18 **Abstract.** Extensive and rigorous model inter-comparison is of great importance before
19 application due to the uncertainties in current land surface models (LSMs). Without
20 considering the uncertainties of forcing data and model parameters, this study designed
21 an ensemble of 55296 experiments to evaluate the Noah land surface model with multi-
22 parameterization (Noah-MP) for snow cover events (SCEs), soil temperature (ST) and
23 soil liquid water (SLW) simulation, and investigated the sensitivity of parameterization
24 schemes at a typical permafrost site on the Qinghai-Tibet Plateau. The results showed
25 that Noah-MP systematically overestimates snow cover, which could be greatly
26 resolved when adopting the sublimation from wind and semi-implicit snow/soil
27 temperature time scheme. As a result of the overestimated snow, Noah-MP generally
28 underestimates ST and ST is mostly influenced by the snow process. Systematic cold
29 bias and large uncertainties of soil temperature remains after eliminating the effects of
30 snow, particularly at the deep layers and during the cold season. The combination of
31 roughness length for heat and under-canopy aerodynamic resistance contributes to
32 resolve the cold bias of soil temperature. In addition, Noah-MP generally
33 underestimates top SLW. The RUN process dominates the SLW simulation in
34 comparison of the very limited impacts of all other physical processes. The analysis of
35 the model structural uncertainties and characteristics of each scheme would be
36 constructive to a better understanding of the land surface processes in the permafrost
37 regions of the QTP and further model improvements towards soil hydrothermal regime
38 modeling using the LSMs.

39

40 1 Introduction

41 The Qinghai-Tibet Plateau (QTP) is underlain by the world's largest high-altitude
42 permafrost covering a contemporary area of 1.06×10^6 km² (Zou et al., 2017). Under
43 the background of climate warming and intensifying human activities, soil
44 hydrothermal dynamics in the permafrost regions on the QTP has been widely suffering
45 from soil warming (Wang et al., 2021), soil wetting (Zhao et al., 2019), and changes in
46 soil freeze-thaw cycle (Luo et al., 2020). Such changes ~~has~~have not only induced the
47 reduction of permafrost extent, disappearing of permafrost patches and thickening of
48 active layer (Chen et al., 2020), but also resulted in alterations in hydrological cycles
49 (Zhao et al., 2019; Woo, 2012), changes of ecosystem (Fountain et al., 2012; Yi et al.,
50 2011) and damages to infrastructures (Hjort et al., 2018). Therefore, it is very important
51 to monitor and simulate the soil hydrothermal regime to adapt to the changes taking
52 place.

53 A number of monitoring sites have been established in the permafrost regions of
54 the QTP (Cao et al., 2019). However, it is inadequate to construct the soil hydrothermal
55 state by considering the spatial variability of the ground thermal regime and an uneven
56 distribution of these observations. In contrast, numerical models are competent
57 alternatives. In recent years, land surface models (LSMs), which describe the exchanges
58 of heat, water, and momentum between the land and atmosphere (Maheu et al., 2018),
59 have received significant improvements in the representation of permafrost and frozen
60 ground processes (Koven et al., 2013; Nicolsky et al., 2007; Melton et al., 2019). LSMs
61 are capable of simulating the transient change of subsurface hydrothermal processes
62 (e.g. soil temperature and moisture) with soil heat conduction (-diffusion) and water
63 movement equations (Daniel et al., 2008). Moreover, they could be integrated with the
64 numerical weather prediction system like WRF (Weather Research and Forecasting),
65 making them as effective tools for comprehensive interactions between climate and
66 permafrost (Nicolsky et al., 2007).

67 Some LSMs have been evaluated and applied in the permafrost regions of the QTP.
68 Guo and Wang (2013) investigated near-surface permafrost and seasonally frozen

69 ground states as well as their changes using the Community Land Model, version 4
70 (CLM4). Hu et al. (2015) applied the coupled heat and mass transfer model to identify
71 the hydrothermal characteristics of the permafrost active layer in the Qinghai-Tibet
72 Plateau. Using an augmented Noah LSM, Wu et al. (2018) modeled the extent of
73 permafrost, active layer thickness, mean annual ground temperature, depth of zero
74 annual amplitude and ground ice content on the QTP in 2010s. Despite those
75 achievements based on different models, LSMs are in many aspects insufficient in
76 permafrost regions. For one thing, large uncertainties still exist in the state-of-the-art
77 LSMs when simulating the soil hydrothermal regime on the QTP (Chen et al., 2019).
78 For instance, 19 LSMs in CMIP5 overestimate snow depth over the QTP (Wei and Dong,
79 2015), which could result in the variations of the soil hydrothermal regime in the aspects
80 of magnitude and vector (cooling or warming) (Zhang, 2005). Moreover, most of the
81 existing LSMs are not originally developed for permafrost regions. Many of their soil
82 processes are designed for shallow soil layers (Westermann et al., 2016), but permafrost
83 would occur in the deep soil. And the soil column is often considered homogeneous,
84 which cannot represent the stratified soil common on the QTP (Yang et al., 2005). Given
85 the numerous LSMs and possible deficiencies, it is necessary to assess the
86 parameterization schemes for permafrost modeling on the QTP, which is helpful to
87 identify the influential sub-processes, enhance our understanding of model behavior,
88 and guide the improvement of model physics (Zhang et al., 2016).

89 Noah land surface model with multi-parameterization (Noah-MP) provides a
90 unified framework in which a given physical process can be interpreted using multiple
91 optional parameterization schemes (Niu et al., 2011). Due to the simplicity in selecting
92 alternative schemes within one modeling framework, it has been attracting increasing
93 attention in inter-comparison work among multiple parameterizations at point and
94 watershed scales (Hong et al., 2014; Zheng et al., 2017; Gan et al., 2019; Zheng et al.,
95 2019; Chang et al., 2020; You et al., 2020^a). For example, Gan et al. (2019) carried out
96 an ensemble of 288 simulations from multi-parameterization schemes of six physical
97 processes, assessed the uncertainties of parameterizations in Noah-MP, and further

98 revealed the best-performing schemes for latent heat, sensible heat and terrestrial water
99 storage simulation over ten watersheds in China. You et al. (2020b) assessed the
100 performance of Noah-MP in simulating snow process at eight sites over distinct snow
101 climates and identified the shared and specific sensitive parameterizations at all sites,
102 finding that sensitive parameterizations contribute most of the uncertainties in the
103 multi-parameterization ensemble simulations. Nevertheless, there is little research on
104 the inter-comparison of soil hydrothermal processes in the permafrost regions. In this
105 study, an ensemble experiment of totally 55296 scheme combinations was conducted
106 at a typical permafrost monitoring site on the QTP. The simulated snow cover events
107 (SCEs), soil temperature (ST) and soil liquid water (SLW) of Noah-MP model was
108 assessed and the sensitivities of parameterization schemes at different depths were
109 further investigated. This study could be expected to present a reference for soil
110 hydrothermal simulation in the permafrost regions on the QTP.

111 This article is structured as follows: Section 2 introduces the study site,
112 atmospheric forcing data, design of ensemble simulation experiments, and sensitivity
113 analysis methods. Section 3 describes the ensemble simulation results of SCEs, ST and
114 SLW, explores the sensitivity and interactions of parameterization schemes. Section 4
115 discusses the schemes in each physical process. Section 5 concludes the main findings.

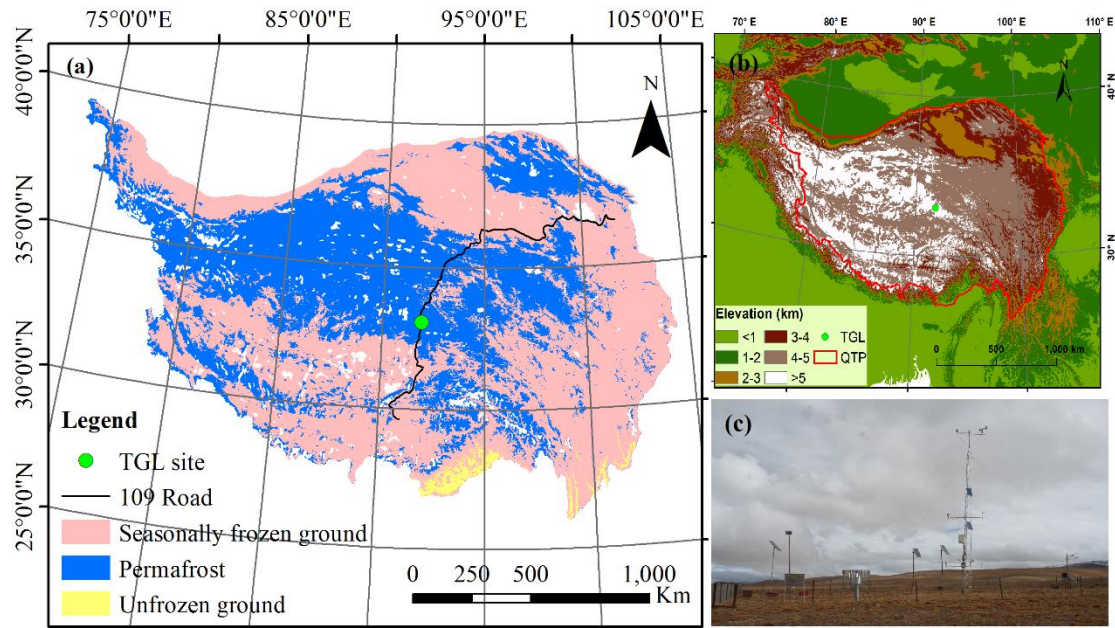

116 **2 Methods and materials**

117 **2.1 Site description and observation datasets**

118 Tanggula observation station (TGL) lies in the continuous permafrost regions of
119 Tanggula Mountain, central QTP (33.07°_N, 91.93°_E, Alt.: 5,100 m a.s.l; Fig. 1). This
120 site a typical permafrost site on the plateau with sub-frigid and semiarid climate (Li et
121 al., 2019), filmy and discontinuous snow cover (Che et al., 2019), sparse grassland (Yao
122 et al., 2011), coarse soil (Wu and Nan, 2016; He et al., 2019), and thick active layer
123 (Luo et al., 2016), which are common features in the permafrost regions of the plateau.
124 According to the observations from 2010–2011, the annual mean air temperature of

125 TGL site was $-4.4\text{ }^{\circ}\text{C}$. The annual precipitation was 375 mm, and of which 80% is
 126 concentrated between May and September. Alpine steppe with low height is the main
 127 land surface, whose coverage range is about 40% ~ 50% (Yao et al., 2011). The active
 128 layer thickness is about 3.15 m (Hu et al., 2017).

129 The atmospheric forcing data, including wind speed/direction, air
 130 temperature/relative humidity/pressure, downward shortwave/longwave radiation, and
 131 precipitation, were used to drive the model. These variables above were measured at a
 132 height of 2 m and covered the period from August 10, 2010 to August 10, 2012 (Beijing
 133 time) with a temporal resolution of 1 hour. Daily soil temperature and liquid moisture
 134 at depths of 5 cm, 25 cm, 70 cm, 140 cm, 220 cm and 300 cm from August 10, 2010 to
 135 August 9, 2011 (Beijing time) were utilized to validate the simulation results.

137 **Figure 1.** Location and geographic features of study site. (a) Location of observation
 138 site and permafrost distribution (Zou et al., 2017). (b) Topography of the Qinghai-Tibet
 139 Plateau. (c) Photo of the Tanggula observation station.

140 2.2 Ensemble experiments of Noah-MP

141 The offline Noah-MP LSM v1.1 was assessed in this study. The default Noah-MP
 142 consists of 12 physical processes that are interpreted by multiple optional

143 parameterization schemes. These sub-processes include vegetation model (VEG),
144 canopy stomatal resistance (CRS), soil moisture factor for stomatal resistance (BTR),
145 runoff and groundwater (RUN), surface layer drag coefficient (SFC), super-cooled
146 liquid water (FRZ), frozen soil permeability (INF), canopy gap for radiation transfer
147 (RAD), snow surface albedo (ALB), precipitation partition (SNF), lower boundary of
148 soil temperature (TBOT) and snow/soil temperature time scheme (STC) (Table 1).
149 Details about the processes and optional parameterizations can be found in Yang et al.
150 (2011a).

151 VEG(1) is adopted in the VEG process, in which the vegetation fraction is
152 prescribed according to the NESDIS/NOAA 0.144 degree monthly 5-year climatology
153 green vegetation fraction (<https://www.emc.ncep.noaa.gov/mmb/gcip.html>), and the
154 monthly leaf area index (LAI) was derived from the Advanced Very High-Resolution
155 Radiometer (AVHRR) (<https://www.ncei.noaa.gov/data/>, Claverie et al., 2016).
156 Previous studies has confirmed that Noah-MP seriously overestimate the snow events
157 and underestimate soil temperature and moisture on the QTP (Jiang et al., 2020; Li et
158 al., 2020; Wang et al., 2020), which can be greatly resolved by considering the
159 sublimation from wind (Gordon scheme) and a combination of roughness length for
160 heat and under-canopy aerodynamic resistance (Y08-UCT) (Zeng et al., 2005; Yang et
161 al., 2008; Li et al., 2020). For a more comprehensive assessment, we added two physical
162 processes based on the default Noah-MP model, i.e. the snow sublimation from wind
163 (SUB) and the combination scheme process (CMB) (Table 1). In the two processes,
164 users can choose to turn on the Gordon and Y08-UCT scheme (described in the study
165 of Li et al., 2020) or not. As a result, in total 55296 combinations are possible for the
166 13 processes and orthogonal experiments were carried out to evaluate their performance
167 in soil hydrothermal dynamics.

