17 **Abstract.** Extensive and rigorous model inter-comparison is of great importance before
18 application due to the uncertainties in current land surface models (LSMs). Without
19 considering the uncertainties of forcing data and model parameters, this study designed
20 an ensemble of 55296 experiments to evaluate the Noah land surface model with multi-
21 parameterization (Noah-MP) for snow cover events (SCEs), soil temperature (ST) and
22 soil liquid water (SLW) simulation, and investigated the sensitivity of parameterization
23 schemes at a typical permafrost site on the Qinghai-Tibet Plateau. The results showed
24 that Noah-MP systematically overestimates snow cover, which could be greatly
25 resolved when adopting the sublimation from wind and semi-implicit snow/soil
26 temperature time scheme. As a result of the overestimated snow, Noah-MP generally
27 underestimates ST and ST is mostly influenced by the snow process. Systematic cold
28 bias and large uncertainties of soil temperature remains after eliminating the effects of
29 snow, particularly at the deep layers and during the cold season. The combination of
30 roughness length for heat and under-canopy aerodynamic resistance contributes to
31 resolve the cold bias of soil temperature. In addition, Noah-MP generally
32 underestimates top SLW. The RUN process dominates the SLW simulation in
33 comparison of the very limited impacts of all other physical processes. The analysis of
34 the model structural uncertainties and characteristics of each scheme would be
35 constructive to a better understanding of the land surface processes in the permafrost
36 regions of the QTP and further model improvements towards soil hydrothermal regime
37 modeling using the LSMs.

38

39 1 Introduction

40 The Qinghai-Tibet Plateau (QTP) is underlain by the world's largest high-altitude
41 permafrost covering a contemporary area of $1.06 \times 10^6 \text{ km}^2$ (Zou et al., 2017). Under
42 the background of climate warming and intensifying human activities, soil
43 hydrothermal dynamics in the permafrost regions on the QTP has been widely suffering
44 from soil warming (Wang et al., 2021), soil wetting (Zhao et al., 2019), and changes in
45 soil freeze-thaw cycle (Luo et al., 2020). Such changes have not only induced the
46 reduction of permafrost extent, disappearing of permafrost patches and thickening of
47 active layer (Chen et al., 2020), but also resulted in alterations in hydrological cycles
48 (Zhao et al., 2019; Woo, 2012), changes of ecosystem (Fountain et al., 2012; Yi et al.,
49 2011) and damages to infrastructures (Hjort et al., 2018). Therefore, it is very important
50 to monitor and simulate the soil hydrothermal regime to adapt to the changes taking
51 place.

52 A number of monitoring sites have been established in the permafrost regions of
53 the QTP (Cao et al., 2019). However, it is inadequate to construct the soil hydrothermal
54 state by considering the spatial variability of the ground thermal regime and an uneven
55 distribution of these observations. In contrast, numerical models are competent
56 alternatives. In recent years, land surface models (LSMs), which describe the exchanges
57 of heat, water, and momentum between the land and atmosphere (Maheu et al., 2018),
58 have received significant improvements in the representation of permafrost and frozen
59 ground processes (Koven et al., 2013; Nicolsky et al., 2007; Melton et al., 2019). LSMs
60 are capable of simulating the transient change of subsurface hydrothermal processes
61 (e.g. soil temperature and moisture) with soil heat conduction (-diffusion) and water
62 movement equations (Daniel et al., 2008). Moreover, they could be integrated with the
63 numerical weather prediction system like WRF (Weather Research and Forecasting),
64 making them as effective tools for comprehensive interactions between climate and
65 permafrost (Nicolsky et al., 2007).

66 Some LSMs have been evaluated and applied in the permafrost regions of the QTP.
67 Guo and Wang (2013) investigated near-surface permafrost and seasonally frozen

68 ground states as well as their changes using the Community Land Model, version 4
69 (CLM4). Hu et al. (2015) applied the coupled heat and mass transfer model to identify
70 the hydrothermal characteristics of the permafrost active layer in the Qinghai-Tibet
71 Plateau. Using an augmented Noah LSM, Wu et al. (2018) modeled the extent of
72 permafrost, active layer thickness, mean annual ground temperature, depth of zero
73 annual amplitude and ground ice content on the QTP in 2010s. Despite those
74 achievements based on different models, LSMs are in many aspects insufficient in
75 permafrost regions. For one thing, large uncertainties still exist in the state-of-the-art
76 LSMs when simulating the soil hydrothermal regime on the QTP (Chen et al., 2019).
77 For instance, 19 LSMs in CMIP5 overestimate snow depth over the QTP (Wei and Dong,
78 2015), which could result in the variations of the soil hydrothermal regime in the aspects
79 of magnitude and vector (cooling or warming) (Zhang, 2005). Moreover, most of the
80 existing LSMs are not originally developed for permafrost regions. Many of their soil
81 processes are designed for shallow soil layers (Westermann et al., 2016), but permafrost
82 would occur in the deep soil. And the soil column is often considered homogeneous,
83 which cannot represent the stratified soil common on the QTP (Yang et al., 2005). Given
84 the numerous LSMs and possible deficiencies, it is necessary to assess the
85 parameterization schemes for permafrost modeling on the QTP, which is helpful to
86 identify the influential sub-processes, enhance our understanding of model behavior,
87 and guide the improvement of model physics (Zhang et al., 2016).

88 Noah land surface model with multi-parameterization (Noah-MP) provides a
89 unified framework in which a given physical process can be interpreted using multiple
90 optional parameterization schemes (Niu et al., 2011). Due to the simplicity in selecting
91 alternative schemes within one modeling framework, it has been attracting increasing
92 attention in inter-comparison work among multiple parameterizations at point and
93 watershed scales (Hong et al., 2014; Zheng et al., 2017; Gan et al., 2019; Zheng et al.,
94 2019; Chang et al., 2020; You et al., 2020a). For example, Gan et al. (2019) carried out
95 an ensemble of 288 simulations from multi-parameterization schemes of six physical
96 processes, assessed the uncertainties of parameterizations in Noah-MP, and further

97 revealed the best-performing schemes for latent heat, sensible heat and terrestrial water
98 storage simulation over ten watersheds in China. You et al. (2020b) assessed the
99 performance of Noah-MP in simulating snow process at eight sites over distinct snow
100 climates and identified the shared and specific sensitive parameterizations at all sites,
101 finding that sensitive parameterizations contribute most of the uncertainties in the
102 multi-parameterization ensemble simulations. Nevertheless, there is little research on
103 the inter-comparison of soil hydrothermal processes in the permafrost regions. In this
104 study, an ensemble experiment of totally 55296 scheme combinations was conducted
105 at a typical permafrost monitoring site on the QTP. The simulated snow cover events
106 (SCEs), soil temperature (ST) and soil liquid water (SLW) of Noah-MP model was
107 assessed and the sensitivities of parameterization schemes at different depths were
108 further investigated. This study could be expected to present a reference for soil
109 hydrothermal simulation in the permafrost regions on the QTP.

110 This article is structured as follows: Section 2 introduces the study site,
111 atmospheric forcing data, design of ensemble simulation experiments, and sensitivity
112 analysis methods. Section 3 describes the ensemble simulation results of SCEs, ST and
113 SLW, explores the sensitivity and interactions of parameterization schemes. Section 4
114 discusses the schemes in each physical process. Section 5 concludes the main findings.

