Figure. 4 compares the influence scores of the 13 physical processes based on the maximum difference of the mean OA over 55296 experiments using the same scheme, for SCEs at TGL site. On the whole, the SUB and STC processes had the largest scores for the whole year as well as during both the warm and cold seasons, and the other processes showed a value less than 0.05 (Fig. 4a, 4b, 4c). Moreover, the SUB process had a consistent influence on SCEs while the influence of STC differed with season. In the cold season, the score of SUB process (0.28) was two times more than that of the STC process (Fig. 4b), indicating the relative importance of snow sublimation for SCEs simulation during the cold season. When it comes to the warm season, the influence score of SUB (0.25) did not change much, while that of STC increased to 0.26 and showed a similar influence on SCEs simulation with SUB.

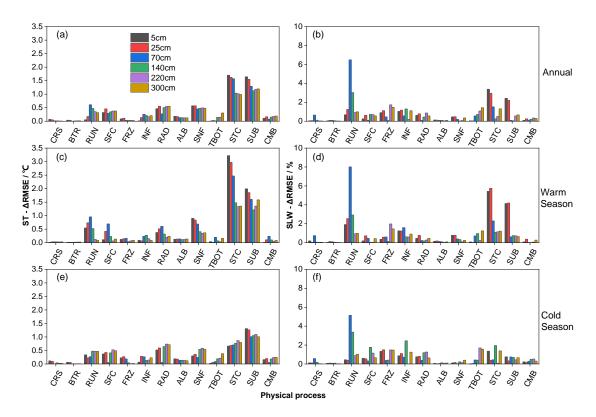

Figure 5. The maximum difference of the mean RMSE for (a, c and e) soil temperature (ST- $\Delta \overline{RMSE}$ in °C) and (b, d and f) soil liquid water (SLW- $\Delta \overline{RMSE}$ in %) in each physical process during the (a and b) annual, (c and d) warm, and (e and f) cold season at different soil depths at TGL site.

Figure. 5 compares the influence scores of the 13 physical processes at different soil depths, based on the maximum difference of the mean RMSE over 55296 experiments using the same scheme, for ST and SLW at TGL site. The snow-related processes, including the STC, SUB and SNF process showed the largest ST- $\Delta RMSE$ at all layers, followed by the RAD, SFC and RUN processes. While the ST- $\Delta RMSE$ of the other 7 physical processes were less than 0.5°C, among which the influence of CRS and BTR processes were negligible. What's more, the FRZ, INF, and TBOT processes had larger influence scores during the cold season than warm season, and the scores of TBOT were greater in deep soils than shallow soils. During the warm season, the physical processes generally showed more influence on shallow soil temperatures. When it comes to the cold season, the influence of the physical processes on deep layers obviously increased and comparable with that on shallow layers, implying the relatively higher uncertainties of Noah-MP during the cold season.

Most of the $\Delta \overline{RMSE}$ for SLW are less than 5%, indicating that all the physical processes have limited influence on the SLW, among which CRS, BTR, ALB, SNF, and CMB showed the smallest effects on SLW (Fig. 5b, 5d, 5f). During the warm season, the RUN process, together with the STC and SUB processes, dominated the performance of SLW simulation, especially at shallow layers (5cm, 25cm and 70cm, Fig. 5d). During the cold season, however, the RUN process dominated the SLW simulation with a great decline of dominance of STC and SUB processes.

3.2.2 Sensitivities of physical processes and general behaviors of

parameterizations

To further investigate the sensitivity of each process and the general performance of the parameterizations, the Independent-sample T-test (2-tailed) and Tukey's test were conducted to test whether the difference between parameterizations within a physical process is significant (Fig. 6 and 7). In a given sub-process, any two schemes labelled with different letters behave significantly different, and this sub-process therefore can be identified as sensitive. Otherwise, the sub-process is considered insensitive. For simplicity, schemes of insensitive sub-process are not labeled. Moreover, schemes with the letters late in the alphabet have smaller mean RMSEs and outperform the ones with the letters forward in the alphabet. Using the two schemes in CRS process (hereafter CRS(1) and CRS(2)) in Fig. 6 as an example. For the annual and warm season, CRS(1) and CRS(2) were labeled with "B" and "A", respectively. In the cold season, none of them were labeled with letters. As described above, the CRS process was sensitive for SCEs simulation during the annual and warm season, and CRS(1) outperformed CRS(2). However, it was not sensitive during the cold season.

Consistent with the influence degrees in Fig. 4, the performance difference between schemes of the STC and SUB for SCEs simulation were significantly greater

Consistent with the influence degrees in Fig. 4, the performance difference between schemes of the STC and SUB for SCEs simulation were significantly greater than other processes. Most other physical processes showed significant but limited difference. Schemes in BTR and TBOT processes, however, had no significant different performance. Specifically, the performance order followed STC(1) > STC(2), SUB(2) > SUB(1), SFC(2) > SFC(1), ALB(2) > ALB(1), CMB(2) > CMB(1) in both annual and

seasonal scales. RAD showed no obvious difference during the warm season, while RAD(3) outperformed RAD(1) and (2) during the cold season. For SNF, SNF(3) generally excel SNF(1) and SNF(2), especially during the warm season.

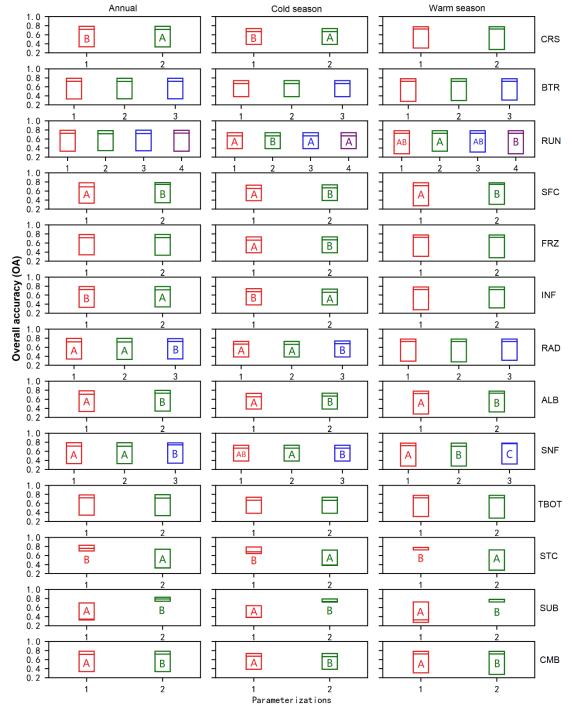

Figure 6. Distinction level for overall accuracy (OA) of snow cover events (SCEs) during the annual, warm, and cold seasons at TGL site. Limits of the boxes represent upper and lower quartiles, lines in the box indicate the median value.