168 The Noah-MP model was modified to consider the vertical heterogeneity in the
169 soil profile by setting the corresponding soil parameters for each layer. The soil
170 hydraulic parameters, including the porosity, saturated hydraulic conductivity,
171 hydraulic potential, the Clapp-Hornberger parameter b , field capacity, wilt point, and

172 saturated soil water diffusivity, were determined using the pedotransfer functions
 173 proposed by Hillel (1980), Cosby et al. (1984), and Wetzel and Chang (1987)
 174 (Equations S1-S7), in which the sand and clay percentages were based on Hu et al.,
 175 (2017) (Table S1). In addition, the simulation depth was extended to 8.0 m to cover the
 176 active layer thickness of the QTP. The soil column was discretized into 20 layers, whose
 177 depths follow the default scheme in CLM 5.0 (Table S1, Lawrence et al., 2018). Due to
 178 the inexact match between observed and simulated depths, the simulations at 4_cm, 26
 179 cm, 80_cm, 136_cm, 208_cm and 299_cm were compared with the observations at 5_cm,
 180 25_cm, 70_cm, 140_cm, 220_cm and 300_cm, respectively. A 30-year spin-up was
 181 conducted in every simulation to reach equilibrium soil states.

182 **Table 1.** The physical processes and options of Noah-MP.

Physical processes	Options
Vegetation model (VEG)	(1) table LAI, prescribed vegetation fraction (2) dynamic vegetation (3) table LAI, calculated vegetation fraction (4) table LAI, prescribed max vegetation fraction
Canopy stomatal resistance (CRS)	(1) Jarvis (2) Ball-Berry
Soil moisture factor for stomatal resistance (BTR)	(1) Noah (2) CLM (3) SSiB
Runoff and groundwater (RUN)	(1) SIMGM with groundwater (2) SIMTOP with equilibrium water table (3) Noah (free drainage) (4) BATS (free drainage)
Surface layer drag coefficient (SFC)	(1) Monin-Obukhov (M-O) (2) Chen97
Super-cooled liquid water (FRZ)	(1) generalized freezing-point depression (2) Variant freezing-point depression
Frozen soil permeability (INF)	(1) Defined by soil moisture, more permeable (2) Defined by liquid water, less permeable
Canopy gap for radiation transfer (RAD)	(1) Gap=F(3D structure, solar zenith angle) (2) Gap=zero (3) Gap=1-vegetated fraction
Snow surface albedo (ALB)	(1) BATS (2) CLASS
Precipitation partition (SNF)	(1) Jordan91 (2) BATS: $T_{sfc} < T_{frz} + 2.2K$ (3) $T_{sfc} < T_{frz}$

Lower boundary of soil temperature (TBOT)	(1) zero heat flux (2) soil temperature at 8m depth
Snow/soil temperature time scheme (STC)	(1) semi-implicit (2) full implicit
Snow sublimation from wind (SUB)	(1) No (2) Yes
Combination scheme by Li et al.(2020) (CMB)	(1) No (2) Yes

183 BATS (Biosphere–Atmosphere Transfer Model); CLASS (Canadian Land Surface Scheme);
 184 SIMGM (Simple topography-based runoff and Groundwater Model); SIMTOP (Simple
 185 Topography-based hydrological model); SSiB (Simplified Simple Biosphere model).

186 **2.3 Methods for sensitivity analysis**

187 The simulated snow cover events (SCEs) was quantitatively evaluated using the
 188 overall accuracy index (OA) (Toure et al., 2016):

$$189 \quad OA = \frac{a + d}{a + b + c + d}$$

190 where a is the positive hits, b represents the false alarm, c is the misses, and d
 191 represents the negative hits. The value of OA range from 0 to 1. A higher OA signifies
 192 better performance. Ground albedo was used as an indicator for snow events due to a
 193 lack of snow depth observations. The days when the daily mean albedo is greater than
 194 the observed mean value of the warm and cold season (0.25 and 0.30, respectively) are
 195 identified as snow cover.

196 The root mean square error (RMSE) between the simulations and observations
 197 were adopted to evaluate the performance of Noah-MP in simulating soil hydrothermal
 198 dynamics.

199 To investigate the influence degrees of each physical process on SCEs, ST and
 200 SLW, we firstly calculated the mean OA (for SCE) and mean RMSE (for ST and SLW)
 201 (\bar{Y}_j^i) of the j th parameterization schemes ($j = 1, 2, \dots$) in the i th process ($i = 1, 2, \dots$).

202 Then, the maximum difference of \bar{Y}_j^i ($\Delta\bar{OA}$ or $\Delta\bar{RMSE}$) was defined to quantify the
 203 sensitivity of the i th process ($i = 1, 2, \dots$) (Li et al., 2015):

$$204 \quad \Delta\bar{OA} \text{ or } \Delta\bar{RMSE} = \bar{Y}_{max}^i - \bar{Y}_{min}^i$$

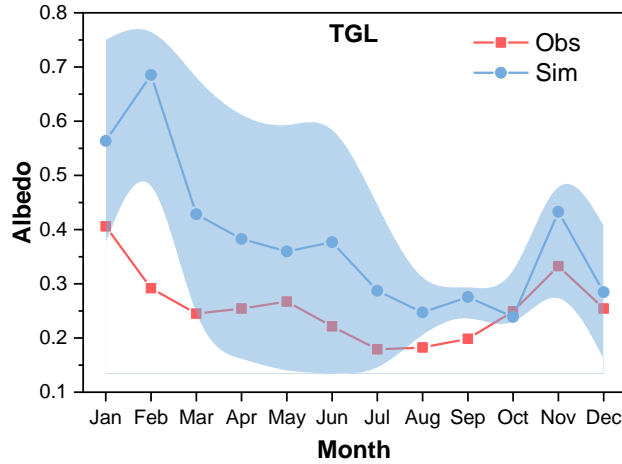

205 where \bar{Y}_{max}^i and \bar{Y}_{min}^i are the largest and the smallest \bar{Y}_j^i in the i th process,
206 respectively. For a given physical process, a high $\Delta\overline{OA}$ or $\Delta\overline{RMSE}$ signifies large
207 difference between parameterizations, indicating high sensitiveness of the i th process
208 for SCEs and ST/SLW simulation.

209 The sensitivities of physical processes were determined by quantifying the
210 statistical distinction level of performance between parameterization schemes. The
211 Independent-sample T-test (2-tailed) was adopted to identify whether the distinction
212 level between two schemes is significant, and that between three or more schemes was
213 tested using the Tukey's test. Tukey's test has been widely used for its simple
214 computation and statistical features (Benjamini, 2010). The detailed descriptions about
215 this method can be found in Zhang et al. (2016), Gan et al. (2019), and You et al. (2020a).
216 A process can be considered sensitive when the schemes show significant difference.
217 Moreover, schemes with large mean OA and small mean RMSE were considered
218 favorable for SCEs and ST/SLW simulation, respectively. We distinguished the
219 differences of the parameterization schemes at 95% confidence level.

220 **3 Results**

221 **3.1 General performance of the ensemble simulation**

222 The performance of Noah-MP for snow simulation was firstly tested by conducting
223 an ensemble of 55296 experiments. Due to a lack of snow depth measurements, ground
224 albedo was used as an indicator for snow cover. Figure 2 shows the monthly variations
225 of observed ground albedo and the simulations produced by the ensemble simulations.
226 The ground albedo was extremely overestimated with large uncertainties when
227 considering the snow options in Noah-MP, indicating the overestimation of snow depth
228 and duration. Such overestimation continued till July.