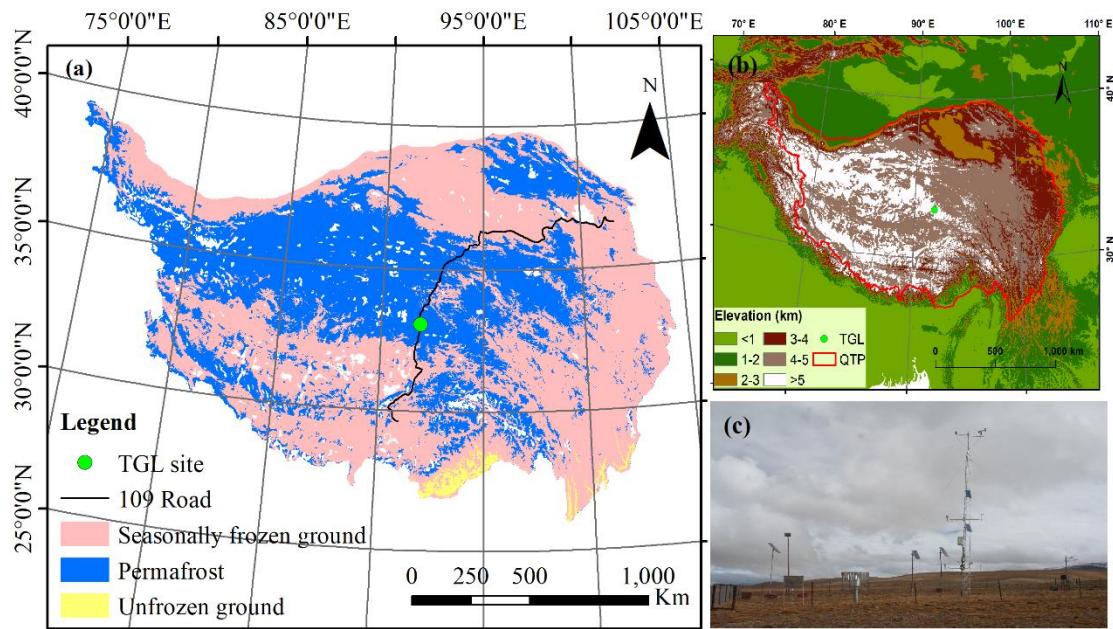

115 **2 Methods and materials**

116 **2.1 Site description and observation datasets**

117 Tanggula observation station (TGL) lies in the continuous permafrost regions of
118 Tanggula Mountain, central QTP (33.07° N, 91.93° E, Alt.: 5,100 m a.s.l; Fig. 1). This
119 site a typical permafrost site on the plateau with sub-frigid and semiarid climate (Li et
120 al., 2019), filmy and discontinuous snow cover (Che et al., 2019), sparse grassland (Yao
121 et al., 2011), coarse soil (Wu and Nan, 2016; He et al., 2019), and thick active layer
122 (Luo et al., 2016), which are common features in the permafrost regions of the plateau.
123 According to the observations from 2010–2011, the annual mean air temperature of

124 TGL site was -4.4°C . The annual precipitation was 375 mm, and of which 80 % is
 125 concentrated between May and September. Alpine steppe with low height is the main
 126 land surface, whose coverage range is about 40 % \sim 50 % (Yao et al., 2011). The active
 127 layer thickness is about 3.15 m (Hu et al., 2017).

128 The atmospheric forcing data, including wind speed/direction, air
 129 temperature/relative humidity/pressure, downward shortwave/longwave radiation, and
 130 precipitation, were used to drive the model. These variables above were measured at a
 131 height of 2 m and covered the period from August 10, 2010 to August 10, 2012 (Beijing
 132 time) with a temporal resolution of 1 hour. Daily soil temperature and liquid moisture
 133 at depths of 5 cm, 25 cm, 70 cm, 140 cm, 220 cm and 300 cm from August 10, 2010 to
 134 August 9, 2011 (Beijing time) were utilized to validate the simulation results.

135

 137 site and permafrost distribution (Zou et al., 2017). (b) Topography of the Qinghai-Tibet
 138 Plateau. (c) Photo of the Tanggula observation station.

139 **2.2 Ensemble experiments of Noah-MP**

140 The offline Noah-MP LSM v1.1 was assessed in this study. The default Noah-MP
 141 consists of 12 physical processes that are interpreted by multiple optional

142 parameterization schemes. These sub-processes include vegetation model (VEG),
143 canopy stomatal resistance (CRS), soil moisture factor for stomatal resistance (BTR),
144 runoff and groundwater (RUN), surface layer drag coefficient (SFC), super-cooled
145 liquid water (FRZ), frozen soil permeability (INF), canopy gap for radiation transfer
146 (RAD), snow surface albedo (ALB), precipitation partition (SNF), lower boundary of
147 soil temperature (TBOT) and snow/soil temperature time scheme (STC) (Table 1).
148 Details about the processes and optional parameterizations can be found in Yang et al.
149 (2011a).

150 VEG(1) is adopted in the VEG process, in which the vegetation fraction is
151 prescribed according to the NESDIS/NOAA 0.144 degree monthly 5-year climatology
152 green vegetation fraction (<https://www.emc.ncep.noaa.gov/mmb/gcip.html>), and the
153 monthly leaf area index (LAI) was derived from the Advanced Very High-Resolution
154 Radiometer (AVHRR) (<https://www.ncei.noaa.gov/data/>, Claverie et al., 2016).
155 Previous studies has confirmed that Noah-MP seriously overestimate the snow events
156 and underestimate soil temperature and moisture on the QTP (Jiang et al., 2020; Li et
157 al., 2020; Wang et al., 2020), which can be greatly resolved by considering the
158 sublimation from wind (Gordon scheme) and a combination of roughness length for
159 heat and under-canopy aerodynamic resistance (Y08-UCT) (Zeng et al., 2005; Yang et
160 al., 2008; Li et al., 2020). For a more comprehensive assessment, we added two physical
161 processes based on the default Noah-MP model, i.e. the snow sublimation from wind
162 (SUB) and the combination scheme process (CMB) (Table 1). In the two processes,
163 users can choose to turn on the Gordon and Y08-UCT scheme (described in the study
164 of Li et al., 2020) or not. As a result, in total 55296 combinations are possible for the
165 13 processes and orthogonal experiments were carried out to evaluate their performance
166 in soil hydrothermal dynamics.

167 The Noah-MP model was modified to consider the vertical heterogeneity in the
168 soil profile by setting the corresponding soil parameters for each layer. The soil
169 hydraulic parameters, including the porosity, saturated hydraulic conductivity,
170 hydraulic potential, the Clapp-Hornberger parameter b, field capacity, wilt point, and

171 saturated soil water diffusivity, were determined using the pedotransfer functions
 172 proposed by Hillel (1980), Cosby et al. (1984), and Wetzel and Chang (1987)
 173 (Equations S1-S7), in which the sand and clay percentages were based on Hu et al.,
 174 (2017) (Table S1). In addition, the simulation depth was extended to 8.0 m to cover the
 175 active layer thickness of the QTP. The soil column was discretized into 20 layers, whose
 176 depths follow the default scheme in CLM 5.0 (Table S1, Lawrence et al., 2018). Due to
 177 the inexact match between observed and simulated depths, the simulations at 4 cm, 26
 178 cm, 80 cm, 136 cm, 208 cm and 299 cm were compared with the observations at 5 cm,
 179 25 cm, 70 cm, 140 cm, 220 cm and 300 cm, respectively. A 30-year spin-up was
 180 conducted in every simulation to reach equilibrium soil states.

181 **Table 1.** The physical processes and options of Noah-MP.

Physical processes	Options
Vegetation model (VEG)	(1) table LAI, prescribed vegetation fraction (2) dynamic vegetation (3) table LAI, calculated vegetation fraction (4) table LAI, prescribed max vegetation fraction
Canopy stomatal resistance (CRS)	(1) Jarvis (2) Ball-Berry
Soil moisture factor for stomatal resistance (BTR)	(1) Noah (2) CLM (3) SSiB
Runoff and groundwater (RUN)	(1) SIMGM with groundwater (2) SIMTOP with equilibrium water table (3) Noah (free drainage) (4) BATS (free drainage)
Surface layer drag coefficient (SFC)	(1) Monin-Obukhov (M-O) (2) Chen97
Super-cooled liquid water (FRZ)	(1) generalized freezing-point depression (2) Variant freezing-point depression
Frozen soil permeability (INF)	(1) Defined by soil moisture, more permeable (2) Defined by liquid water, less permeable
Canopy gap for radiation transfer (RAD)	(1) Gap=F(3D structure, solar zenith angle) (2) Gap=zero (3) Gap=1-vegetated fraction
Snow surface albedo (ALB)	(1) BATS (2) CLASS
Precipitation partition (SNF)	(1) Jordan91 (2) BATS: $T_{sfc} < T_{frz} + 2.2K$ (3) $T_{sfc} < T_{frz}$

Lower boundary of soil temperature (TBOT)	(1) zero heat flux (2) soil temperature at 8m depth
Snow/soil temperature time scheme (STC)	(1) semi-implicit (2) full implicit
Snow sublimation from wind (SUB)	(1) No (2) Yes
Combination scheme by Li et al.(2020) (CMB)	(1) No (2) Yes

182 BATS (Biosphere–Atmosphere Transfer Model); CLASS (Canadian Land Surface Scheme);
 183 SIMGM (Simple topography-based runoff and Groundwater Model); SIMTOP (Simple
 184 Topography-based hydrological model); SSiB (Simplified Simple Biosphere model).