All the physical processes showed sensitivities for ST and SLW simulation in

varying magnitudes except the BTR process and CRS process in most layers. For ST, 327 the performance difference between schemes of the STC, SUB and SNF were obviously 328 greater than other processes, indicating the importance of snow on ST, followed by the 329 RAD, SFC and RUN processes. The performance orders followed STC(1) > STC(2), 330 SUB(2) > SUB(1), SNF(3) > SNF(1) > SNF(2), RAD(3) > RAD(1) > RAD(2), and 331 SFC(2) > SFC(1). For SLW, the RUN, STC, and SUB processes showed significant and 332 higher sensitivities than other physical processes, especially during the warm season 333 334 and at the shallow layers (Fig. xx). Consistent with that of ST, the performance orders for SLW simulation were STC(1) > STC(2), and SUB(2) > SUB(1). For the RUN 335 process, the performance orders for both ST and SLW simulation generally followed 336 RUN(4) > RUN(1) > RUN(3) > RUN(2) as a whole, among which RUN(1) and RUN(4)337 presented similar performance during both warm and cold seasons. During both warm 338 and cold seasons, the performance orders for ST simulations were SFC(2) > SFC(1) for 339 SFC process, FRZ(2) > FRZ(1) for FRZ process, and RAD(3) > RAD(1) > RAD(2) for 340 RAD process (Fig. S2 and S3), which are particularly so for SLW simulations at shallow 341 342 and deep layers. For ST, both FRZ and INF showed higher sensitivities during the cold season, 343 especially at shallow soils for FRZ and deep soils for INF. FRZ(2)/INF(1) outperformed 344 FRZ(1)/INF(2) for the whole year for ST simulation. Specifically, FRZ(1)/INF(2) 345 performed better at the shallow soils during the warm season while did worse during 346 the cold season compared with FRZ(2)/INF(1). For SLW, FRZ(2)/INF(2) generally 347 preceded FRZ(1)/INF(1) at shallow and deep soils (5cm, 25cm, 220cm, and 300cm) 348 while did worse at middle soil layers (140cm and 220cm). 349 350 For ST simulation, the performance sequence in RAD and SNF was RAD(3) > RAD(1) > RAD(2) and SNF(3) > SNF(1) > SNF(2), respectively. For SLW simulation, 351 the sequence become complicated. However, RAD(3) and RAD (3) still outperformed 352 the other two schemes, respectively. ALB(2) was superior to ALB(1) for both ST and 353 SLW simulation. The influence of TBOT on soil hydrothermal arose at deep soils and 354 during cold season, and TBOT(1) excel TBOT (2). CMB(2) outperformed CMB(1) for 355

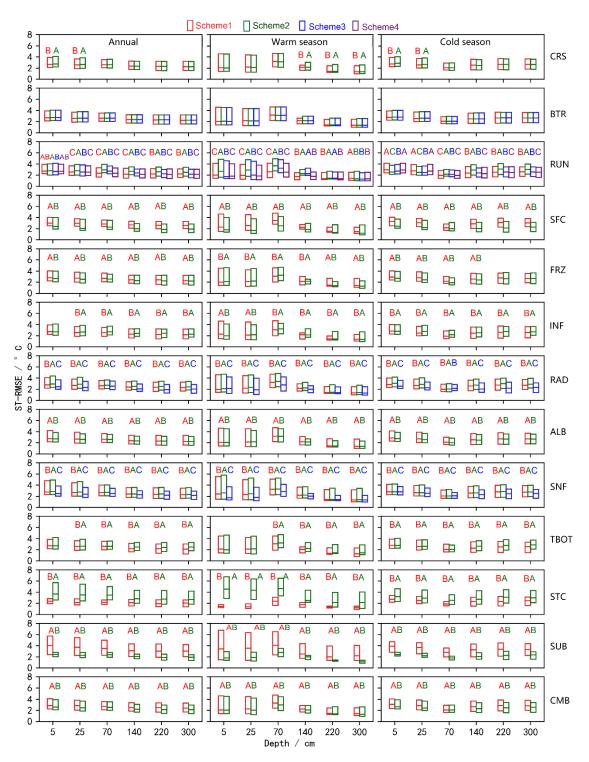

Figure 7. Distinction level for RMSE of ST at different layers during the annual, warm, and cold seasons in the ensemble simulations at TGL site. Limits of the boxes represent upper and lower quartiles, —lines in the box indicate the median value.

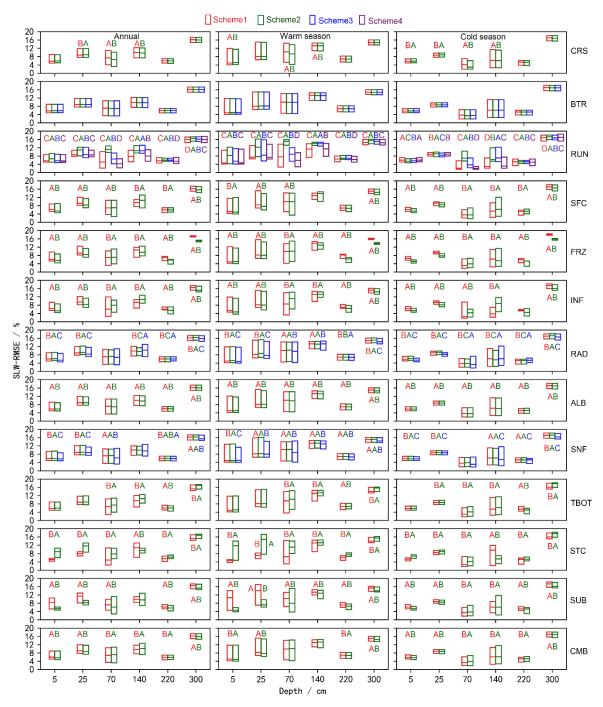

Figure 8. Same as in Figure 7 but for SLW.

3.3 Influence of snow cover and surface drag coefficient on soil hydrothermal dynamics

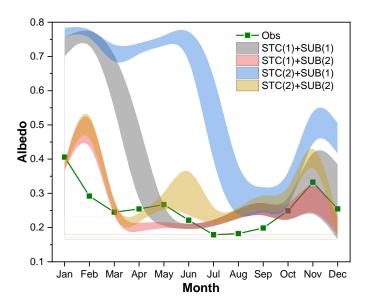

Figure 9. Uncertainty interval of ground albedo at TGL site in dominant physical processes (STC and SUB) for snow cover event simulation.