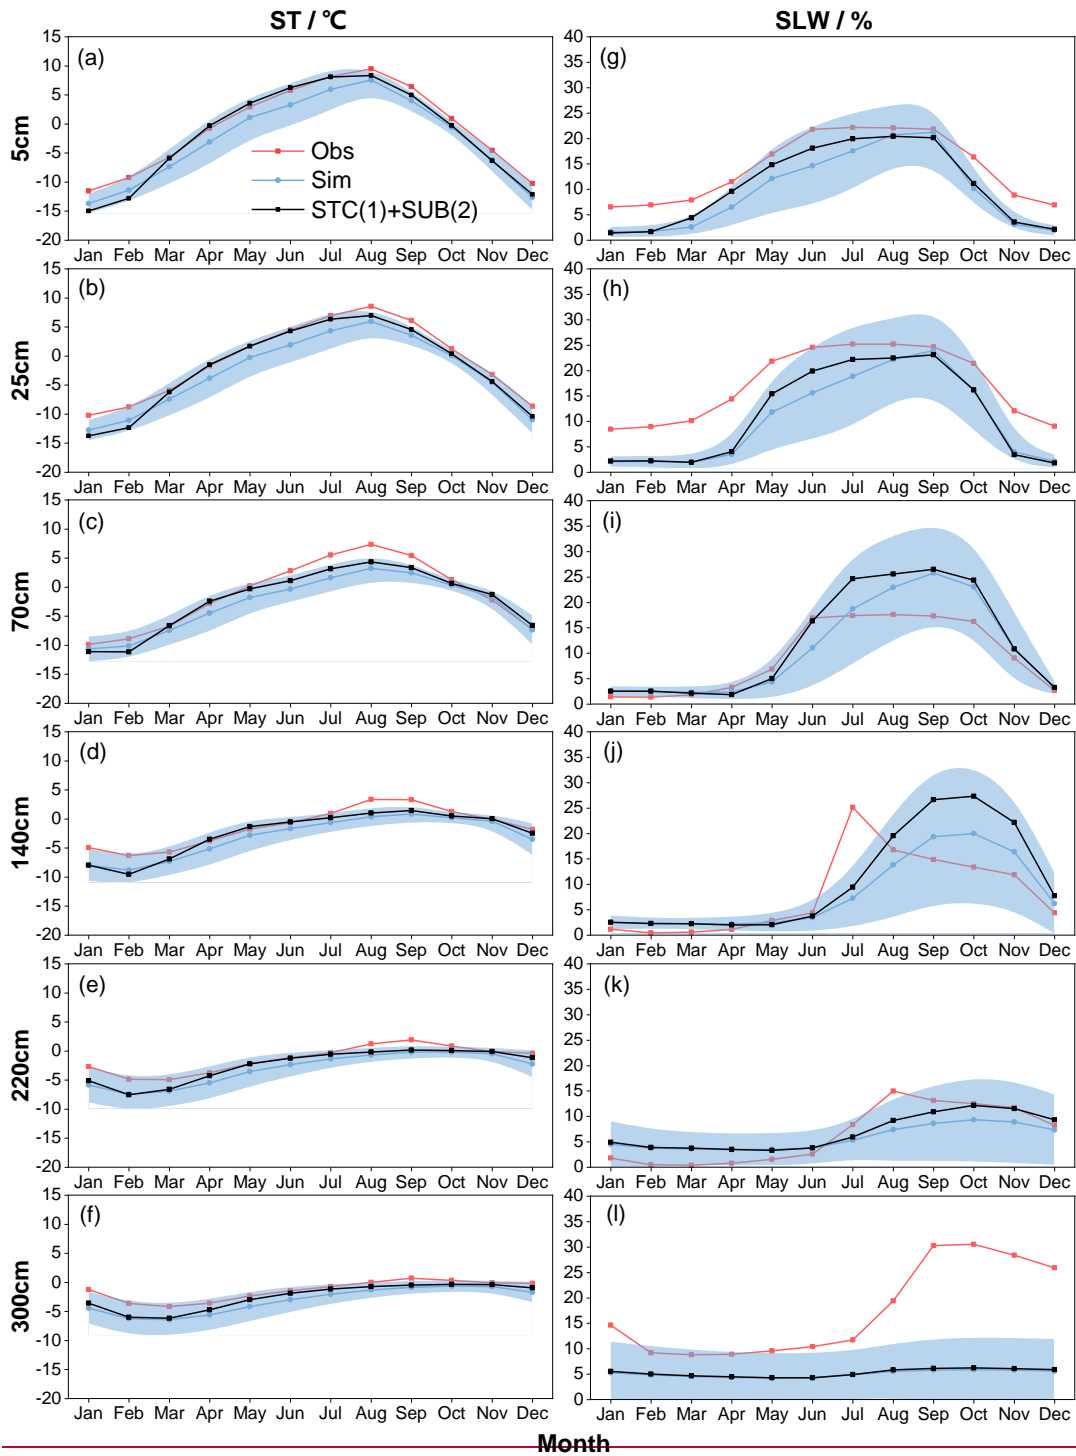

229

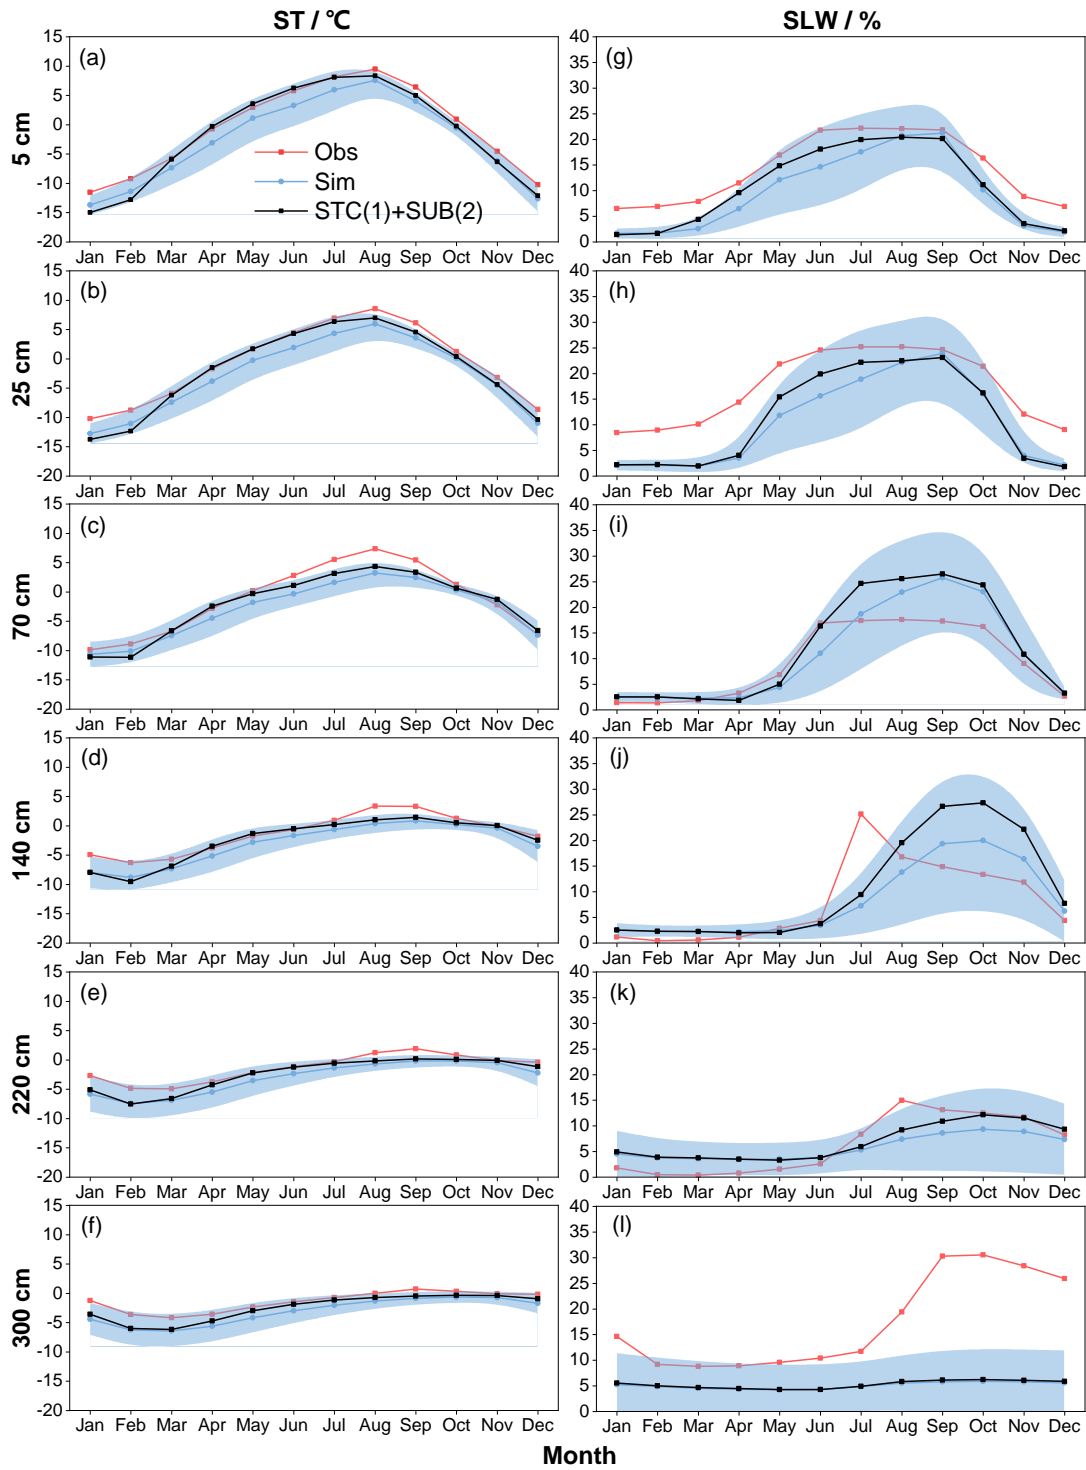

230 **Figure 2.** Monthly variations of ground albedo at TGL site for observation (Obs), and
 231 the ensemble simulation (Sim). The light blue shadow represents the standard deviation
 232 of the ensemble simulation.

233 Figure 3 illustrates the ensemble simulated and observed annual cycle of ST and
 234 SLW at TGL site. The ensemble experiments basically captured the seasonal variability
 235 of ST, whose magnitude decreased with soil depth. In addition, the simulated ST in the
 236 snow-affected season (October-July) showed relatively wide uncertainty ranges,
 237 particularly at the shallow layers. This indicates that the selected schemes perform
 238 much differently for snow simulation, resulting in large uncertainties of shallow STs.
 239 The simulated ST were generally smaller than the observations with relatively large
 240 gaps during the snow-affected season. It indicates that the Noah-MP model generally
 241 underestimates the ST, especially during the snow-affected months.

242 Since the observation equipment can only record the liquid water, soil liquid water
 243 (SLW) was evaluated against simulations from the ensemble experiments (Fig. 3). The
 244 Noah-MP model generally underestimated surface (5_cm and 25_cm) and deep (220_cm
 245 and 300_cm) SLW (Fig. 3g, 3h, 3k, 3l). However, Noah-MP tended to overestimate the
 246 SLW at the middle layers of 70_cm and 140_cm. Moreover, the simulated SLW exhibited
 247 relatively wide uncertainty ranges, particularly during the warm season (Fig. 3).

248

250

251 **Figure 3.** Monthly soil temperature (ST in °C) and soil liquid water (SLW in %) at (a,
 252 g) 5 cm, (b, h) 25 cm, (c, i) 70 cm, (d, j) 140 cm, (e, k) 220 cm, (f, l) 300 cm at TGL
 253 site. The light blue shadow represents the standard deviation of the ensemble simulation.
 254 The black line-symbol represents the ensemble mean of simulations with STC(1) and
 255 SUB(2).

256 3.2 Sensitivity of physical processes

257 3.2.1 Influence degrees of physical processes

258
259 **Figure 4.** The maximum difference of the mean overall accuracy (OA) for albedo
260 (ALB- ΔOA) in each physical process during the (a) annual, (b) cold season, and (c)
261 warm season at TGL site.

262 Figure. 4 compares the influence scores of the 13 physical processes based on the
263 maximum difference of the mean OA over 55296 experiments using the same scheme,
264 for SCEs at TGL site. On the whole, the SUB and STC processes had the largest scores
265 for the whole year as well as during both the warm and cold seasons, and the other
266 processes showed a value less than 0.05 (Fig. 4a, 4b, 4c). Moreover, the SUB process
267 had a consistent influence on SCEs while the influence of STC differed with season. In
268 the cold season, the score of SUB process (0.28) was two times more than that of the
269 STC process (Fig. 4b), indicating the relative importance of snow sublimation for SCEs
270 simulation during the cold season. When it comes to the warm season, the influence
271 score of SUB (0.25) did not change much, while that of STC increased to 0.26 and
272 showed a similar influence on SCEs simulation with SUB.

273

274 **Figure 5.** The maximum difference of the mean RMSE for (a, c and e) soil temperature
 275 ($ST-\overline{\Delta RMSE}$ in $^{\circ}C$) and (b, d and f) soil liquid water ($SLW-\overline{\Delta RMSE}$ in %)
 276 in each physical process during the (a and b) annual, (c and d) warm, and (e and f) cold season
 277 at different soil depths at TGL site.

278 Figure. 5 compares the influence scores of the 13 physical processes at different
 279 soil depths, based on the maximum difference of the mean RMSE over 55296
 280 experiments using the same scheme, for ST and SLW at TGL site. The snow-related
 281 processes, including the STC, SUB and SNF process showed the largest $ST-\overline{\Delta RMSE}$ at
 282 all layers, followed by the RAD, SFC and RUN processes. While the $ST-\overline{\Delta RMSE}$ of
 283 the other 7 physical processes were less than $0.5^{\circ}C$, among which the influence of CRS
 284 and BTR processes were negligible. What's more, the FRZ, INF, and TBOT processes
 285 had larger influence scores during the cold season than warm season, and the scores of
 286 TBOT were greater in deep soils than shallow soils. During the warm season, the
 287 physical processes generally showed more influence on shallow soil temperatures.
 288 When it comes to the cold season, the influence of the physical processes on deep layers
 289 obviously increased and comparable with that on shallow layers, implying the relatively
 290 higher uncertainties of Noah-MP during the cold season.

291 Most of the $\overline{\Delta RMSE}$ for SLW are less than 5%, indicating that all the physical
292 processes have limited influence on the SLW, among which CRS, BTR, ALB, SNF, and
293 CMB showed the smallest effects on SLW (Fig. 5b, 5d, 5f). During the warm season,
294 the RUN process, together with the STC and SUB processes, dominated the
295 performance of SLW simulation, especially at shallow layers (5 cm, 25 cm and 70 cm,
296 Fig. 5d). During the cold season, however, the RUN process dominated the SLW
297 simulation with a great decline of dominance of STC and SUB processes.

298 **3.2.2 Sensitivities of physical processes and general behaviors of** 299 **parameterizations**

300 To further investigate the sensitivity of each process and the general performance
301 of the parameterizations, the Independent-sample T-test (2-tailed) and Tukey's test were
302 conducted to test whether the difference between parameterizations within a physical
303 process is significant (Fig. 6 and 7). In a given sub-process, any two schemes labelled
304 with different letters behave significantly different, and this sub-process therefore can
305 be identified as sensitive. Otherwise, the sub-process is considered insensitive. For
306 simplicity, schemes of insensitive sub-process are not labeled. Moreover, schemes with
307 the letters late in the alphabet have smaller mean RMSEs and outperform the ones with
308 the letters forward in the alphabet. Using the two schemes in CRS process (hereafter
309 CRS(1) and CRS(2)) in Fig. 6 as an example. For the annual and warm season, CRS(1)
310 and CRS(2) were labeled with "B" and "A", respectively. In the cold season, none of
311 them were labeled with letters. As described above, the CRS process was sensitive for
312 SCEs simulation during the annual and warm season, and CRS(1) outperformed
313 CRS(2). However, it was not sensitive during the cold season.

314 Consistent with the influence degrees in Fig. 4, the performance difference
315 between schemes of the STC and SUB for SCEs simulation were significantly greater
316 than other processes. Most other physical processes showed significant but limited
317 difference. Schemes in BTR and TBOT processes, however, had no significant different
318 performance. Specifically, the performance order followed $STC(1) > STC(2)$, $SUB(2) >$
319 $SUB(1)$, $SFC(2) > SFC(1)$, $ALB(2) > ALB(1)$, $CMB(2) > CMB(1)$ in both annual and

320 seasonal scales. RAD showed no obvious difference during the warm season, while
 321 RAD(3) outperformed RAD(1) and (2) during the cold season. For SNF, SNF(3)
 322 generally excel SNF(1) and SNF(2), especially during the warm season.

323
 324 **Figure 6.** Distinction level for overall accuracy (OA) of snow cover events (SCEs)
 325 during the annual, warm, and cold seasons at TGL site. Limits of the boxes represent
 326 upper and lower quartiles, lines in the box indicate the median value.