185 **2.3 Methods for sensitivity analysis**

186 The simulated snow cover events (SCEs) was quantitatively evaluated using the
 187 overall accuracy index (OA) (Toure et al., 2016):

$$188 \quad OA = \frac{a + d}{a + b + c + d}$$

189 where a is the positive hits, b represents the false alarm, c is the misses, and d
 190 represents the negtive hits. The value of OA range from 0 to 1. A higher OA signifies
 191 better performance. Ground albedo was used as an indicator for snow events due to a
 192 lack of snow depth observations. The days when the daily mean albedo is greater than
 193 the observed mean value of the warm and cold season (0.25 and 0.30, respectively) are
 194 identified as snow cover.

195 The root mean square error (RMSE) between the simulations and observations
 196 were adopted to evaluate the performance of Noah-MP in simulating soil hydrothermal
 197 dynamics.

198 To investigate the influence degrees of each physical process on SCEs, ST and
 199 SLW, we firstly calculated the mean OA (for SCE) and mean RMSE (for ST and SLW)
 200 (\bar{Y}_j^i) of the j th parameterization schemes ($j = 1, 2, \dots$) in the i th process ($i = 1, 2, \dots$).

201 Then, the maximum difference of \bar{Y}_j^i ($\Delta \bar{OA}$ or $\Delta \bar{RMSE}$) was defined to quantify the
 202 sensitivity of the i th process ($i = 1, 2, \dots$) (Li et al., 2015):

$$203 \quad \Delta \bar{OA} \text{ or } \Delta \bar{RMSE} = \bar{Y}_{max}^i - \bar{Y}_{min}^i$$

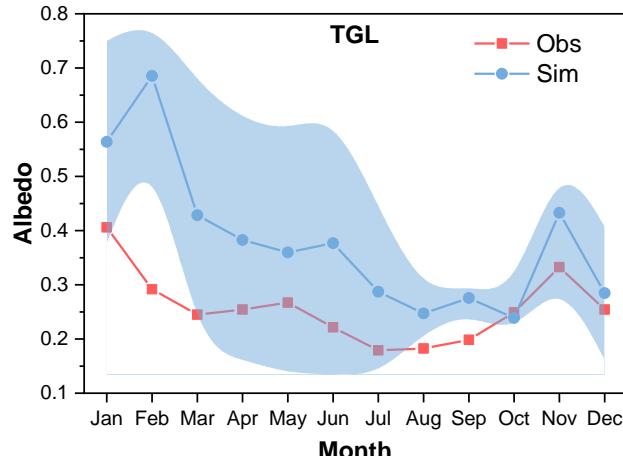

204 where \bar{Y}_{max}^i and \bar{Y}_{min}^i are the largest and the smallest \bar{Y}_j^i in the i th process,
205 respectively. For a given physical process, a high $\Delta\overline{OA}$ or $\Delta\overline{RMSE}$ signifies large
206 difference between parameterizations, indicating high sensitiveness of the i th process
207 for SCEs and ST/SLW simulation.

208 The sensitivities of physical processes were determined by quantifying the
209 statistical distinction level of performance between parameterization schemes. The
210 Independent-sample T-test (2-tailed) was adopted to identify whether the distinction
211 level between two schemes is significant, and that between three or more schemes was
212 tested using the Tukey's test. Tukey's test has been widely used for its simple
213 computation and statistical features (Benjamini, 2010). The detailed descriptions about
214 this method can be found in Zhang et al. (2016), Gan et al. (2019), and You et al. (2020a).
215 A process can be considered sensitive when the schemes show significant difference.
216 Moreover, schemes with large mean OA and small mean RMSE were considered
217 favorable for SCEs and ST/SLW simulation, respectively. We distinguished the
218 differences of the parameterization schemes at 95 % confidence level.

219 **3 Results**

220 **3.1 General performance of the ensemble simulation**

221 The performance of Noah-MP for snow simulation was firstly tested by conducting
222 an ensemble of 55296 experiments. Due to a lack of snow depth measurements, ground
223 albedo was used as an indicator for snow cover. Figure 2 shows the monthly variations
224 of observed ground albedo and the simulations produced by the ensemble simulations.
225 The ground albedo was extremely overestimated with large uncertainties when
226 considering the snow options in Noah-MP, indicating the overestimation of snow depth
227 and duration. Such overestimation continued till July.