The influence of snow on soil temperature is firstly investigated. The dominant role of STC and SUB in the simulation of SCEs has been identified (Fig. 4 and 6). Interactions between the two physical processes are further analyzed here. Figure 9 compares the uncertainly intervals of the two physics. The duration of snow cover is the longest when STC(2)+SUB(1), followed when STC(2)+SUB(1). Simulations considering SUB(2) generally has a short snow duration. Among the four combinations, STC(1)+SUB(2) is in best agreement with the measurements.

Given the good performance of STC(1)+SUB(2) in simulating SCEs, the influence of snow on soil hydrothermal dynamics is investigated by comparing the total ensemble mean ST and SLW with those adopting STC(1)+SUB(2) (Fig. 3). It can be seen that the ensemble mean ST of simulations adopting STC(1) and SUB(2) are generally higher than the total ensemble means, especially during the spring and summer (Mar.-Aug.). In January and February at shallow layers (5cm, 25cm and 70cm), STC(1)+SUB(2) had a lower ST and showed an insulation effect on ST during the two months. As a whole, however, snow cover has a cooling effect on ST. In addition, along with the improved SCEs and elevated ST, STC(1)+SUB(2) induced moister soil with higher SLW (Fig. 3).

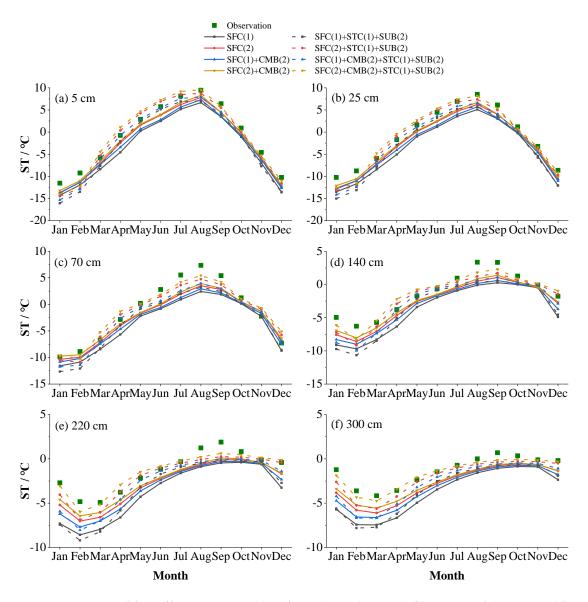

Figure 10. Monthly soil temperature (ST in °C) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the SFC process that consider the CMB(2) and STC(1)+SUB(2) processes or not.

SFC and CMB process using different ways to calculate the surface drag coefficient, which is of great influence for surface energy partitioning and thus ST and SLW. The influence of surface drag coefficient is assessed by comparing the soil temperature before and after considering the combined scheme (CMB(2)) and the effect of snow (STC(1)+SUB(2)) (Fig. 10). SFC(2) tended to produce higher ST than SFC(1), especially during the warming period (January-August). When adopting the combined scheme of Y08 and UCT (CMB(2)), the cold bias were significantly resolved. The performance order followed SFC(2)+CMB(2) > SFC(2) > SFC(1)+CMB(2) > SFC(1).

However, considerable underestimations of ST still exist at all layers due to the poor 401 representation of snow process. After eliminating the effects of snow (STC(1)+SUB(2), 402 dash lines in Fig. 10), the simulated ST accordingly increased except in January and 403 February. SFC(2) and SFC(2)+CMB(2) overestimated STs from March to July at 404 shallow layers (5cm and 25cm), resulting in good agreements of deep STs with 405 observations. In contrast, the simulated STs at shallow layers (5cm and 25cm) by SFC(1) 406 and SFC(1)+CMB(2) were basically consistent with observations from March to July. 407 408 While large cold bias remained at deep layers.

4 Discussion

409

410

4.1 Snow cover on the QTP and its influence on soil hydrothermal regime

Snow cover in the permafrost regions of the QTP is thin, patchy, and short-lived 411 (Che et al., 2019), whose influence on soil temperature and permafrost state is usually 412 considered weak (Jin et al., 2008; Zou et al., 2017; Wu et al., 2018; Zhang et al., 2018; 413 414 Yao et al., 2019). However, our ensemble simulations showed that the surface albedo 415 is extremely overestimated in both magnitude and duration (Fig. 2), implying an extreme overestimation of snow cover, which is consistent with the studies using Noah-416 MP model (Jiang et al., 2020; Li et al., 2020; Wang et al., 2020) and widely found in 417 other state-of-the-art LSMs (Wei and Dong, 2015) on the QTP. 418 Great efforts to resolve the overestimation of snow cover in LSMs include 419 considering the vegetation effect (Park et al., 2016), the snow cover fraction (Jiang et 420 al., 2020), the blowing snow (Xie et al., 2019), and the fresh snow albedo (Wang et al. 421 422 2020). Our results illustrated the superiority of considering the snow sublimation from wind (SUB(2)) and using semi-implicit snow/soil temperature time scheme (STC(1)) 423 (Fig. 4, 6 and 9) when simulating snow cover on the QTP. It is consistent with previous 424 conclusions that accounting for the loss resulting from wind contributes to improve 425 snow cover days and depth (Yuan et al., 2016), and that STC(1) has a rapid snow 426 ablation than STC(2) (You et al., 2020). 427

The impacts of snow cover on soil temperature in magnitude and vector (cooling or warming) depend on its timing, duration, and depth (Zhang et al., 2005). In January and February, the ground heat flux mainly goes upward, the warming effect of simulated snow can be related to the overestimated snow depth that prevent heat loss from the ground. During the spring and summer when snow melts, the cooling effects occurs, mainly because considerable energy that used to heat the ground is reflected due to the high albedo of snow. With the improvement of snow (STC(1)+SUB(2)), the originally overestimated snow melts and infiltrated into the soil, resulting in improved SLWs (Fig. 3). And higher soil temperature also contributed to the SLWs according to the freezing-point depression equation, in which SLW exponentially increase with soil temperature for a given site (Niu and Yang, 2006).

4.2 Discussions on the sensitivity of physical processes on soil hydrothermal

simulation

4.2.1 Canopy stomatal resistance (CRS) and soil moisture factor for stomatal

resistance (BTR)

The biophysical process BTR and CRS directly affect the canopy stomatal resistance and thus the plant transpiration (Niu et al., 2011). The transpiration of plants could impact the ST/SLW through its cooling effect (Shen et al., 2015) and the water balance of root zone (Chang et al., 2020). However, the annual transpiration of alpine steppe is weak due to the shallow effective root zone and lower stomatal control in this dry environment (Ma et al., 2015), which may explain the indistinctive or very small difference among the schemes of the BTR and CRS processes for SCEs (Fig. 8), ST (Fig. 7) and SLW (Fig. 8).