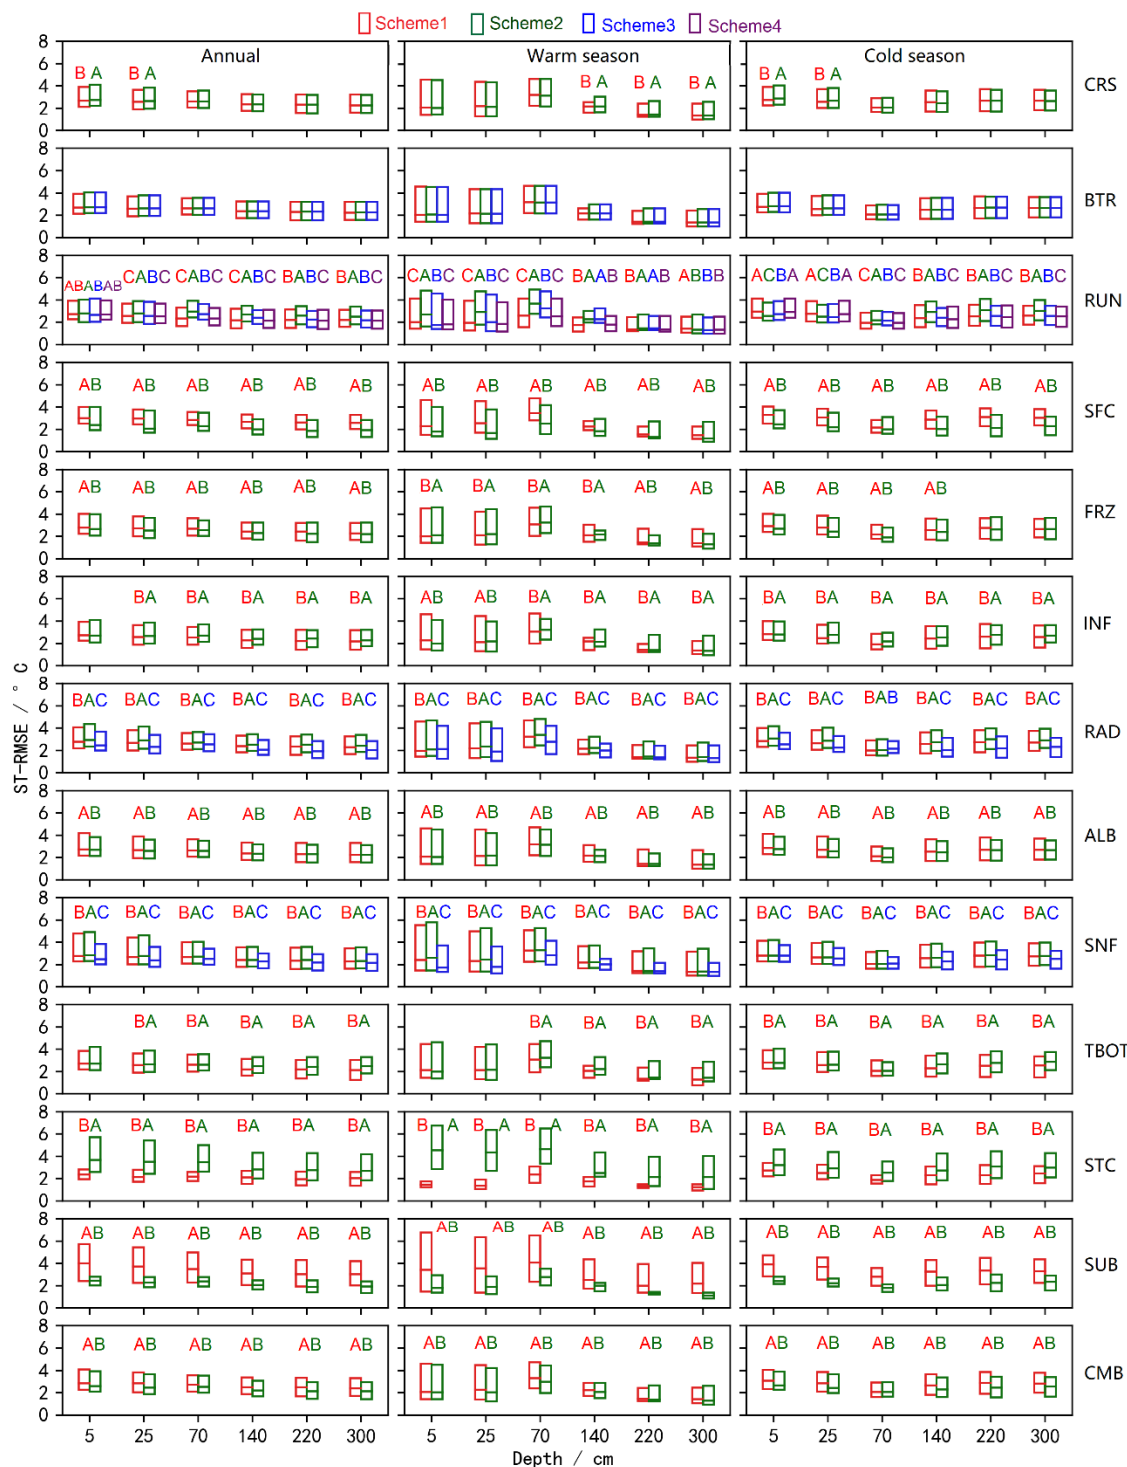

327 All the physical processes showed sensitivities for ST and SLW simulation in

328 varying magnitudes except the BTR process and CRS process in most layers. For ST,
329 the performance difference between schemes of the STC, SUB and SNF were obviously
330 greater than other processes, indicating the importance of snow on ST, followed by the
331 RAD, SFC and RUN processes. The performance orders followed $STC(1) > STC(2)$,
332 $SUB(2) > SUB(1)$, $SNF(3) > SNF(1) > SNF(2)$, $RAD(3) > RAD(1) > RAD(2)$, and
333 $SFC(2) > SFC(1)$. For SLW, the RUN, STC, and SUB processes showed significant and
334 higher sensitivities than other physical processes, especially during the warm season
335 and at the shallow layers (Fig. xx). Consistent with that of ST, the performance orders
336 for SLW simulation were $STC(1) > STC(2)$, and $SUB(2) > SUB(1)$. For the RUN
337 process, the performance orders for both ST and SLW simulation generally followed
338 $RUN(4) > RUN(1) > RUN(3) > RUN(2)$ as a whole, among which $RUN(1)$ and $RUN(4)$
339 presented similar performance during both warm and cold seasons. During both warm
340 and cold seasons, the performance orders for ST simulations were $SFC(2) > SFC(1)$ for
341 SFC process, $FRZ(2) > FRZ(1)$ for FRZ process, and $RAD(3) > RAD(1) > RAD(2)$ for
342 RAD process (Fig. S2 and S3), which are particularly so for SLW simulations at shallow
343 and deep layers.

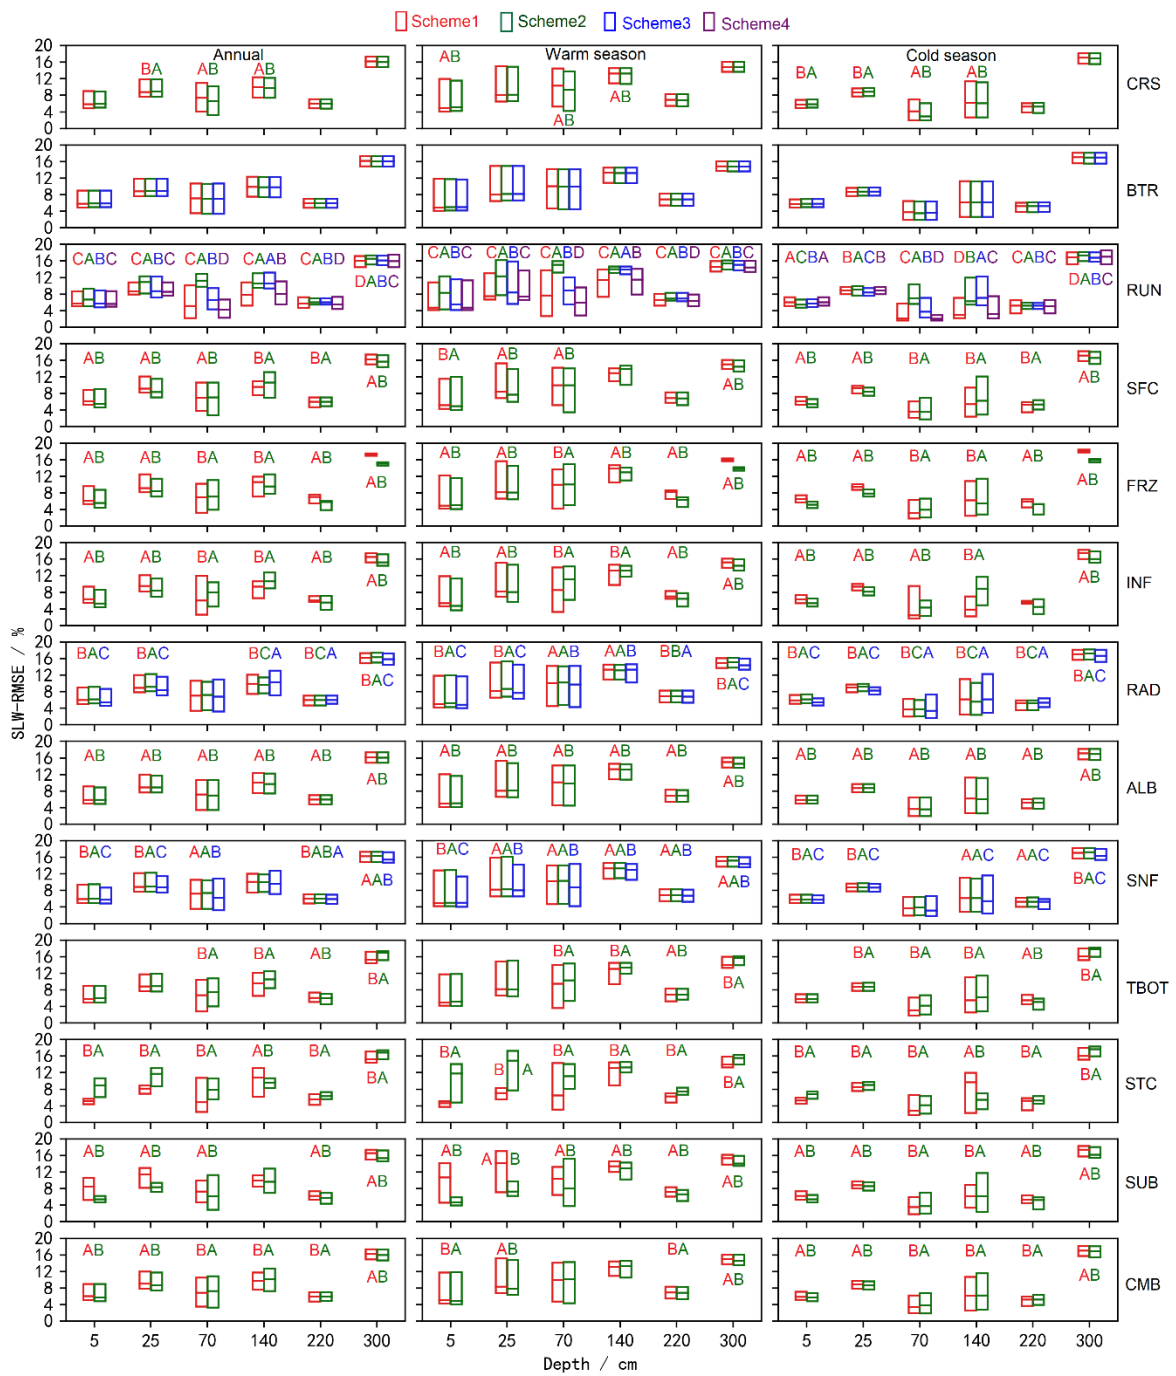

344 For ST, both FRZ and INF showed higher sensitivities during the cold season,
345 especially at shallow soils for FRZ and deep soils for INF. $FRZ(2)/INF(1)$ outperformed
346 $FRZ(1)/INF(2)$ for the whole year for ST simulation. Specifically, $FRZ(1)/INF(2)$
347 performed better at the shallow soils during the warm season while did worse during
348 the cold season compared with $FRZ(2)/INF(1)$. For SLW, $FRZ(2)/INF(2)$ generally
349 preceded $FRZ(1)/INF(1)$ at shallow and deep soils (5_cm, 25_cm, 220_cm, and 300_cm)
350 while did worse at middle soil layers (140_cm and 220_cm).

351 For ST simulation, the performance sequence in RAD and SNF was $RAD(3) >$
352 $RAD(1) > RAD(2)$ and $SNF(3) > SNF(1) > SNF(2)$, respectively. For SLW simulation,
353 the sequence become complicated. However, $RAD(3)$ and $RAD(3)$ still outperformed
354 the other two schemes, respectively. $ALB(2)$ was superior to $ALB(1)$ for both ST and
355 SLW simulation. The influence of TBOT on soil hydrothermal arose at deep soils and
356 during cold season, and $TBOT(1)$ excel $TBOT(2)$. $CMB(2)$ outperformed $CMB(1)$ for

357 ST simulation, so did that for SLW simulation at shallow and deep soils (5_cm, 25_cm,
 358 and 300_cm).

359
 360 **Figure 7.** Distinction level for RMSE of ST at different layers during the annual, warm,
 361 and cold seasons in the ensemble simulations at TGL site. Limits of the boxes represent
 362 upper and lower quartiles, lines in the box indicate the median value.