228

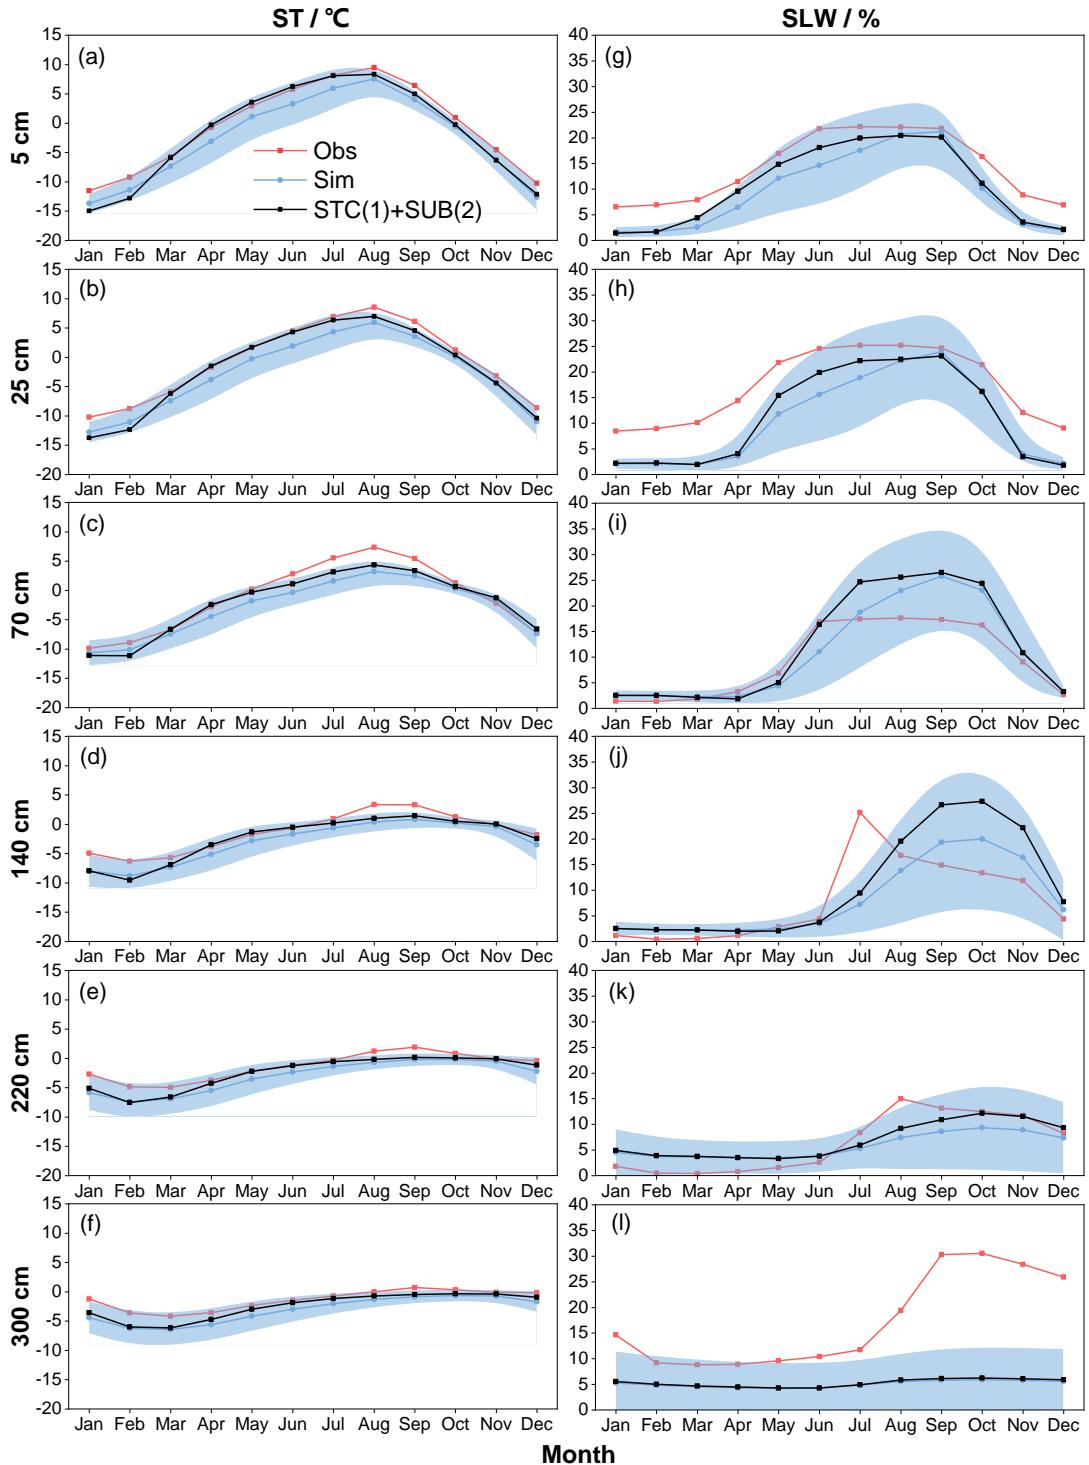

229 **Figure 2.** Monthly variations of ground albedo at TGL site for observation (Obs), and
 230 the ensemble simulation (Sim). The light blue shadow represents the standard deviation
 231 of the ensemble simulation.

232 Figure 3 illustrates the ensemble simulated and observed annual cycle of ST and
 233 SLW at TGL site. The ensemble experiments basically captured the seasonal variability
 234 of ST, whose magnitude decreased with soil depth. In addition, the simulated ST in the
 235 snow-affected season (October-July) showed relatively wide uncertainty ranges,
 236 particularly at the shallow layers. This indicates that the selected schemes perform
 237 much differently for snow simulation, resulting in large uncertainties of shallow STs.
 238 The simulated ST were generally smaller than the observations with relatively large
 239 gaps during the snow-affected season. It indicates that the Noah-MP model generally
 240 underestimates the ST, especially during the snow-affected months.

241 Since the observation equipment can only record the liquid water, soil liquid water
 242 (SLW) was evaluated against simulations from the ensemble experiments (Fig. 3). The
 243 Noah-MP model generally underestimated surface (5 cm and 25 cm) and deep (220 cm
 244 and 300 cm) SLW (Fig. 3g, 3h, 3k, 3l). However, Noah-MP tended to overestimate the
 245 SLW at the middle layers of 70 cm and 140 cm. Moreover, the simulated SLW exhibited
 246 relatively wide uncertainty ranges, particularly during the warm season (Fig. 3).

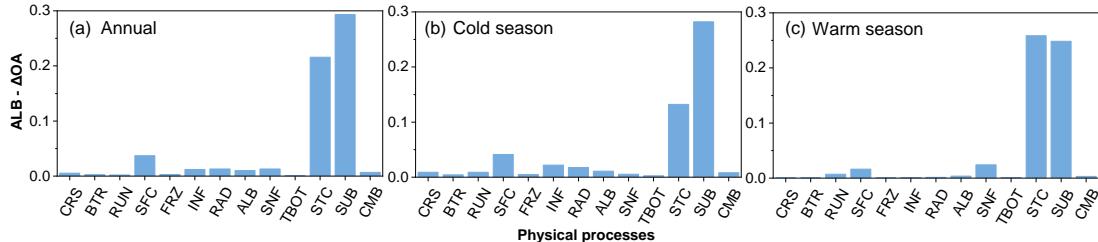

247

248

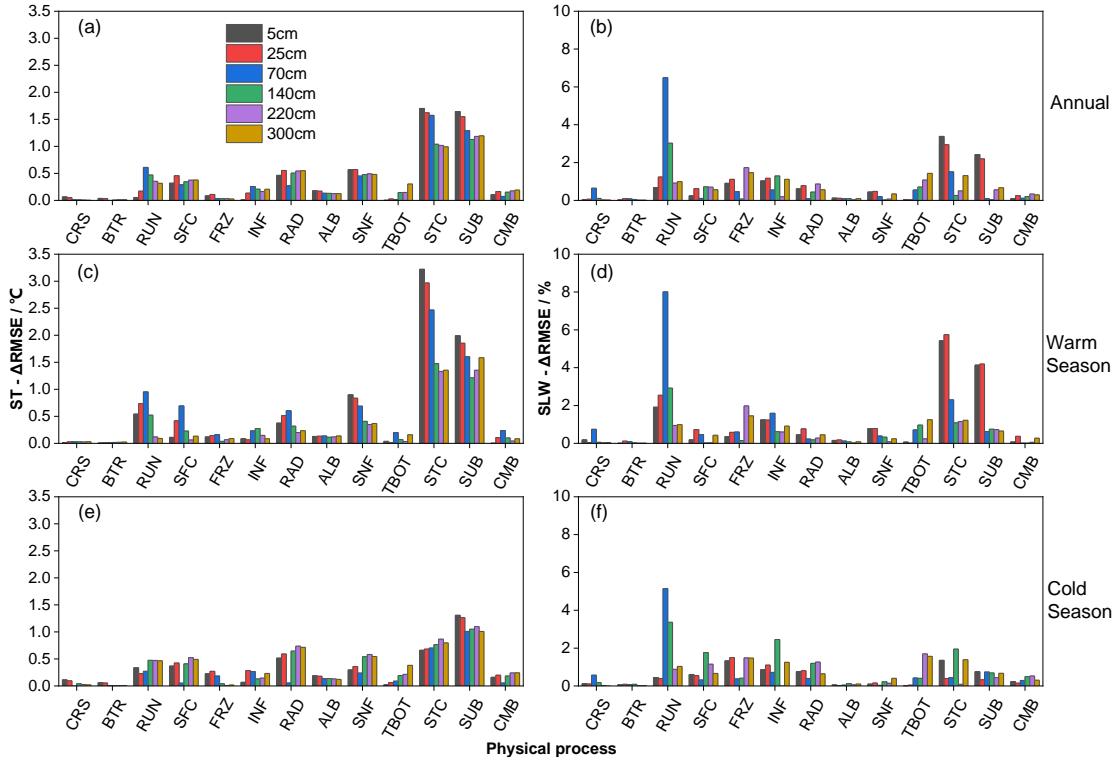

249

250 **Figure 3.** Monthly soil temperature (ST in °C) and soil liquid water (SLW in %) at (a,
 251 (b, h) 5 cm, (c, i) 25 cm, (d, j) 70 cm, (e, k) 140 cm, (f, l) 220 cm, (g, l) 300 cm at TGL
 252 site. The light blue shadow represents the standard deviation of the ensemble simulation.
 253 The black line-symbol represents the ensemble mean of simulations with STC(1) and
 254 SUB(2).

255 **3.2 Sensitivity of physical processes**256 **3.2.1 Influence degrees of physical processes**

257
258 **Figure 4.** The maximum difference of the mean overall accuracy (OA) for albedo
259 (ALB- Δ OA) in each physical process during the (a) annual, (b) cold season, and (c)
260 warm season at TGL site.