4.2.2 Runoff and groundwater (RUN)

In the warm season, different SLWs would result in the difference of the surface energy partitioning and thus different soil temperatures. RUN(2) had the worst performance for simulating ST and SLW (Fig. 7 and 8) among the four schemes, likely

due to its higher estimation of soil moisture (Fig. S1) and thus greater sensible heat and smaller ST (Gao et al., 2015). Likewise, RUN(4) was on a par with RUN(1) in the simulation of ST at most layers due to the very small difference in SLW of two schemes (Fig. 8 and S1). For the whole soil column, RUN(4) surpassed RUN(1) and RUN(2) for SLW simulation, both of which define surface/subsurface runoff as functions of groundwater table depth (Niu et al., 2005; Niu et al., 2007). This is in keeping with the study of Zheng et al. (2017) that soil water storage-based parameterizations outperform the groundwater table-based parameterizations in simulating the total runoff in a seasonally frozen and high-altitude Tibetan river. Besides, RUN(4) is designed based on the infiltration-excess runoff (Yang and Dickinson, 1996) in spite of the saturationexcess runoff in RUN(1) and RUN(2) (Gan et al., 2019), which is more common in arid and semiarid areas like the permafrost regions of QTP (Pilgrim et al., 1988). In the cold season, much of the liquid water freezes into ice, which would greatly influence the thermal conductivity of frozen soil considering thermal conductivity of ice is nearly four times that of the equivalent liquid water. Therefore, the impact of RUN is important for the soil temperature simulations at both warm and cold seasons (Fig. 5 and 7).

4.2.3 Surface layer drag coefficient (SFC and CMB)

SFC defines the calculations of the surface exchange coefficient for heat and water vapor (CH), which greatly impact the energy and water balance and thus the temperature and moisture of soil (Zeng et al., 2012; Zheng et al., 2012). SFC(1) adopts the Monin-Obukhov similarity theory (MOST) with a general form, while the SFC(2) uses the improved MOST modified by Chen et al. (1997). In SFC(1), the roughness length for heat (Z_{0h}) is taken as the same with the roughness length for momentum (Z_{0m} , Niu et al., 2011). SFC(2) adopts the Zilitinkevitch approach for $Z_{0,h}$ calculation (Zilitinkevich, 1995). The difference between SFC(1) and SFC(2) has a great impact on the CH value. Several studies have reported that SFC(2) has a better performance for the simulation of sensible and latent heat on the QTP (Zhang et al., 2016; Gan et al., 2019). The results of T-test in this study showed remarkable distinctions between the two schemes, where SFC(2) was dramatically superior to SFC(1) (Fig. 7, and 8). SFC(2)

produces lower CH than SFC(1) (Zhang et al., 2014), resulting in less efficient ventilation and greater heating of the land surface (Yang et al., 2011b), and substantial improvement of the cold bias of Noah-MP in this study (Fig. 7 and 10).

Both SFC(1) and SFC(2) couldn't produce the diurnal variation of $Z_{0,h}$ (Chen et al., 2010). CMB offers a scheme that considered the diurnal variation of $Z_{0,h}$ in bare ground and under-canopy turbulent exchange in sparse vegetated surfaces (Li et al., 2020). Consistent with previous studies in the QTP (Chen et al., 2010; Guo et al., 2011; Zheng et al., 2015; Li et al., 2020), the simulated ST generally followed SFC(2)+CMB(2) > SFC(2) > SFC(1)+CMB(2) > SFC(1) with/without removing the overestimation of snow (Fig. 10), indicating that CMB(2) contributes to resolve the cold bias of LSMs. However, none of the four combinations could well reproduce the shallow and deep STs simultaneously. When the snow is well-simulated, SFC(2)+CMB(2) performed the best at deep layers at the cost of overestimating shallow STs. Meanwhile, SFC(1)+CMB(1) showed the best agreements at shallow layers with considerable cold bias at deep layers, which can be related to the overestimated frozen soil thermal conductivity (Luo et al., 2009; Chen et al., 2012; Li et al., 2019).

4.2.4 Super-cooled liquid water (FRZ) and frozen soil permeability (INF)

FRZ and INF describe the unfrozen water and permeability of frozen soil, and had a larger influence on ST/SLW during the cold season than warm season as expected (Fig. 5). Specifically, FRZ treats liquid water in frozen soil (super-cooled liquid water) using two forms of freezing-point depression equation. FRZ(1) takes a general form (Niu and Yang, 2006), while FRZ(2) exhibits a variant form that considers the increased surface area of icy soil particles (Koren et al., 1999). FRZ(2) generally yields more liquid water in comparison of FRZ(1) (Fig. S2). INF(1) uses soil moisture (Niu and Yang, 2006) while INF(2) employs only the liquid water (Koren et al., 1999) to parameterize soil hydraulic properties. INF(2) generally produces more impermeable frozen soil than INF(1), which is also found in this study (Fig. S3). For the whole year, INF(1) surpassed INF(2) in simulating STs, which may be related to the more realistic SLWs produced by INF(1) for the whole soil column (Fig. S3).

4.2.5 Canopy gap for radiation transfer (RAD)

RAD treats the radiation transfer process within the vegetation, and adopts three methods to calculate the canopy gap. RAD(1) defines canopy gap as a function of the 3D vegetation structure and the solar zenith angle, RAD(2) employs no gap within canopy, and RAD(3) treat the canopy gap from unity minus the FVEG (Niu and Yang, 2004). The RAD(3) scheme penetrates the most solar radiation to the ground, followed by the RAD(1) and RAD(2) schemes. As an alpine grassland, there is a relative low LAI at TGL site, and thus a quite high canopy gap. So, schemes with a larger canopy gap could realistically reflect the environment. Consequently, the performance decreased in the order of RAD(3) > RAD(1) > RAD(2) for ST/SLW simulation.

4.2.6 Snow surface albedo (ALB) and precipitation partition (SNF)

The ALB describe two ways for calculating snow surface albedo, in which the ALB(1) and ALB(2) adopt the scheme from BATS and CLASS LSM, respectively. ALB(2) generally produce lower albedo than ALB(1), especially when the ground covered by snow (Fig. S4). As a result, higher net radiation absorbed by the land surface and more heat is available for heating the soil in ALB(2), which is beneficial for counteracting the cooling effect of overestimated snow on ST (Fig. S5). Along with the higher ST, ALB(2) outperformed ALB(1) for SLW simulation, likely due to more snow melt water offset the dry bias in Noah-MP (Fig. S5).

The SNF defines the snowfall fraction of precipitation as a function of surface air temperature. SNF(1) is the most complicated of the three schemes, in which the precipitation is considered rain/snow when the surface air temperature is greater/less than or equal to 2.5/0.5 °C, otherwise, it is recognized as sleet. While SNF(2) and SNF(3) simply distinguish rain or snow by judging whether the air temperature is above 2.2 °C and 0 °C or not. The significant difference between three schemes for SCEs simulation during the warm season is consistent with the large difference of snowfall fraction in this period (Fig. 6 and S6). SNF(3) is the most rigorous scheme and produce the minimum amount of snow, followed by SNF(1) and SNF(2) with limited difference (Fig. S6). This exactly explains superiority of SNF(3) for ST and SLW simulation (Fig.