364

365

366

3.3 Influence of snow cover and surface drag coefficient on soil hydrothermal dynamics

367

368

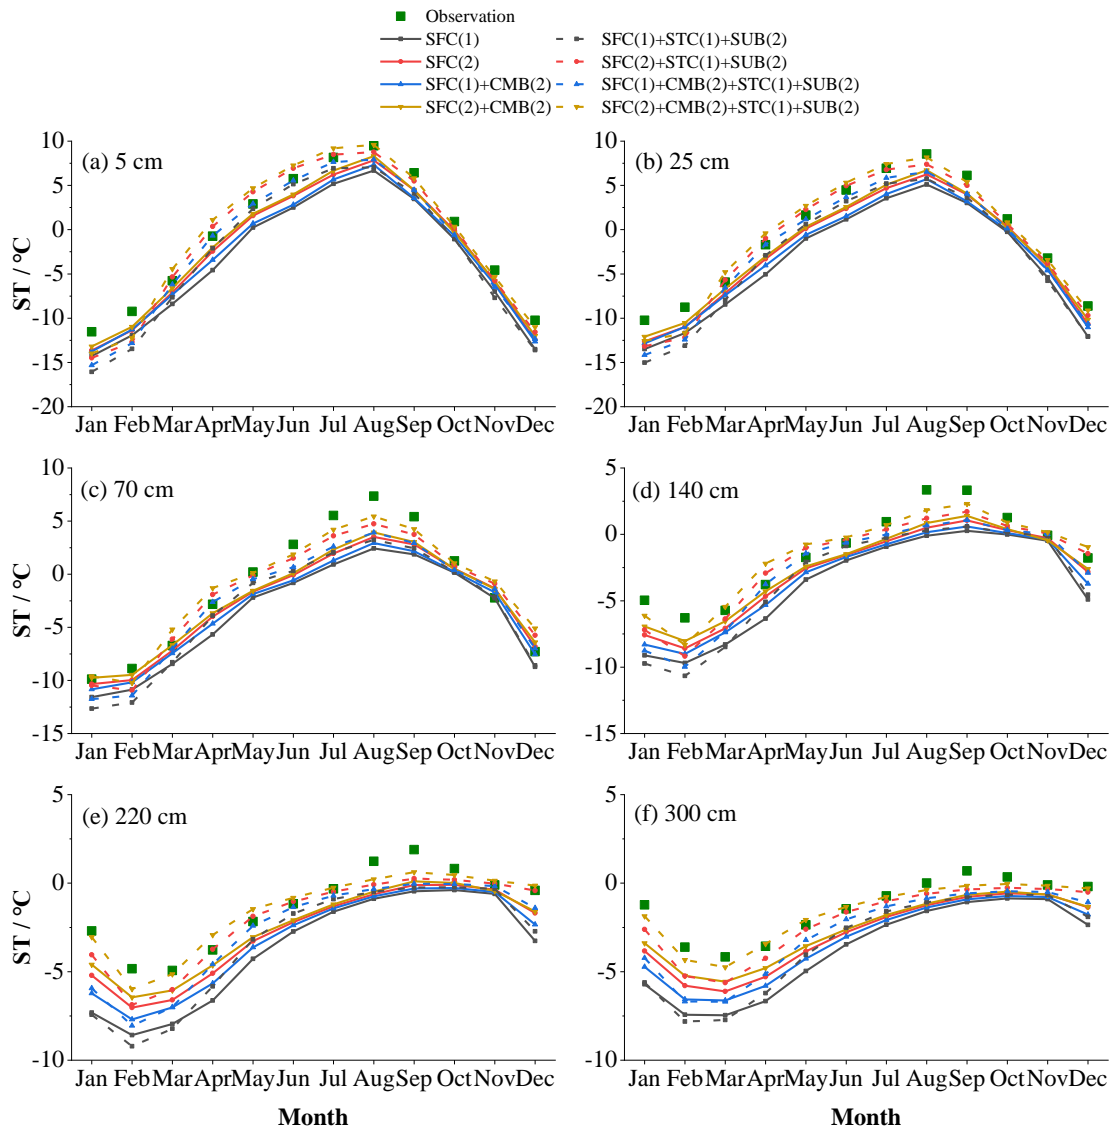

369

370 **Figure 9.** Uncertainty interval of ground albedo at TGL site in dominant physical
 371 processes (STC and SUB) for snow cover event simulation.

372 The influence of snow on soil temperature is firstly investigated. The dominant
 373 role of STC and SUB in the simulation of SCEs has been identified (Fig. 4 and 6).
 374 Interactions between the two physical processes are further analyzed here. Figure 9
 375 compares the uncertainly intervals of the two physics. The duration of snow cover is
 376 the longest when STC(2)+SUB(1), followed when STC(2)+SUB(1). Simulations
 377 considering SUB(2) generally has a short snow duration. Among the four combinations,
 378 STC(1)+SUB(2) is in best agreement with the measurements.

379 Given the good performance of STC(1)+SUB(2) in simulating SCEs, the influence
 380 of snow on soil hydrothermal dynamics is investigated by comparing the total ensemble
 381 mean ST and SLW with those adopting STC(1)+SUB(2) (Fig. 3). It can be seen that the
 382 ensemble mean ST of simulations adopting STC(1) and SUB(2) are generally higher
 383 than the total ensemble means, especially during the spring and summer (Mar.-Aug.).
 384 In January and February at shallow layers (5_cm, 25_cm and 70_cm), STC(1)+SUB(2)
 385 had a lower ST and showed an insulation effect on ST during the two months. As a
 386 whole, however, snow cover has a cooling effect on ST. In addition, along with the
 387 improved SCEs and elevated ST, STC(1)+SUB(2) induced moister soil with higher
 388 SLW (Fig. 3).

389

391

392 **Figure 10.** Monthly soil temperature (ST in °C) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d)
 393 140 cm, (e) 220 cm, (f) 300 cm for the SFC process that consider the CMB(2) and
 394 STC(1)+SUB(2) processes or not.

395 SFC and CMB process using different ways to calculate the surface drag
 396 coefficient, which is of great influence for surface energy partitioning and thus ST and
 397 SLW. The influence of surface drag coefficient is assessed by comparing the soil
 398 temperature before and after considering the combined scheme (CMB(2)) and the effect
 399 of snow (STC(1)+SUB(2)) (Fig. 10). SFC(2) tended to produce higher ST than SFC(1),
 400 especially during the warming period (January-August). When adopting the combined
 401 scheme of Y08 and UCT (CMB(2)), the cold bias were significantly resolved. The

402 performance order followed $SFC(2)+CMB(2) > SFC(2) > SFC(1)+CMB(2) > SFC(1)$.
403 However, considerable underestimations of ST still exist at all layers due to the poor
404 representation of snow process. After eliminating the effects of snow (STC(1)+SUB(2),
405 dash lines in Fig. 10), the simulated ST accordingly increased except in January and
406 February. SFC(2) and SFC(2)+CMB(2) overestimated STs from March to July at
407 shallow layers (5_cm and 25_cm), resulting in good agreements of deep STs with
408 observations. In contrast, the simulated STs at shallow layers (5_cm and 25_cm) by
409 SFC(1) and SFC(1)+CMB(2) were basically consistent with observations from March
410 to July. While large cold bias remained at deep layers.

411 **4 Discussion**

412 **4.1 Snow cover on the QTP and its influence on soil hydrothermal regime**

413 Snow cover in the permafrost regions of the QTP is thin, patchy, and short-lived
414 (Che et al., 2019), whose influence on soil temperature and permafrost state is usually
415 considered weak (Jin et al., 2008; Zou et al., 2017; Wu et al., 2018; Zhang et al., 2018;
416 Yao et al., 2019). However, our ensemble simulations showed that the surface albedo
417 is extremely overestimated in both magnitude and duration (Fig. 2), implying an
418 extreme overestimation of snow cover, which is consistent with the studies using Noah-
419 MP model (Jiang et al., 2020; Li et al., 2020; Wang et al., 2020) and widely found in
420 other state-of-the-art LSMs (Wei and Dong, 2015) on the QTP.

421 Great efforts to resolve the overestimation of snow cover in LSMs include
422 considering the vegetation effect (Park et al., 2016), the snow cover fraction (Jiang et
423 al., 2020), the blowing snow (Xie et al., 2019), and the fresh snow albedo (Wang et al.
424 2020). Our results illustrated the superiority of considering the snow sublimation from
425 wind (SUB(2)) and using semi-implicit snow/soil temperature time scheme (STC(1))
426 (Fig. 4, 6 and 9) when simulating snow cover on the QTP. It is consistent with previous
427 conclusions that accounting for the loss resulting from wind contributes to improve
428 snow cover days and depth (Yuan et al., 2016), and that STC(1) has a rapid snow

429 ablation than STC(2) (You et al., 2020a).

430 The impacts of snow cover on soil temperature in magnitude and vector (cooling or
431 warming) depend on its timing, duration, and depth (Zhang et al., 2005). In January and
432 February, the ground heat flux mainly goes upward, the warming effect of simulated
433 snow can be related to the overestimated snow depth that prevent heat loss from the
434 ground. During the spring and summer when snow melts, the cooling effects occurs,
435 mainly because considerable energy that used to heat the ground is reflected due to the
436 high albedo of snow. With the improvement of snow (STC(1)+SUB(2)), the originally
437 overestimated snow melts and infiltrated into the soil, resulting in improved SLWs (Fig.
438 3). And higher soil temperature also contributed to the SLWs according to the freezing-
439 point depression equation, in which SLW exponentially increase with soil temperature
440 for a given site (Niu and Yang, 2006).

441 **4.2 Discussions on the sensitivity of physical processes on soil hydrothermal** 442 **simulation**

443 **4.2.1 Canopy stomatal resistance (CRS) and soil moisture factor for stomatal** 444 **resistance (BTR)**

445 The biophysical process BTR and CRS directly affect the canopy stomatal
446 resistance and thus the plant transpiration (Niu et al., 2011). The transpiration of plants
447 could impact the ST/SLW through its cooling effect (Shen et al., 2015) and the water
448 balance of root zone (Chang et al., 2020). However, the annual transpiration of alpine
449 steppe is weak due to the shallow effective root zone and lower stomatal control in this
450 dry environment (Ma et al., 2015), which may explain the indistinctive or very small
451 difference among the schemes of the BTR and CRS processes for SCEs (Fig. 8), ST
452 (Fig. 7) and SLW (Fig. 8).

453 **4.2.2 Runoff and groundwater (RUN)**

454 In the warm season, different SLWs would result in the difference of the surface
455 energy partitioning and thus different soil temperatures. RUN(2) had the worst

456 performance for simulating ST and SLW (Fig. 7 and 8) among the four schemes, likely
457 due to its higher estimation of soil moisture (Fig. S1) and thus greater sensible heat and
458 smaller ST (Gao et al., 2015). Likewise, RUN(4) was on a par with RUN(1) in the
459 simulation of ST at most layers due to the very small difference in SLW of two schemes
460 (Fig. 8 and S1). For the whole soil column, RUN(4) surpassed RUN(1) and RUN(2) for
461 SLW simulation, both of which define surface/subsurface runoff as functions of
462 groundwater table depth (Niu et al., 2005; Niu et al., 2007). This is in keeping with the
463 study of Zheng et al. (2017) that soil water storage-based parameterizations outperform
464 the groundwater table-based parameterizations in simulating the total runoff in a
465 seasonally frozen and high-altitude Tibetan river. Besides, RUN(4) is designed based
466 on the infiltration-excess runoff (Yang and Dickinson, 1996) in spite of the saturation-
467 excess runoff in RUN(1) and RUN(2) (Gan et al., 2019), which is more common in arid
468 and semiarid areas like the permafrost regions of QTP (Pilgrim et al., 1988). In the cold
469 season, much of the liquid water freezes into ice, which would greatly influence the
470 thermal conductivity of frozen soil considering thermal conductivity of ice is nearly
471 four times that of the equivalent liquid water. Therefore, the impact of RUN is important
472 for the soil temperature simulations at both warm and cold seasons (Fig. 5 and 7).

473 **4.2.3 Surface layer drag coefficient (SFC and CMB)**

474 SFC defines the calculations of the surface exchange coefficient for heat and water
475 vapor (CH), which greatly impact the energy and water balance and thus the
476 temperature and moisture of soil (Zeng et al., 2012; Zheng et al., 2012). SFC(1) adopts
477 the Monin-Obukhov similarity theory (MOST) with a general form, while the SFC(2)
478 uses the improved MOST modified by Chen et al. (1997). In SFC(1), the roughness
479 length for heat (Z_{0h}) is taken as the same with the roughness length for momentum (Z_{0m} ,
480 Niu et al., 2011). SFC(2) adopts the Zilitinkevitch approach for $Z_{0,h}$ calculation
481 (Zilitinkevich, 1995). –The difference between SFC(1) and SFC(2) has a great impact
482 on the CH value. Several studies have reported that SFC(2) has a better performance
483 for the simulation of sensible and latent heat on the QTP (Zhang et al., 2016; Gan et al.,
484 2019). The results of T-test in this study showed remarkable distinctions between the

485 two schemes, where SFC(2) was dramatically superior to SFC(1) (Fig. 7 and 8). SFC(2)
486 produces lower CH than SFC(1) (Zhang et al., 2014), resulting in less efficient
487 ventilation and greater heating of the land surface (Yang et al., 2011b), and substantial
488 improvement of the cold bias of Noah-MP in this study (Fig. 7 and 10).

489 Both SFC(1) and SFC(2) couldn't produce the diurnal variation of $Z_{0,h}$ (Chen et al.,
490 2010). CMB offers a scheme that considered the diurnal variation of $Z_{0,h}$ in bare ground
491 and under-canopy turbulent exchange in sparse vegetated surfaces (Li et al., 2020).
492 Consistent with previous studies in the QTP (Chen et al., 2010; Guo et al., 2011; Zheng
493 et al., 2015; Li et al., 2020), the simulated ST generally followed $SFC(2)+CMB(2) >$
494 $SFC(2) > SFC(1)+CMB(2) > SFC(1)$ with/without removing the overestimation of
495 snow (Fig. 10), indicating that CMB(2) contributes to resolve the cold bias of LSMs.
496 However, none of the four combinations could well reproduce the shallow and deep
497 STs simultaneously. When the snow is well-simulated, SFC(2)+CMB(2) performed the
498 best at deep layers at the cost of overestimating shallow STs. Meanwhile,
499 SFC(1)+CMB(1) showed the best agreements at shallow layers with considerable cold
500 bias at deep layers, which can be related to the overestimated frozen soil thermal
501 conductivity (Luo et al., 2009; Chen et al., 2012; Li et al., 2019).