261 Figure. 4 compares the influence scores of the 13 physical processes based on the
262 maximum difference of the mean OA over 55296 experiments using the same scheme,
263 for SCEs at TGL site. On the whole, the SUB and STC processes had the largest scores
264 for the whole year as well as during both the warm and cold seasons, and the other
265 processes showed a value less than 0.05 (Fig. 4a, 4b, 4c). Moreover, the SUB process
266 had a consistent influence on SCEs while the influence of STC differed with season. In
267 the cold season, the score of SUB process (0.28) was two times more than that of the
268 STC process (Fig. 4b), indicating the relative importance of snow sublimation for SCEs
269 simulation during the cold season. When it comes to the warm season, the influence
270 score of SUB (0.25) did not change much, while that of STC increased to 0.26 and
271 showed a similar influence on SCEs simulation with SUB.

272

273 **Figure 5.** The maximum difference of the mean RMSE for (a, c and e) soil temperature
 274 (ST- $\Delta\overline{RMSE}$ in $^{\circ}\text{C}$) and (b, d and f) soil liquid water (SLW- $\Delta\overline{RMSE}$ in %) in each
 275 physical process during the (a and b) annual, (c and d) warm, and (e and f) cold season
 276 at different soil depths at TGL site.

277 Figure 5 compares the influence scores of the 13 physical processes at different
 278 soil depths, based on the maximum difference of the mean RMSE over 55296
 279 experiments using the same scheme, for ST and SLW at TGL site. The snow-related
 280 processes, including the STC, SUB and SNF process showed the largest ST- $\Delta\overline{RMSE}$ at
 281 all layers, followed by the RAD, SFC and RUN processes. While the ST- $\Delta\overline{RMSE}$ of
 282 the other 7 physical processes were less than 0.5°C , among which the influence of CRS
 283 and BTR processes were negligible. What's more, the FRZ, INF, and TBOT processes
 284 had larger influence scores during the cold season than warm season, and the scores of
 285 TBOT were greater in deep soils than shallow soils. During the warm season, the
 286 physical processes generally showed more influence on shallow soil temperatures.
 287 When it comes to the cold season, the influence of the physical processes on deep layers
 288 obviously increased and comparable with that on shallow layers, implying the relatively
 289 higher uncertainties of Noah-MP during the cold season.

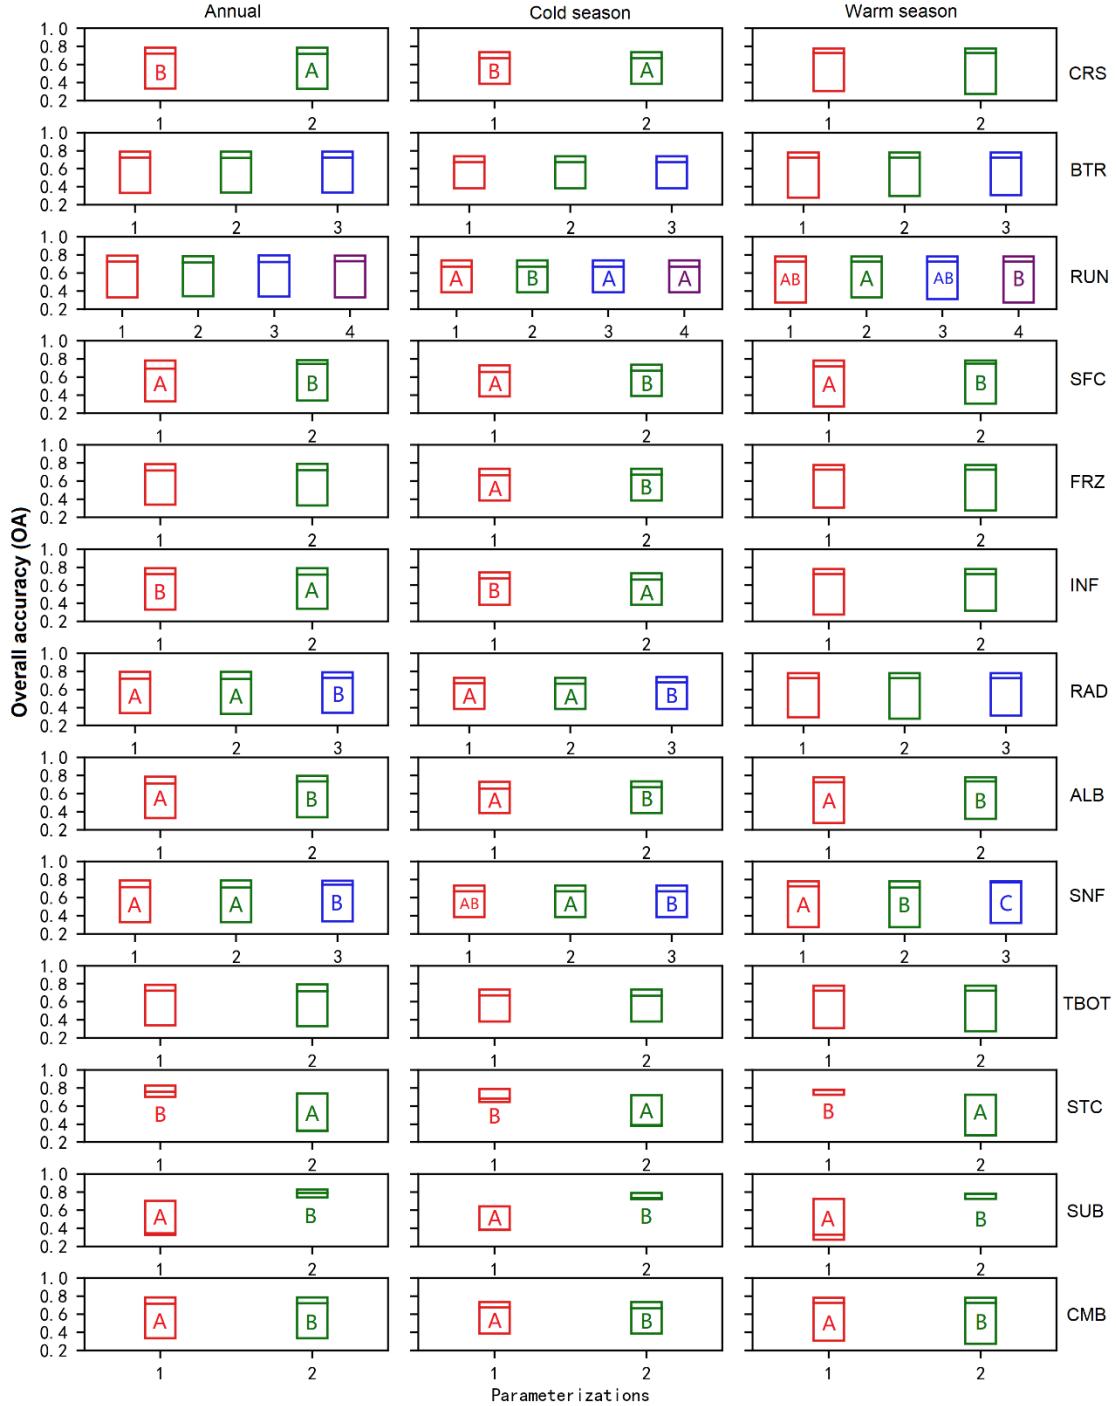

290 Most of the $\Delta\overline{RMSE}$ for SLW are less than 5 %, indicating that all the physical
291 processes have limited influence on the SLW, among which CRS, BTR, ALB, SNF, and
292 CMB showed the smallest effects on SLW (Fig. 5b, 5d, 5f). During the warm season,
293 the RUN process, together with the STC and SUB processes, dominated the
294 performance of SLW simulation, especially at shallow layers (5 cm, 25 cm and 70 cm,
295 Fig. 5d). During the cold season, however, the RUN process dominated the SLW
296 simulation with a great decline of dominance of STC and SUB processes.