7 and 8).

4.2.7 Lower boundary of soil temperature (TBOT) and snow/soil temperature time

scheme (STC)

TBOT process adopts two schemes to describe the soil temperature boundary conditions. TBOT (1) assumes zero heat flux at the bottom of the model, while TBOT(2) adopts the soil temperature at the 8 m depth (Yang et al., 2011a). In general, TBOT(1) is expected to accumulate heat in the deep soil and produce higher ST than TBOT(2). In this study, the two assumptions performed significantly different, especially at the deep soils and during the cold season. Although TBOT(2) is more representative of the realistic condition, TBOT(1) surpassed TBOT(2) in this study. It can be related to the overall underestimation of the model, which can be alleviated by TBOT(1) because of heat accumulation (Fig. S7). Two time discretization strategies are implemented in the STC process, where STC(1) adopts the semi-implicit scheme while STC(2) uses the full implicit scheme, to solve the thermal diffusion equation in first soil or snow layers (Yang et al., 2011a). STC(1) and STC(2) are not strictly a physical processes but different upper boundary conditions of soil column (You et al., 2019). The differences between STC(1) and STC(2) were significant (Fig. 7). The impacts of the two options on ST is remarkable (Fig. 6), particularly in the shallow layers and during the warm season (Fig. 5). In addition, STC(1) outperformed STC(2) in the ensemble simulated ST(Fig. 7), because STC(1) greatly alleviated the cold bias in Noah-MP (Fig. S8) by producing the higher

4.3 Perspectives

OA of SCEs (Fig. 6)

This study analyzed the characteristics and general behaviors of each parameterization scheme of Noah-MP at a typical permafrost site on the QTP, hoping to provide a reference for simulating permafrost state on the QTP. We identified the systematic overestimation of snow cover, cold bias and dry bias in Noah-MP, and

discussed the role of snow and surface drag coefficient on soil hydrothermal dynamics. Further tests at another permafrost site (BLH site, 34.82°N, 92.92°E, Alt.: 4,659 m a.s.l) basically showed consistent conclusions with that at TGL site (see Supplementary files for details), indicating that Rrelevant results and methodologies can be practical guidelines for improving the parameterizations of physical processes and testing their uncertainties towards near surface permafrostsoil hydrothermal modeling on in the permafrost regions of the plateau. Although the site we selected may be representative for the typical environment on the plateau, continued investigation with a broad spectrum of climate and environmental conditions is required to make a general conclusion at regional scale.

5 Conclusions

An ensemble simulation using multi-parameterizations was conducted using the Noah-MP model at the TGL site, aiming to present a reference for simulating soil hydrothermal dynamics in the permafrost regions of QTP using LSMs. The model was modified to consider the vertical heterogeneity in the soil and the simulation depth was extended to cover the whole active layer. The ensemble simulation consists of 55296 experiments, combining thirteen physical processes (CRS, BTR, RUN, SFC, FRZ, INF, RAD, ALB, SNF, TBOT, STC, SUB, and CMB) each with multiple optional schemes. On this basis, the general performance of Noah-MP was assessed by comparing simulation results with in situ observations, and the sensitivity of snow cover event, soil temperature and moisture at different depths of active layer to parameterization schemes was explored. The main conclusions are as follows:

- (1) Noah-MP model tends to overestimate snow cover, which is most influenced by the STC and SUB processes. Such overestimation can be greatly resolved by considering the snow sublimation from wind (SUB(2)) and semi-implicit snow/soil temperature time scheme (STC(1)).
- (2) Soil temperature is largely underestimated by the overestimated snow cover and thus dominated by the STC and SUB processes. Systematic cold bias and large

uncertainties of soil temperature still exist after eliminating the effects of snow, 597 particularly at the deep layers and during the cold season. The combination of Y08 598 and UCT contributes to resolve the cold bias of soil temperature. 599 (3) Noah-MP tend to underestimate soil liquid water content. Most physical processes 600 have limited influence on soil liquid water content, among which the RUN process 601 plays a dominant role during the whole year. The STC and SUB process have a 602 considerable influence on topsoil liquid water during the warm season. 603 604 Code availability. The source code of offline 1D Noah-MP LSM v1.1 is available at 605 https://ral.ucar.edu/solutions/products/noah-multiparameterization-land-surface-606 model-noah-mp-lsm (last access: 15 May 2020). The modified Noah-MP with the 607 consideration of vertical heterogeneity, extended soil depth, and pedotransfer functions 608 is available upon request to the corresponding author. The data processing code are 609 available at http://dx.doi.org/10.17632/gc7vfgkyng.1. 610 611 612 Data availability. The 1-hourly forcing data and daily soil temperature data at the TGL site are available at http://dx.doi.org/10.17632/gc7vfgkyng.1. Soil texture data can be 613 obtained at https://doi.org/10.1016/j.catena.2017.04.011 (Hu et al., 2017). The AVHRR 614 LAI data can be downloaded from https://www.ncei.noaa.gov/data/ (Claverie et al., 615 2016). 616 617 Author contributions. TW and XL conceived the idea and designed the model 618 619 experiments. XL performed the simulations, analyzed the output, and wrote the paper. 620 JC and GZ helped to compile the model in a Linux environment. XW, SY, XZ, GH, RL contributed to the conduction of the simulation and interpretation of the results. YQ 621 provided the observations of atmospheric forcing and soil temperature. CY and JH 622 helped in downloading and processing the AVHRR LAI data. JN and WM provide 623 624 guidelines for the visualization. Everyone revised and polished the paper.

Supplement of

Assessing the simulated soil hydrothermal regime of active layer

from Noah-MP LSM v1.1 in the permafrost regions of the

Qinghai-Tibet Plateau

Xiangfei Li et al.