502 **4.2.4 Super-cooled liquid water (FRZ) and frozen soil permeability (INF)**

503 FRZ and INF describe the unfrozen water and permeability of frozen soil, and had
504 a larger influence on ST/SLW during the cold season than warm season as expected
505 (Fig. 5). Specifically, FRZ treats liquid water in frozen soil (super-cooled liquid water)
506 using two forms of freezing-point depression equation. FRZ(1) takes a general form
507 (Niu and Yang, 2006), while FRZ(2) exhibits a variant form that considers the increased
508 surface area of icy soil particles (Koren et al., 1999). FRZ(2) generally yields more
509 liquid water in comparison of FRZ(1) (Fig. S2). INF(1) uses soil moisture (Niu and
510 Yang, 2006) while INF(2) employs only the liquid water (Koren et al., 1999) to
511 parameterize soil hydraulic properties. INF(2) generally produces more impermeable
512 frozen soil than INF(1), which is also found in this study (Fig. S3). For the whole year,
513 INF(1) surpassed INF(2) in simulating STs, which may be related to the more realistic

514 SLWs produced by INF(1) for the whole soil column (Fig. S3).

515 **4.2.5 Canopy gap for radiation transfer (RAD)**

516 RAD treats the radiation transfer process within the vegetation, and adopts three
517 methods to calculate the canopy gap. RAD(1) defines canopy gap as a function of the
518 3D vegetation structure and the solar zenith angle, RAD(2) employs no gap within
519 canopy, and RAD(3) treat the canopy gap from unity minus the FVEG (Niu and Yang,
520 2004). The RAD(3) scheme penetrates the most solar radiation to the ground, followed
521 by the RAD(1) and RAD(2) schemes. As an alpine grassland, there is a relative low
522 LAI at TGL site, and thus a quite high canopy gap. So, schemes with a larger canopy
523 gap could realistically reflect the environment. Consequently, the performance
524 decreased in the order of RAD(3) > RAD(1) > RAD(2) for ST/SLW simulation.

525 **4.2.6 Snow surface albedo (ALB) and precipitation partition (SNF)**

526 The ALB describe two ways for calculating snow surface albedo, in which the
527 ALB(1) and ALB(2) adopt the scheme from BATS and CLASS LSM, respectively.
528 ALB(2) generally produce lower albedo than ALB(1), especially when the ground
529 covered by snow (Fig. S4). As a result, higher net radiation absorbed by the land surface
530 and more heat is available for heating the soil in ALB(2), which is beneficial for
531 counteracting the cooling effect of overestimated snow on ST (Fig. S5). Along with the
532 higher ST, ALB(2) outperformed ALB(1) for SLW simulation, likely due to more snow
533 melt water offset the dry bias in Noah-MP (Fig. S5).

534 The SNF defines the snowfall fraction of precipitation as a function of surface air
535 temperature. SNF(1) is the most complicated of the three schemes, in which the
536 precipitation is considered rain/snow when the surface air temperature is greater/less
537 than or equal to 2.5/0.5 °C, otherwise, it is recognized as sleet. While SNF(2) and
538 SNF(3) simply distinguish rain or snow by judging whether the air temperature is above
539 2.2 °C and 0 °C or not. The significant difference between three schemes for SCEs
540 simulation during the warm season is consistent with the large difference of snowfall
541 fraction in this period (Fig. 6 and S6). SNF(3) is the most rigorous scheme and produce
542 the minimum amount of snow, followed by SNF(1) and SNF(2) with limited difference

543 (Fig. S6). This exactly explains superiority of SNF(3) for ST and SLW simulation (Fig.
544 7 and 8).

545 **4.2.7 Lower boundary of soil temperature (TBOT) and snow/soil temperature time** 546 **scheme (STC)**

547 TBOT process adopts two schemes to describe the soil temperature boundary
548 conditions. TBOT (1) assumes zero heat flux at the bottom of the model, while TBOT(2)
549 adopts the soil temperature at the 8 m depth (Yang et al., 2011a). In general, TBOT(1)
550 is expected to accumulate heat in the deep soil and produce higher ST than TBOT(2).
551 In this study, the two assumptions performed significantly different, especially at the
552 deep soils and during the cold season. Although TBOT(2) is more representative of the
553 realistic condition, TBOT(1) surpassed TBOT(2) in this study. It can be related to the
554 overall underestimation of the model, which can be alleviated by TBOT(1) because of
555 heat accumulation (Fig. S7).

556 Two time discretization strategies are implemented in the STC process, where
557 STC(1) adopts the semi-implicit scheme while STC(2) uses the full implicit scheme, to
558 solve the thermal diffusion equation in first soil or snow layers (Yang et al., 2011a).
559 STC(1) and STC(2) are not strictly a physical processes but different upper boundary
560 conditions of soil column (You et al., [20192020a](#)). The differences between STC(1) and
561 STC(2) were significant (Fig. 7). The impacts of the two options on ST is remarkable
562 (Fig. 6), particularly in the shallow layers and during the warm season (Fig. 5). In
563 addition, STC(1) outperformed STC(2) in the ensemble simulated ST(Fig. 7), because
564 STC(1) greatly alleviated the cold bias in Noah-MP (Fig. S8) by producing the higher
565 OA of SCEs (Fig. 6)

566 **4.3 Perspectives**

567 This study analyzed the characteristics and general behaviors of each
568 parameterization scheme of Noah-MP at a typical permafrost site on the QTP, hoping
569 to provide a reference for simulating permafrost state on the QTP. We identified the

570 systematic overestimation of snow cover, cold bias and dry bias in Noah-MP, and
571 discussed the role of snow and surface drag coefficient on soil hydrothermal dynamics.
572 Further tests at another permafrost site (BLH site, 34.82°_N, 92.92°_E, Alt.: 4,659 m
573 a.s.l) basically showed consistent conclusions with that at TGL site (see Supplementary
574 files for details), indicating that relevant results and methodologies can be practical
575 guidelines for improving the parameterizations of physical processes and testing their
576 uncertainties towards soil hydrothermal modeling in the permafrost regions of the
577 plateau. Although the site we selected may be representative for the typical environment
578 on the plateau, continued investigation with a broad spectrum of climate and
579 environmental conditions is required to make a general conclusion at regional scale.

580 **5 Conclusions**

581 An ensemble simulation using multi-parameterizations was conducted using the
582 Noah-MP model at the TGL site, aiming to present a reference for simulating soil
583 hydrothermal dynamics in the permafrost regions of QTP using LSMs. The model was
584 modified to consider the vertical heterogeneity in the soil and the simulation depth was
585 extended to cover the whole active layer. The ensemble simulation consists of 55296
586 experiments, combining thirteen physical processes (CRS, BTR, RUN, SFC, FRZ, INF,
587 RAD, ALB, SNF, TBOT, STC, SUB, and CMB) each with multiple optional schemes.
588 On this basis, the general performance of Noah-MP was assessed by comparing
589 simulation results with in situ observations, and the sensitivity of snow cover event, soil
590 temperature and moisture at different depths of active layer to parameterization
591 schemes was explored. The main conclusions are as follows:

- 592 (1) Noah-MP model tends to overestimate snow cover, which is most influenced by the
593 STC and SUB processes. Such overestimation can be greatly resolved by
594 considering the snow sublimation from wind (SUB(2)) and semi-implicit snow/soil
595 temperature time scheme (STC(1)).
- 596 (2) Soil temperature is largely underestimated by the overestimated snow cover and
597 thus dominated by the STC and SUB processes. Systematic cold bias and large

598 uncertainties of soil temperature still exist after eliminating the effects of snow,
599 particularly at the deep layers and during the cold season. The combination of Y08
600 and UCT contributes to resolve the cold bias of soil temperature.

601 (3) Noah-MP tend to underestimate soil liquid water content. Most physical processes
602 have limited influence on soil liquid water content, among which the RUN process
603 plays a dominant role during the whole year. The STC and SUB process have a
604 considerable influence on topsoil liquid water during the warm season.

Supplement of

**Assessing the simulated soil hydrothermal regime of active layer
from Noah-MP LSM v1.1 in the permafrost regions of the
Qinghai-Tibet Plateau**

Xiangfei Li et al.

Correspondence to: Tonghua Wu (thuawu@lzb.ac.cn)

Content: Equations S1-S7; Table S1; Figures S1-S17

The soil hydraulic parameters of each layer, including the porosity (θ_s), saturated hydraulic conductivity (K_s), hydraulic potential (ψ_s), the Clapp-Hornberger parameter (b), field capacity (θ_{ref}), wilt point (θ_w), and saturated soil water diffusivity (D_s), were determined using the pedotransfer functions proposed by Hillel (1980), Cosby et al. (1984), and Wetzels and Chang (1987):

$$\theta_s = 0.489 - 0.00126(\%sand) \quad (S1)$$

$$K_s = 7.0556 \times 10^{-6.884+0.0153(\%sand)} \quad (S2)$$

$$\psi_s = -0.01 \times 10^{1.88-0.0131(\%sand)} \quad (S3)$$

$$b = 2.91 + 0.159(\%clay) \quad (S4)$$

$$\theta_{ref} = \theta_s \left[\frac{1}{3} + \frac{2}{3} \left(\frac{5.79 \times 10^{-9}}{K_s} \right)^{1/(2b+3)} \right] \quad (S5)$$

$$\theta_w = 0.5\theta_s \left(\frac{-200}{\psi_s} \right)^{-1/b} \quad (S6)$$

$$D_s = b \cdot K_s \cdot \left(\frac{\psi_s}{\theta_s} \right) \quad (S7)$$

where *%sand* and *%clay* represent the percentage (%) of sand and clay content in soil, respectively.

Table S1 Soil discretization scheme and soil particle fraction in this study.

Layer	Z_i	ΔZ_i	$Z_{h,i}$	Sand (%)	Silt (%)	Clay (%)
1	0.010	0.020	0.020	85.48	12.59	1.93

Layer node depth (Z_i), thickness (ΔZ_i), and depth at layer interface ($Z_{h,i}$) for default soil column. All in meters.

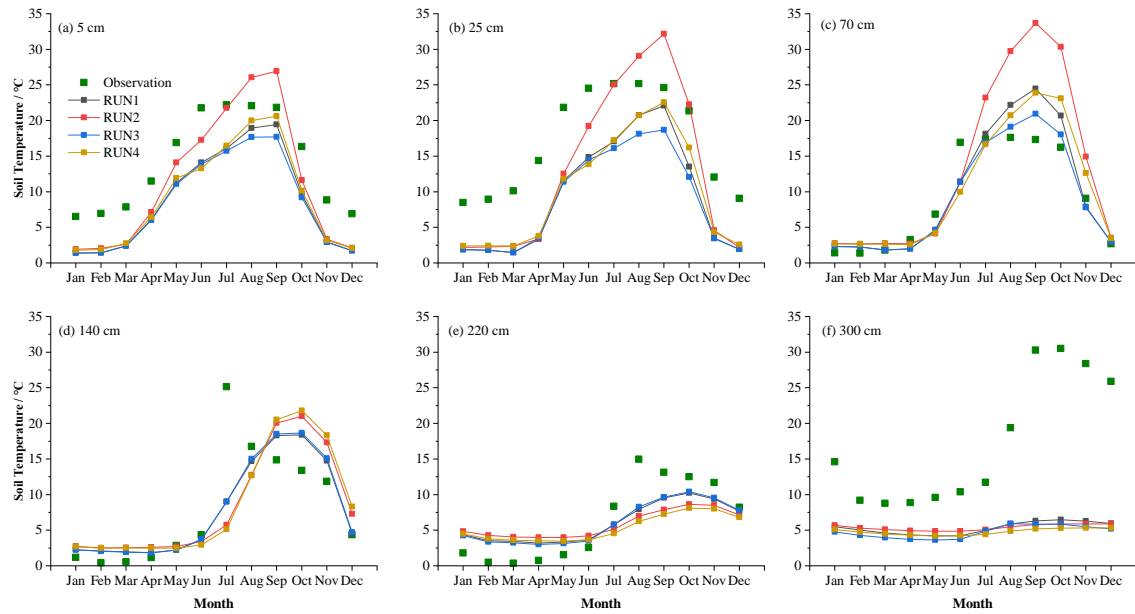

Figure. S1 Monthly soil liquid water (SLW in %) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the RUN process.