297 **3.2.2 Sensitivities of physical processes and general behaviors of
298 parameterizations**

299 To further investigate the sensitivity of each process and the general performance
300 of the parameterizations, the Independent-sample T-test (2-tailed) and Tukey's test were
301 conducted to test whether the difference between parameterizations within a physical
302 process is significant (Fig. 6 and 7). In a given sub-process, any two schemes labelled
303 with different letters behave significantly different, and this sub-process therefore can
304 be identified as sensitive. Otherwise, the sub-process is considered insensitive. For
305 simplicity, schemes of insensitive sub-process are not labeled. Moreover, schemes with
306 the letters late in the alphabet have smaller mean RMSEs and outperform the ones with
307 the letters forward in the alphabet. Using the two schemes in CRS process (hereafter
308 CRS(1) and CRS(2)) in Fig. 6 as an example. For the annual and warm season, CRS(1)
309 and CRS(2) were labeled with "B" and "A", respectively. In the cold season, none of
310 them were labeled with letters. As described above, the CRS process was sensitive for
311 SCEs simulation during the annual and warm season, and CRS(1) outperformed
312 CRS(2). However, it was not sensitive during the cold season.

313 Consistent with the influence degrees in Fig. 4, the performance difference
314 between schemes of the STC and SUB for SCEs simulation were significantly greater
315 than other processes. Most other physical processes showed significant but limited
316 difference. Schemes in BTR and TBOT processes, however, had no significant different
317 performance. Specifically, the performance order followed STC(1)>STC(2), SUB(2)>
318 SUB(1), SFC(2)>SFC(1), ALB(2)>ALB(1), CMB(2)>CMB(1) in both annual and

319 seasonal scales. RAD showed no obvious difference during the warm season, while
 320 RAD(3) outperformed RAD(1) and (2) during the cold season. For SNF, SNF(3)
 321 generally excel SNF(1) and SNF(2), especially during the warm season.

322
 323 **Figure 6.** Distinction level for overall accuracy (OA) of snow cover events (SCEs)
 324 during the annual, warm, and cold seasons at TGL site. Limits of the boxes represent
 325 upper and lower quartiles, lines in the box indicate the median value.

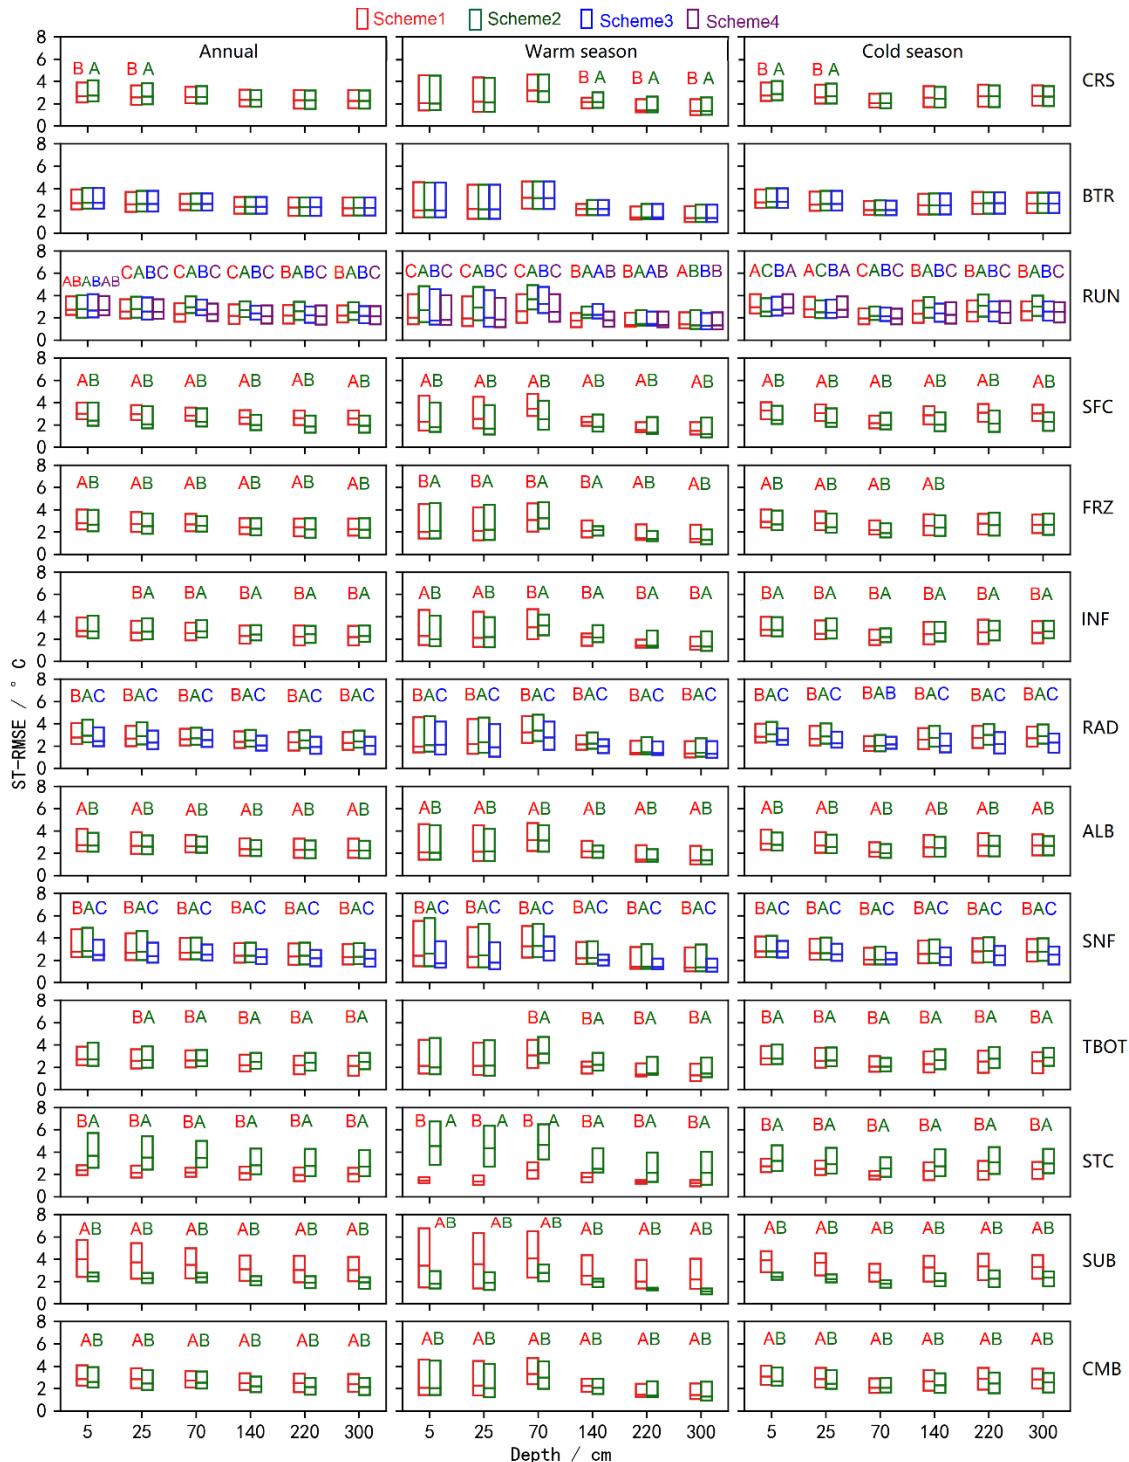

326 All the physical processes showed sensitivities for ST and SLW simulation in

327 varying magnitudes except the BTR process and CRS process in most layers. For ST,
328 the performance difference between schemes of the STC, SUB and SNF were obviously
329 greater than other processes, indicating the importance of snow on ST, followed by the
330 RAD, SFC and RUN processes. The performance orders followed STC(1) > STC(2),
331 SUB(2) > SUB(1), SNF(3) > SNF(1) > SNF(2), RAD(3) > RAD(1) > RAD(2), and
332 SFC(2) > SFC(1). For SLW, the RUN, STC, and SUB processes showed significant and
333 higher sensitivities than other physical processes, especially during the warm season
334 and at the shallow layers (Fig. xx). Consistent with that of ST, the performance orders
335 for SLW simulation were STC(1) > STC(2), and SUB(2) > SUB(1). For the RUN
336 process, the performance orders for both ST and SLW simulation generally followed
337 RUN(4) > RUN(1) > RUN(3) > RUN(2) as a whole, among which RUN(1) and RUN(4)
338 presented similar performance during both warm and cold seasons. During both warm
339 and cold seasons, the performance orders for ST simulations were SFC(2) > SFC(1) for
340 SFC process, FRZ(2) > FRZ(1) for FRZ process, and RAD(3) > RAD(1) > RAD(2) for
341 RAD process (Fig. S2 and S3), which are particularly so for SLW simulations at shallow
342 and deep layers.