Correspondence to: Tonghua Wu (thuawu@lzb.ac.cn)

Content: Equations S1-S7; Table S1; Figures S1-S<u>817</u>

The soil hydraulic parameters of each layer, including the porosity (θ_s) , saturated hydraulic conductivity (K_s) , hydraulic potential (ψ_s) , the Clapp-Hornberger parameter (b), field capacity (θ_{ref}) , wilt point (θ_w) , and saturated soil water diffusivity (D_s) , were determined using the pedotransfer functions proposed by Hillel (1980), Cosby et al. (1984), and Wetzel and Chang (1987):

$$\theta_s = 0.489 - 0.00126(\%sand)$$
 (S1)

$$K_s = 7.0556 \times 10^{-6.884 + 0.0153(\%sand)}$$
 (S2)

$$\psi_s = -0.01 \times 10^{1.88 - 0.0131(\% sand)}$$
 (S3)

$$b = 2.91 + 0.159(\%clay) \tag{S4}$$

$$\theta_{ref} = \theta_s \left[\frac{1}{3} + \frac{2}{3} \left(\frac{5.79 \times 10^{-9}}{K_s} \right)^{1/(2b+3)} \right]$$
 (S5)

$$\theta_w = 0.5\theta_s \left(\frac{-200}{\psi_s}\right)^{-1/b} \tag{S6}$$

$$D_s = b \cdot K_s \cdot \left(\frac{\psi_s}{\theta_s}\right) \tag{S7}$$

where *%sand* and *%clay* represent the percentage (%) of sand and clay content in soil, respectively.

Table S1 Soil discretization scheme and soil particle fraction in this study.

Layer	Zi	ΔZ_i	$\mathbf{Z}_{\mathrm{h,i}}$	Sand (%)	Silt (%)	Clay (%)
1	0.010	0.020	0.020	85.48	12.59	1.93

Layer node depth (Z_i) , thickness (ΔZ_i) , and depth at layer interface $(Z_{h,i})$ for default soil column. All in meters.

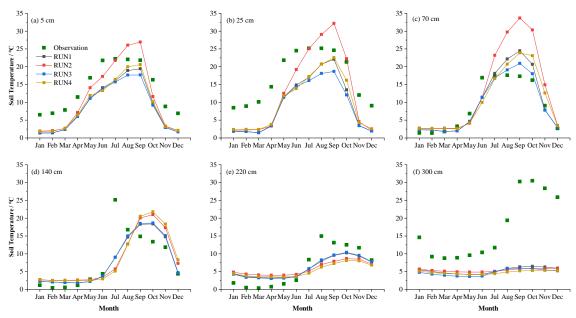

Figure. S1 Monthly soil liquid water (SLW in %) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the RUN process.

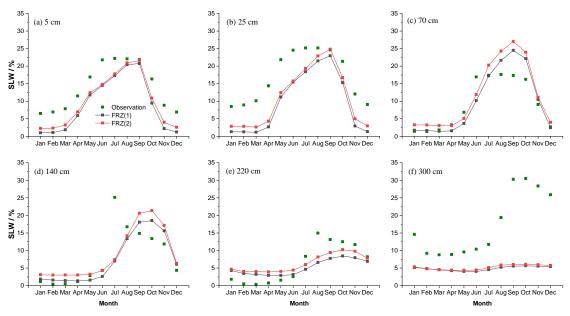

Figure. S2 Monthly soil liquid water (SLW in %) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the FRZ process.

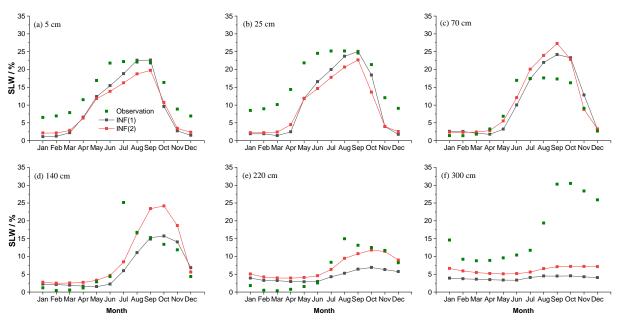

Figure. S3 Monthly soil liquid water (SLW in %) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the INF process.

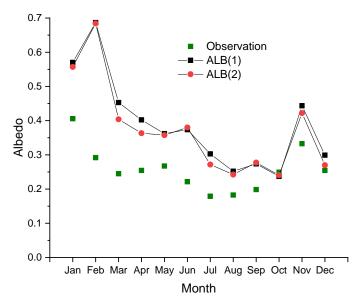

Figure. S4 Monthly ground albedo for the ALB process.

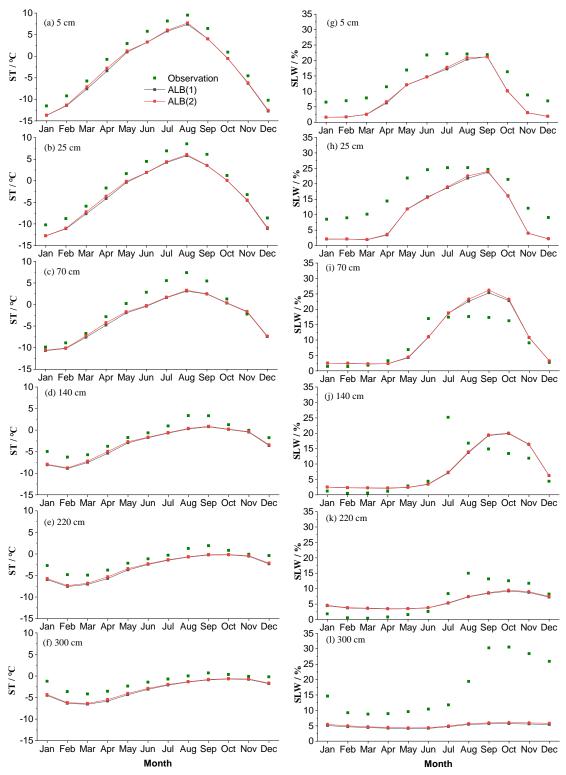

Figure. S5 Monthly soil temperature (ST in °C) and liquid water (SLW in %) at (a, g) 5 cm, (b, h) 25 cm, (c, i) 70 cm, (d, j) 140 cm, (e, k) 220 cm, (f, l) 300 cm for the ALB process.

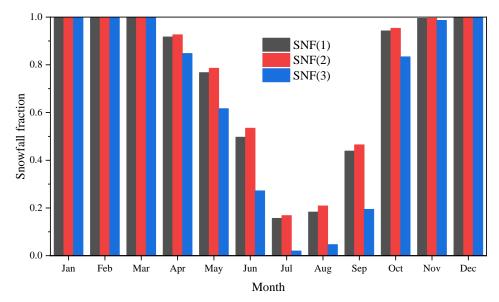

Figure. S6 Monthly snowfall fraction for the SNF process.

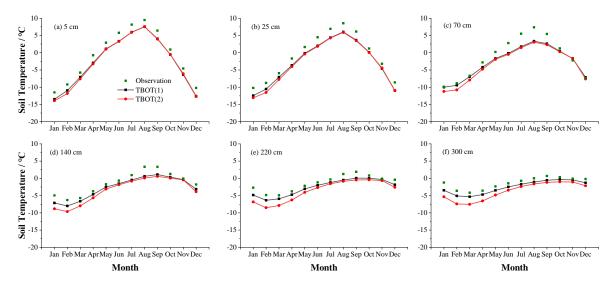

Figure. S7 Monthly soil temperature at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the TBOT process.