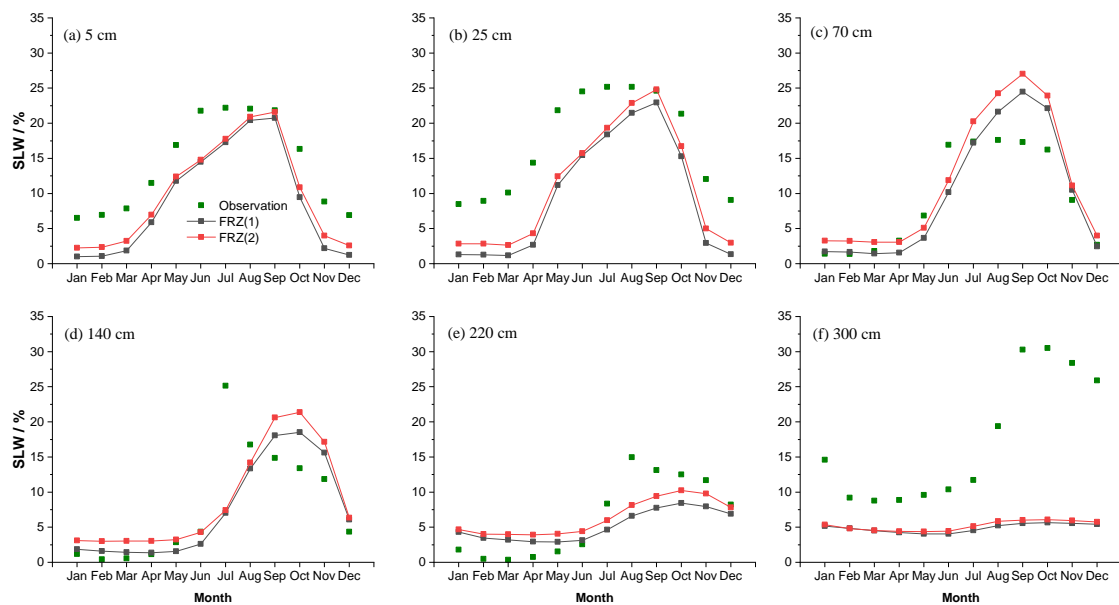

Figure. S2 Monthly soil liquid water (SLW in %) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the FRZ process.

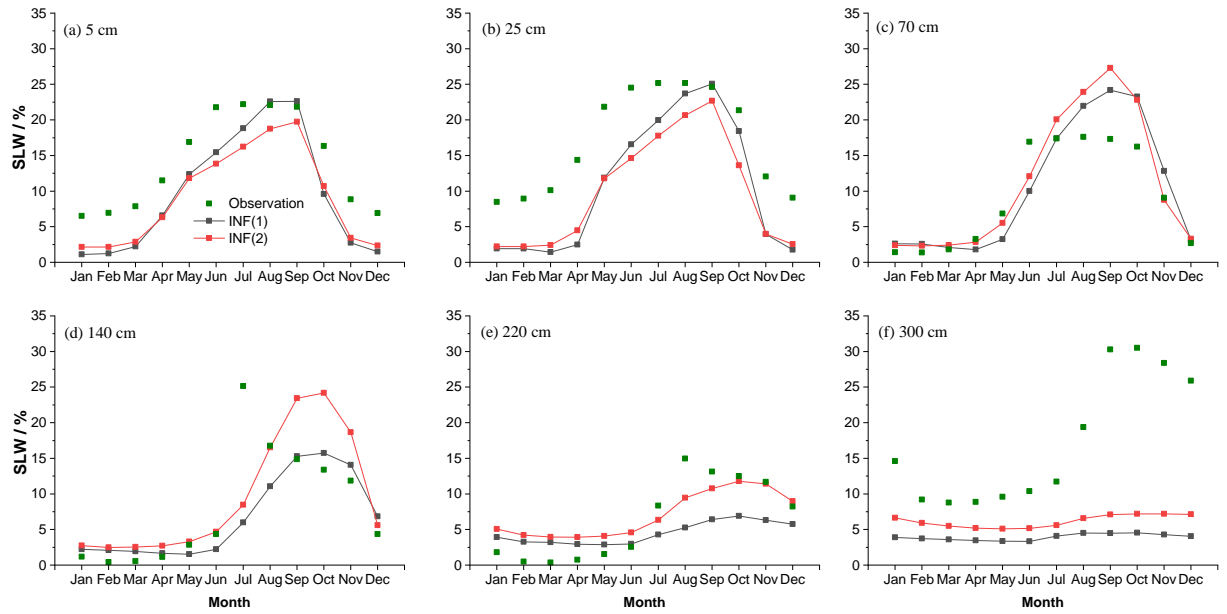

Figure. S3 Monthly soil liquid water (SLW in %) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the INF process.

Figure. S4 Monthly ground albedo for the ALB process.

Figure. S5 Monthly soil temperature (ST in °C) and liquid water (SLW in %) at (a, g) 5 cm, (b, h) 25 cm, (c, i) 70 cm, (d, j) 140 cm, (e, k) 220 cm, (f, l) 300 cm for the ALB process.

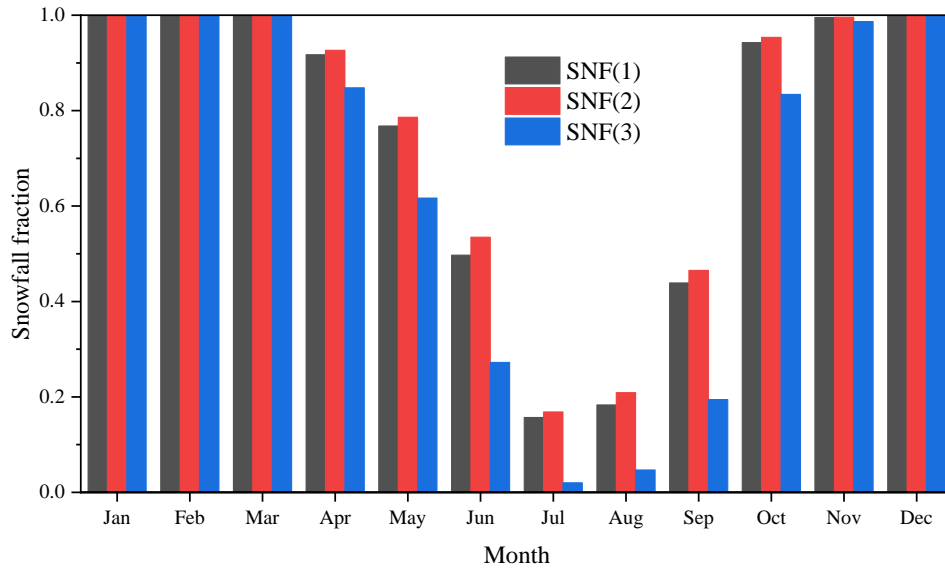

Figure. S6 Monthly snowfall fraction for the SNF process.

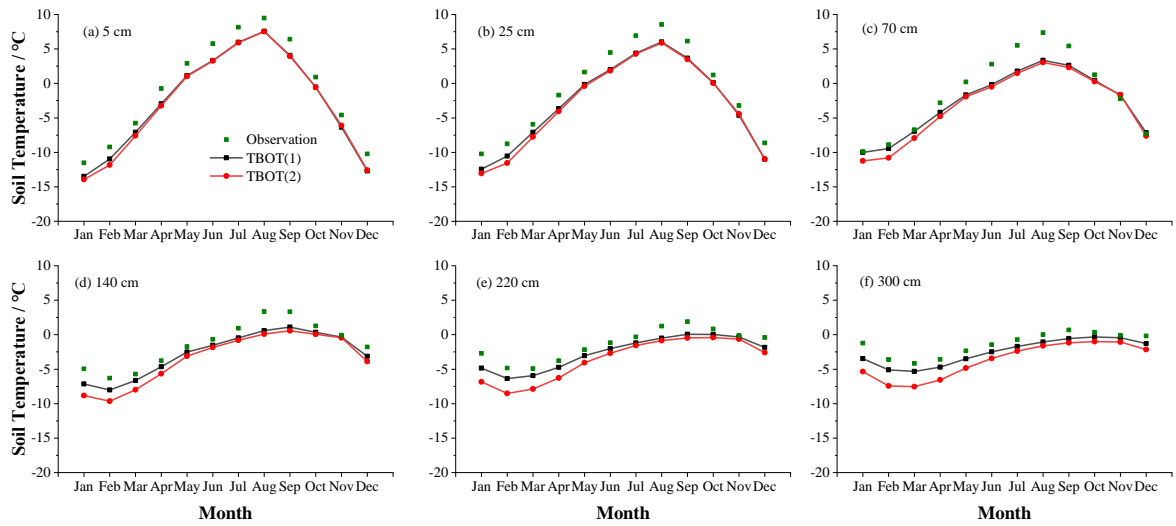

Figure. S7 Monthly soil temperature at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the TBOT process.

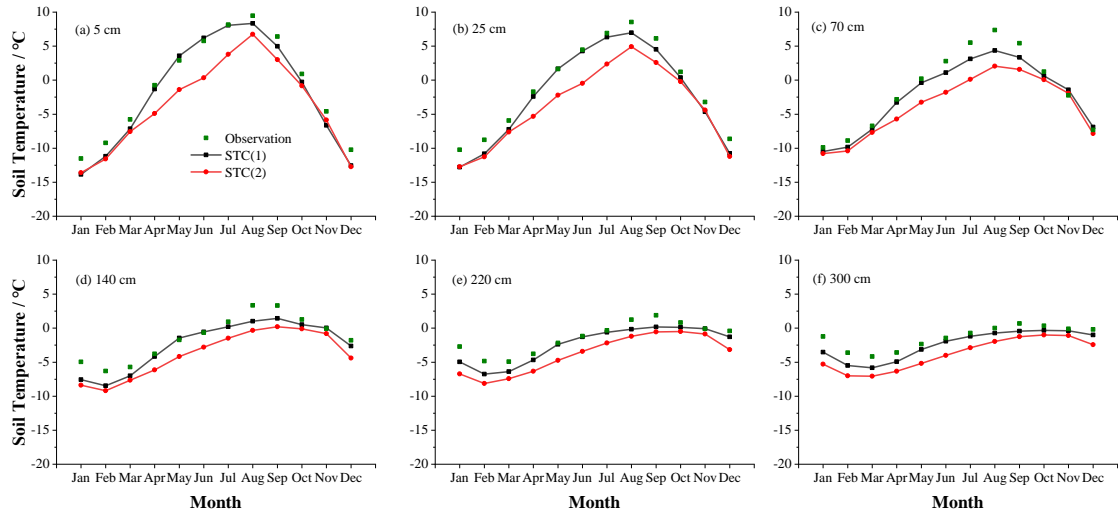

Figure. S8 Monthly soil temperature at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d) 140 cm, (e) 220 cm, (f) 300 cm for the STC process.

Main findings at BLH site:

- (1) Noah-MP tend to overestimate snow cover events at BLH site with large uncertainties during the cold months (Nov.-Mar). Moreover, snow cover events are mostly influenced by the STC and SUB process (Figure S11), and the combination of STC(1) and SUB(2) tend to produce better results (Figure 8). The small influence of physical processes during the warm season (Figure S11c) is because there are limited snow events, and its inability of reproducing snow cover in May (Figure S9).
- (2) Noah-MP generally underestimate STs with relatively large gaps during the snow-affected months (Nov.-Mar.), and the simulated ST in the snow-affected months (Nov.-Mar.) showed relatively wide uncertainty ranges (Figure S10). STs is mostly influenced by the snow processes, i.e. the STC and SUB process (Figure S12), especially during the cold season. In the warm season, the SFC and RUN process dominate the simulation of STs (Figure S12c). The combination of roughness length for heat and under-canopy aerodynamic resistance contributes to elevated soil temperature (Figure S17).
- (3) Noah-MP totally underestimate SLW at BLH site (Figure S10). The RUN process dominates the SLW at most layers simulation with limit impacts (Figure S12).

● **General performance of the ensemble simulation**

Figure S9. Monthly variations of ground albedo at BLH site for observation (Obs), and the ensemble simulation (Sim). The light blue shadow represents the standard deviation of the ensemble simulation.