343 For ST, both FRZ and INF showed higher sensitivities during the cold season,
344 especially at shallow soils for FRZ and deep soils for INF. FRZ(2)/INF(1) outperformed
345 FRZ(1)/INF(2) for the whole year for ST simulation. Specifically, FRZ(1)/INF(2)
346 performed better at the shallow soils during the warm season while did worse during
347 the cold season compared with FRZ(2)/INF(1). For SLW, FRZ(2)/INF(2) generally
348 preceded FRZ(1)/INF(1) at shallow and deep soils (5 cm, 25 cm, 220 cm, and 300 cm)
349 while did worse at middle soil layers (140 cm and 220 cm).

350 For ST simulation, the performance sequence in RAD and SNF was RAD(3) >
351 RAD(1) > RAD(2) and SNF(3) > SNF(1) > SNF(2), respectively. For SLW simulation,
352 the sequence become complicated. However, RAD(3) and RAD(3) still outperformed
353 the other two schemes, respectively. ALB(2) was superior to ALB(1) for both ST and
354 SLW simulation. The influence of TBOT on soil hydrothermal arose at deep soils and
355 during cold season, and TBOT(1) excel TBOT(2). CMB(2) outperformed CMB(1) for

356 ST simulation, so did that for SLW simulation at shallow and deep soils (5 cm, 25 cm,
 357 and 300 cm).|

358
 359 **Figure 7.** Distinction level for RMSE of ST at different layers during the annual, warm,
 360 and cold seasons in the ensemble simulations at TGL site. Limits of the boxes represent
 361 upper and lower quartiles, lines in the box indicate the median value.

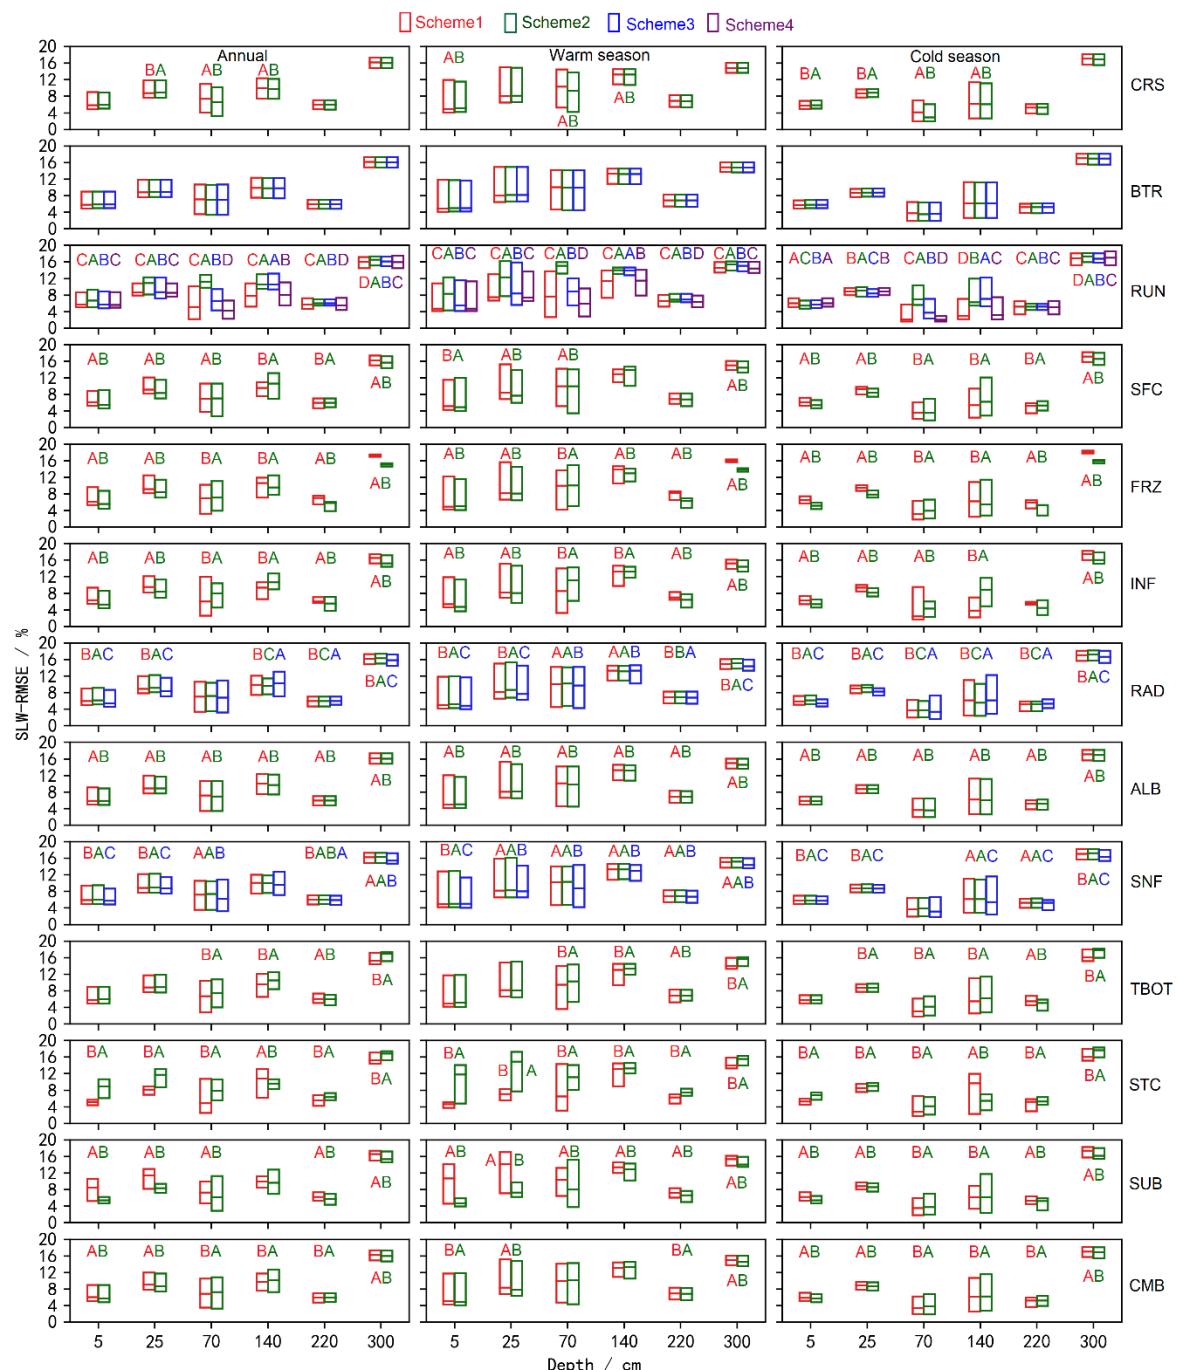

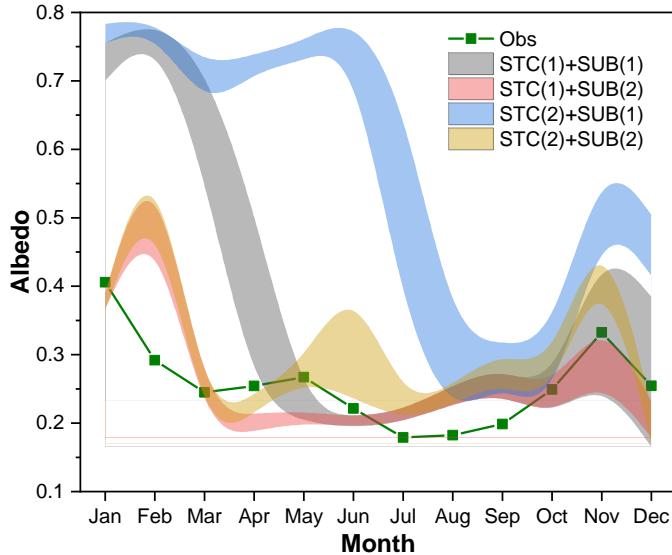

Figure 8. Same as in Figure 7 but for SLW.