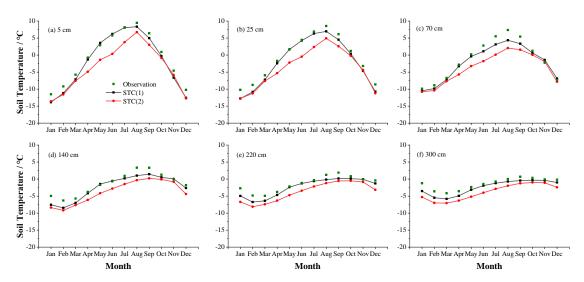

Figure. S8 Monthly soil temperature at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the STC process.

Main findings at BLH site:

- (1) Noah-MP tend to overestimate snow cover events at BLH site with large uncertainties during the cold months (Nov.-Mar). Moreover, snow cover events are mostly influenced by the STC and SUB process (Figure S11), and the combination of STC(1) and SUB(2) tend to produce better results (Figure 8). The small influence of physical processes during the warm season (Figure S11c) is because there are limited snow events, and its inability of reproducing snow cover in May (Figure S9).
- (2) Noah-MP generally underestimate STs with relatively large gaps during the snow-affected months (Nov.-Mar.), and the simulated ST in the snow-affected months (Nov.-Mar.) showed relatively wide uncertainty ranges (Figure S10). STs is mostly influenced by the snow processes, i.e. the STC and SUB process (Figure S12), especially during the cold season. In the warm season, the SFC and RUN process dominate the simulation of STs (Figure S12c). The combination of roughness length for heat and under-canopy aerodynamic resistance contributes to elevated soil temperature (Figure S17).
- (3) Noah-MP totally underestimate SLW at BLH site (Figure S10). The RUN process dominates the SLW at most layers simulation with limit impacts (Figure S12).

• General performance of the ensemble simulation

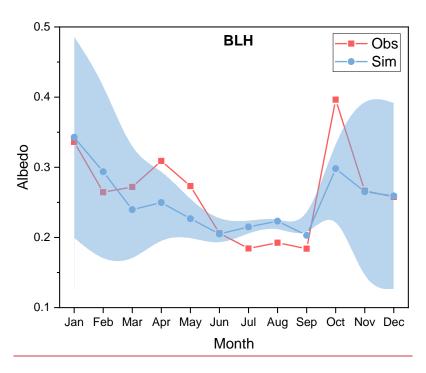

Figure S9. Monthly variations of ground albedo at BLH site for observation (Obs), and the ensemble simulation (Sim). The light blue shadow represents the standard deviation of the ensemble simulation.

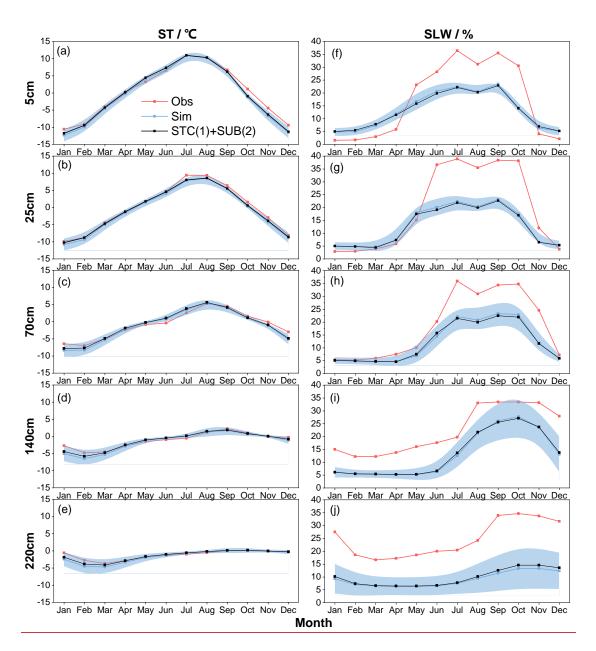

Figure S10. Monthly soil temperature (ST in °C) and soil liquid water (SLW in %) at (a, g) 5 cm, (b, h) 25 cm, (c, i) 70 cm, (d, j) 140 cm, (e, k) 220 cm, (f, l) 300 cm at BLH site. The light blue shadow represents the standard deviation of the ensemble simulation. The black line-symbol represents the ensemble mean of simulations with STC(1) and SUB(2).

Influence degrees of physical processes

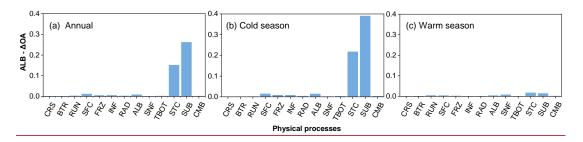

Figure S11. The maximum difference of the mean overall accuracy (OA) for albedo (ALB- ΔOA) in each physical process during the (a) annual, (b) cold season, and (c) warm season at BLH site.

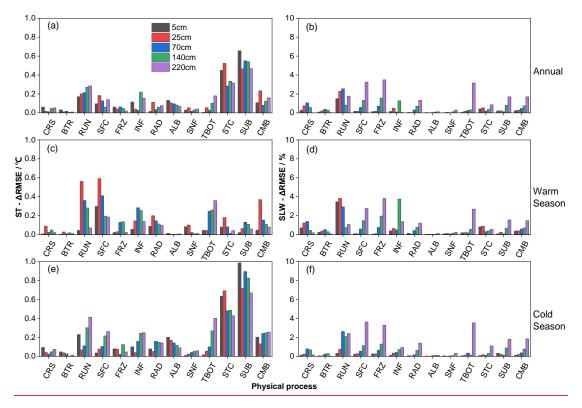

Figure S12. The maximum difference of the mean RMSE for (a, c and e) soil temperature (ST- $\Delta \overline{RMSE}$ in °C) and (b, d and f) soil liquid water (SLW- $\Delta \overline{RMSE}$ in %) in each physical process during the (a and b) annual, (c and d) warm, and (e and f) cold season at different soil depths at BLH site.