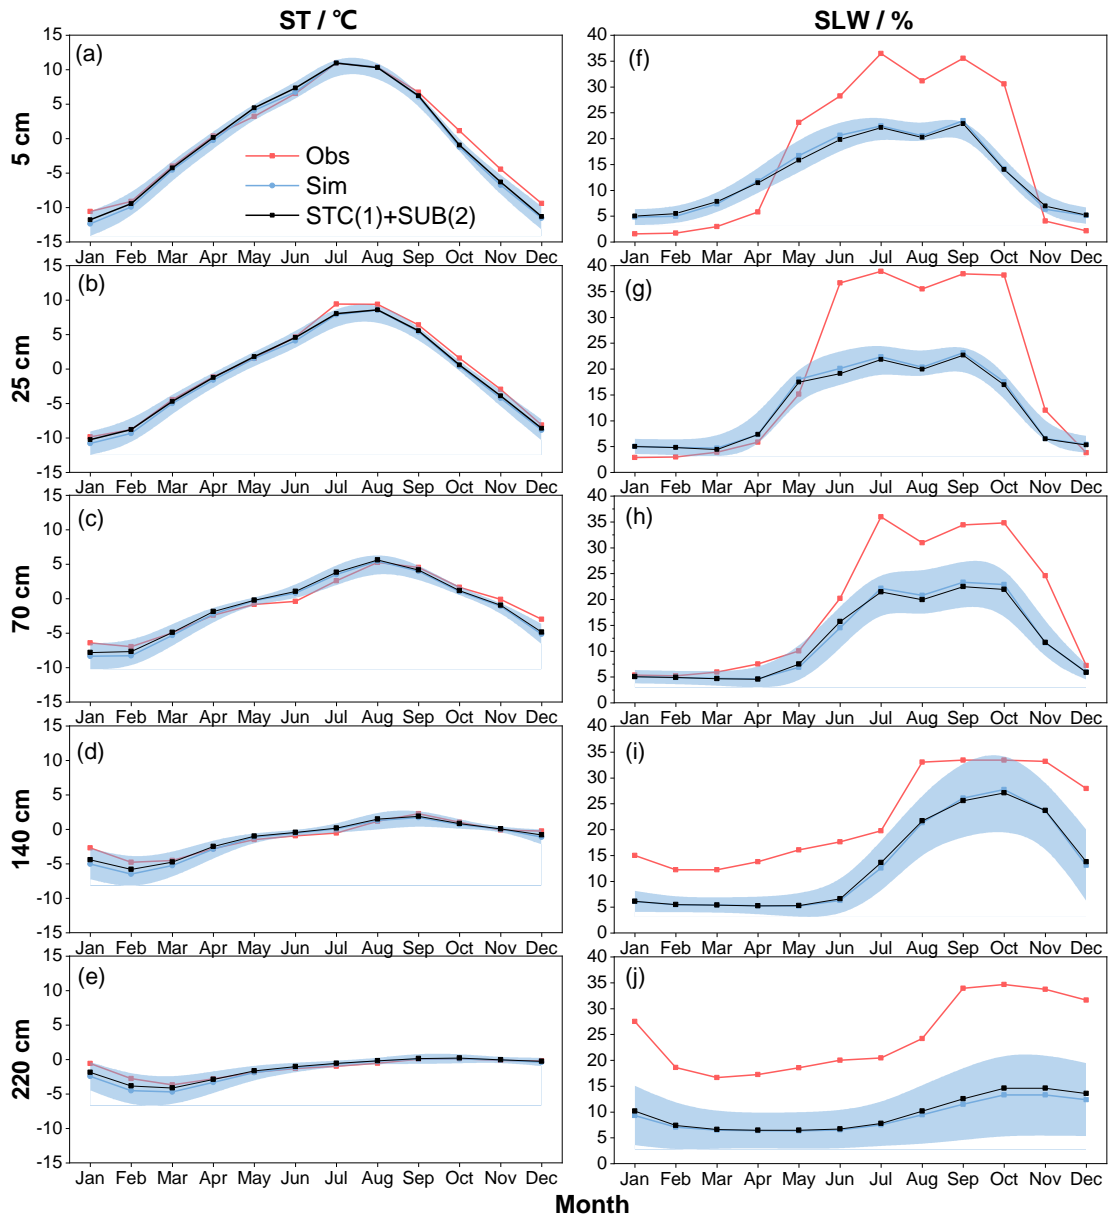

Figure S10. Monthly soil temperature (ST in °C) and soil liquid water (SLW in %) at (a, g) 5 cm, (b, h) 25 cm, (c, i) 70 cm, (d, j) 140 cm, (e, k) 220 cm, (f, l) 300 cm at BLH site. The light blue shadow represents the standard deviation of the ensemble simulation. The black line-symbol represents the ensemble mean of simulations with STC(1) and SUB(2).

● Influence degrees of physical processes

Figure S11. The maximum difference of the mean overall accuracy (OA) for albedo (ALB- Δ OA) in each physical process during the (a) annual, (b) cold season, and (c) warm season at BLH site.

Figure S12. The maximum difference of the mean RMSE for (a, c and e) soil temperature ($ST-\Delta\overline{RMSE}$ in °C) and (b, d and f) soil liquid water ($SLW-\Delta\overline{RMSE}$ in %) in each physical process during the (a and b) annual, (c and d) warm, and (e and f) cold season at different soil depths at BLH site.

● Sensitivities of physical processes and general behaviors of parameterizations

Figure S13. Distinction level for overall accuracy (OA) of snow cover events (SCEs) during the annual, warm, and cold seasons in the ensemble simulations at BLH site.

Limits of the boxes represent upper and lower quartiles, lines in the box indicate the median value.

Figure S14. Distinction level for RMSE of ST at different layers during the annual, warm, and cold seasons in the ensemble simulations at BLH site. Limits of the boxes represent upper and lower quartiles, lines in the box indicate the median value.

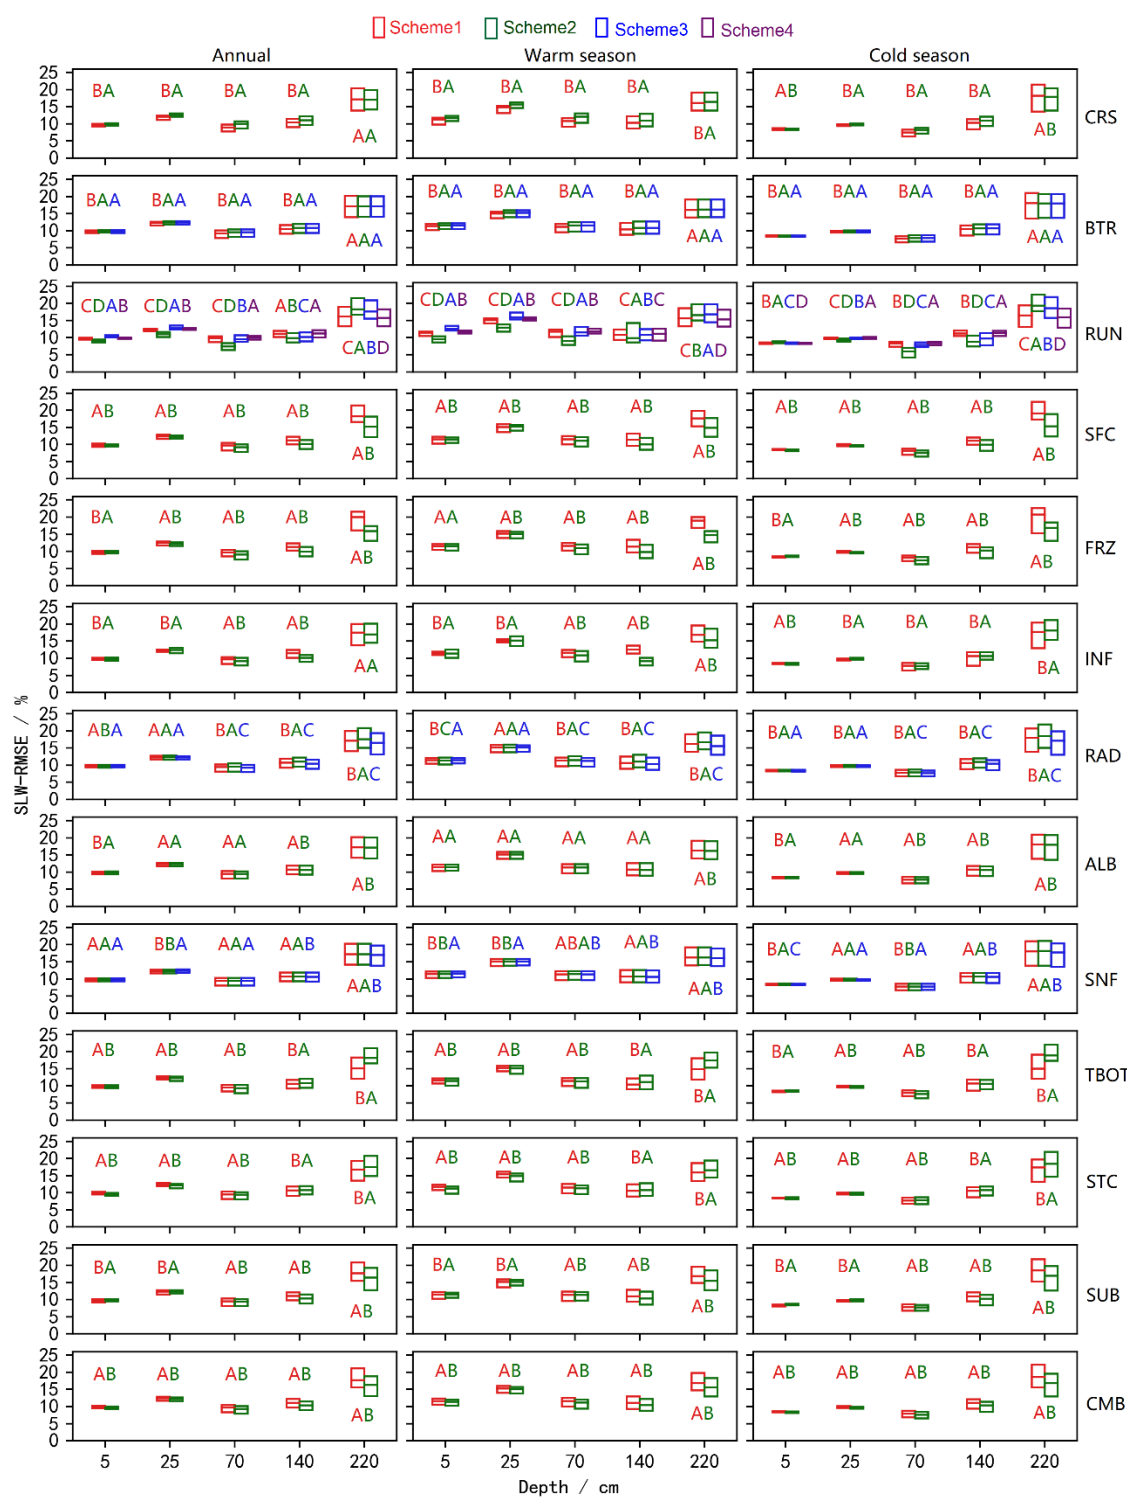

Figure S15. Distinction level for RMSE of SH2O at different layers during the annual, warm, and cold seasons in the ensemble simulations at BLH site. Limits of the boxes represent upper and lower quartiles, lines in the box indicate the median value.

Figure S16. Uncertainty interval of ground albedo at BLH site in dominant physical processes (STC and SUB) for snow cover event simulation.

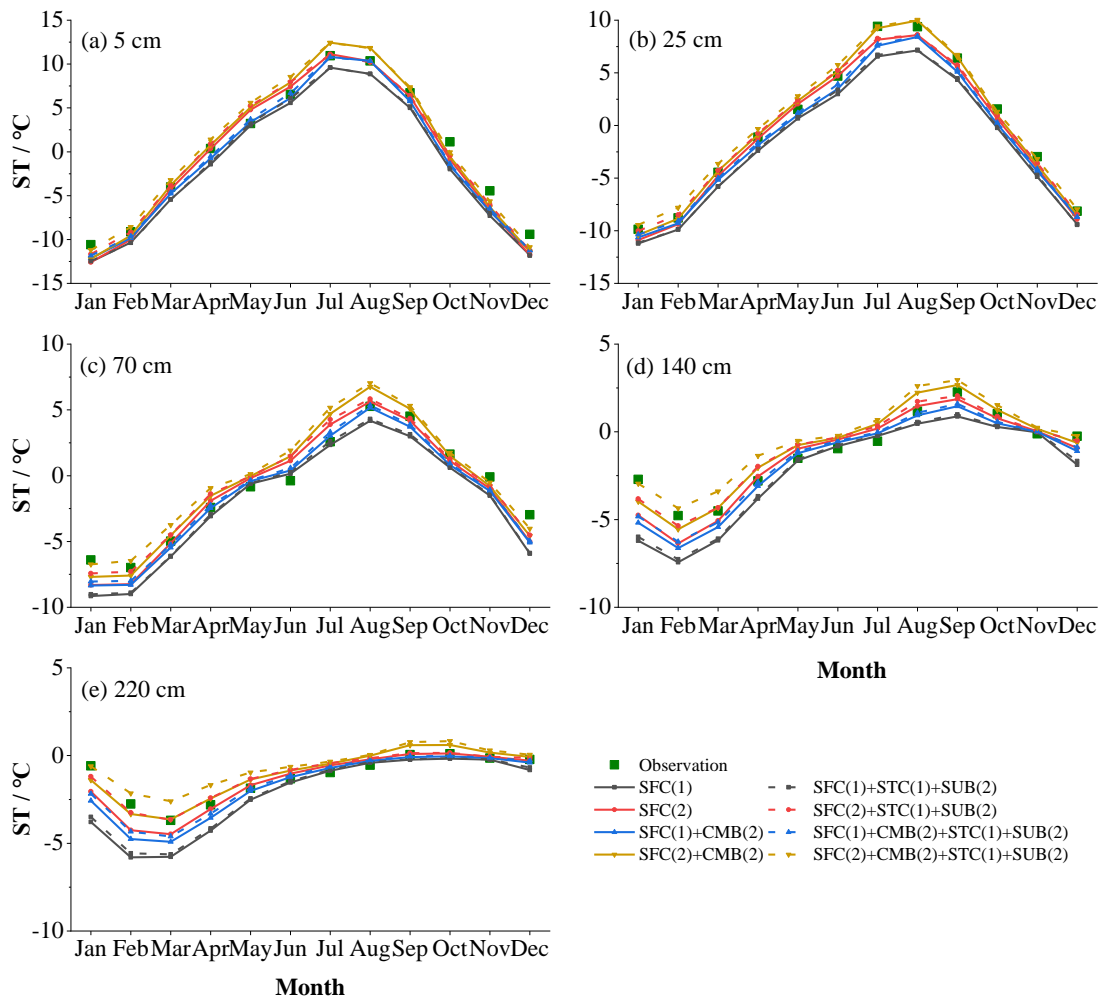

Figure S17. Monthly soil temperature (ST in °C) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d)

140 cm, (e) 220 cm, (f) 300 cm for the SFC process that consider the CMB(2) and STC(1)+SUB(2) processes or not.