• Sensitivities of physical processes and general behaviors of parameterizations

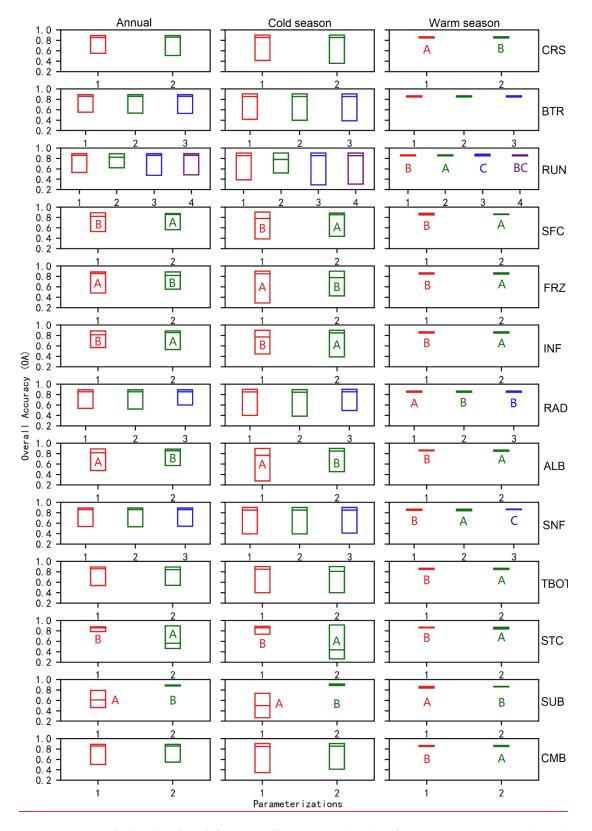

Figure S13. Distinction level for overall accuracy (OA) of snow cover events (SCEs) during the annual, warm, and cold seasons in the ensemble simulations at BLH site.

Limits of the boxes represent upper and lower quartiles, lines in the box indicate the median value.

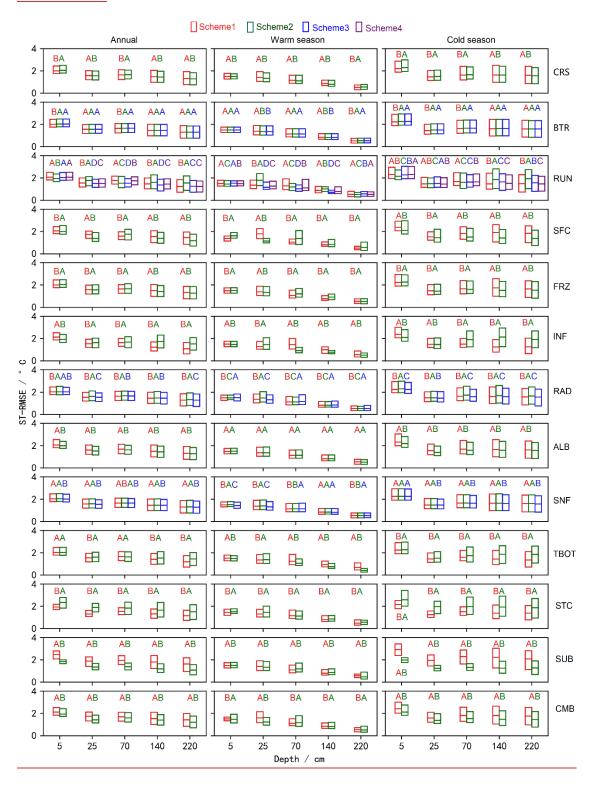

Figure S14. Distinction level for RMSE of ST at different layers during the annual, warm, and cold seasons in the ensemble simulations at BLH site. Limits of the boxes represent upper and lower quartiles, lines in the box indicate the median value.

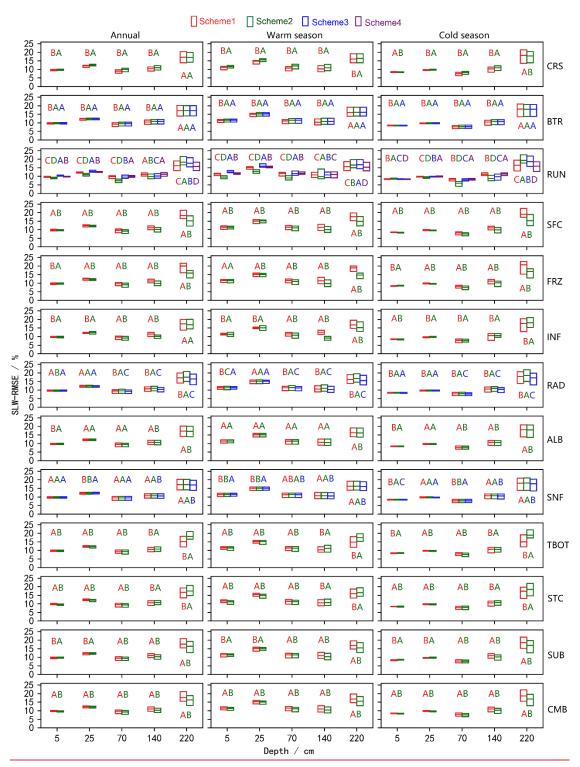

Figure S15. Distinction level for RMSE of SH2O at different layers during the annual, warm, and cold seasons in the ensemble simulations at BLH site. Limits of the boxes represent upper and lower quartiles, lines in the box indicate the median value.

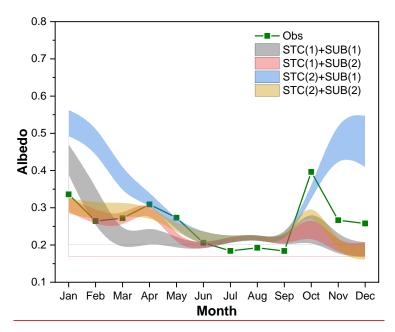

Figure S16. Uncertainty interval of ground albedo at BLH site in dominant physical processes (STC and SUB) for snow cover event simulation.

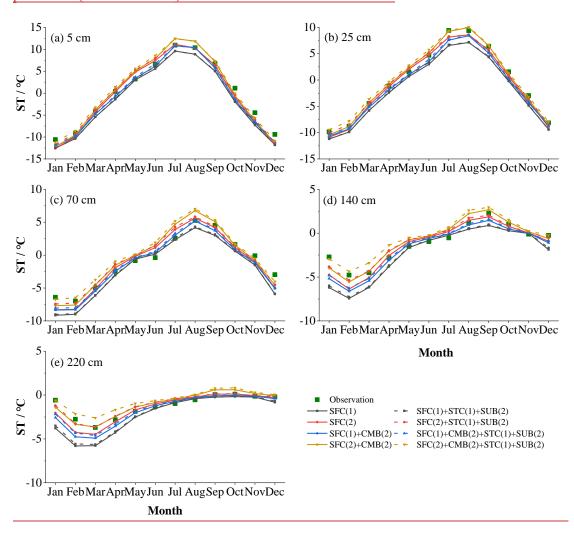

Figure S17. Monthly soil temperature (ST in °C) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d)

140 cm, (e) 220 cm, (f) 300 cm for the SFC process that consider the CMB(2) and STC(1)+SUB(2) processes or not.