365 **3.3 Influence of snow cover and surface drag coefficient on soil hydrothermal
366 dynamics**

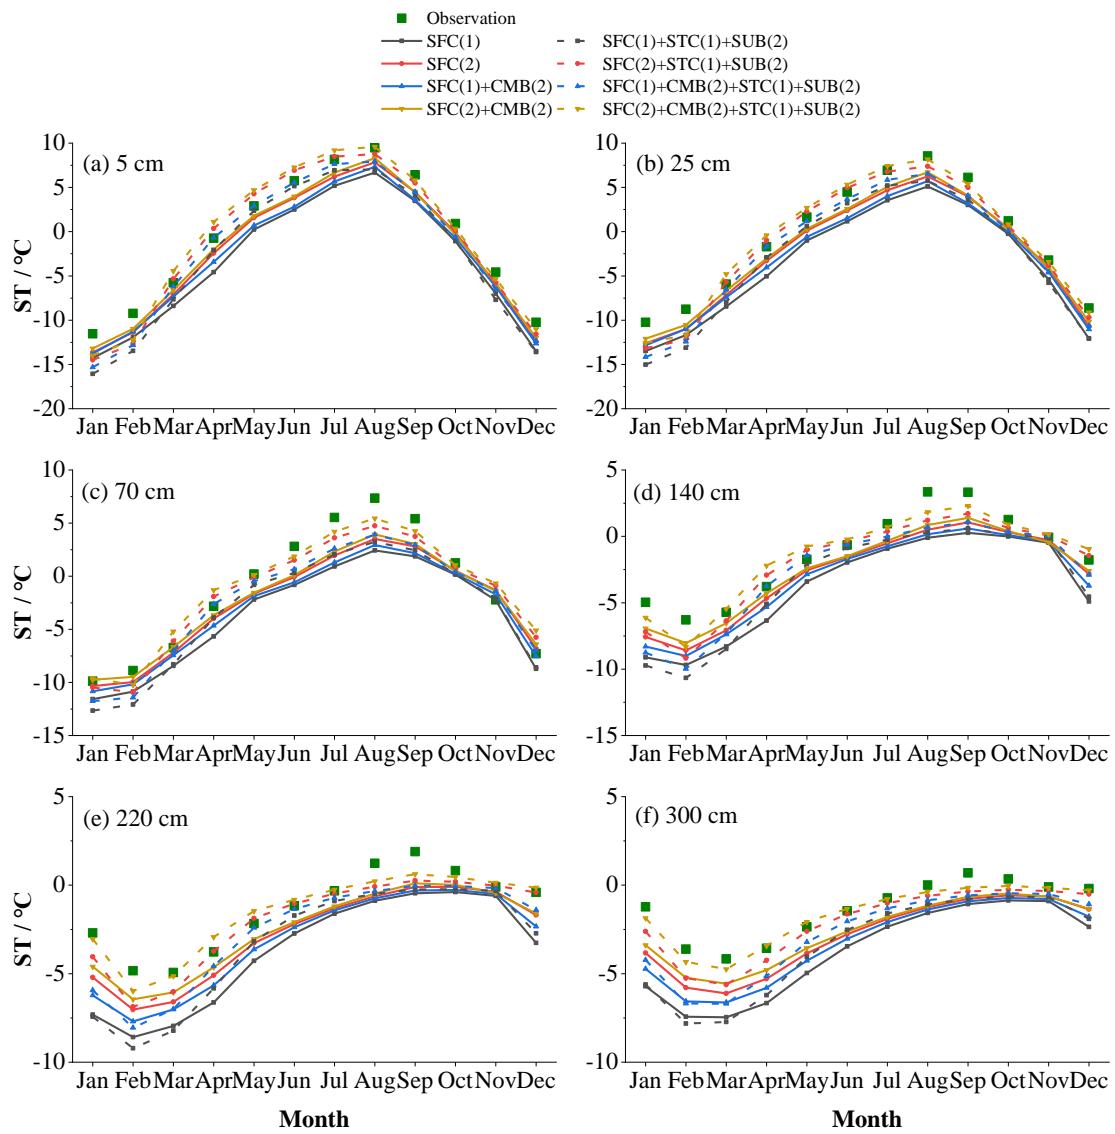

368

369 **Figure 9.** Uncertainty interval of ground albedo at TGL site in dominant physical
370 processes (STC and SUB) for snow cover event simulation.

371 The influence of snow on soil temperature is firstly investigated. The dominant
372 role of STC and SUB in the simulation of SCEs has been identified (Fig. 4 and 6).
373 Interactions between the two physical processes are further analyzed here. Figure 9
374 compares the uncertainty intervals of the two physics. The duration of snow cover is
375 the longest when STC(2)+SUB(1), followed when STC(2)+SUB(1). Simulations
376 considering SUB(2) generally has a short snow duration. Among the four combinations,
377 STC(1)+SUB(2) is in best agreement with the measurements.

378 Given the good performance of STC(1)+SUB(2) in simulating SCEs, the influence
379 of snow on soil hydrothermal dynamics is investigated by comparing the total ensemble
380 mean ST and SLW with those adopting STC(1)+SUB(2) (Fig. 3). It can be seen that the
381 ensemble mean ST of simulations adopting STC(1) and SUB(2) are generally higher
382 than the total ensemble means, especially during the spring and summer (Mar.-Aug.).
383 In January and February at shallow layers (5 cm, 25 cm and 70 cm), STC(1)+SUB(2)
384 had a lower ST and showed an insulation effect on ST during the two months. As a
385 whole, however, snow cover has a cooling effect on ST. In addition, along with the
386 improved SCEs and elevated ST, STC(1)+SUB(2) induced moister soil with higher
387 SLW (Fig. 3).

388

391 **Figure 10.** Monthly soil temperature (ST in °C) at (a) 5 cm, (b) 25 cm, (c) 70 cm, (d)
 392 140 cm, (e) 220 cm, (f) 300 cm for the SFC process that consider the CMB(2) and
 393 STC(1)+SUB(2) processes or not.

394 SFC and CMB process using different ways to calculate the surface drag
 395 coefficient, which is of great influence for surface energy partitioning and thus ST and
 396 SLW. The influence of surface drag coefficient is assessed by comparing the soil
 397 temperature before and after considering the combined scheme (CMB(2)) and the effect
 398 of snow (STC(1)+SUB(2)) (Fig. 10). SFC(2) tended to produce higher ST than SFC(1),
 399 especially during the warming period (January-August). When adopting the combined
 400 scheme of Y08 and UCT (CMB(2)), the cold bias were significantly resolved. The

401 performance order followed SFC(2)+CMB(2) > SFC(2) > SFC(1)+CMB(2) > SFC(1).
402 However, considerable underestimations of ST still exist at all layers due to the poor
403 representation of snow process. After eliminating the effects of snow (STC(1)+SUB(2),
404 dash lines in Fig. 10), the simulated ST accordingly increased except in January and
405 February. SFC(2) and SFC(2)+CMB(2) overestimated STs from March to July at
406 shallow layers (5 cm and 25 cm), resulting in good agreements of deep STs with
407 observations. In contrast, the simulated STs at shallow layers (5 cm and 25 cm) by
408 SFC(1) and SFC(1)+CMB(2) were basically consistent with observations from March
409 to July. While large cold bias remained at deep layers.

410 **4 Discussion**

411 **4.1 Snow cover on the QTP and its influence on soil hydrothermal regime**

412 Snow cover in the permafrost regions of the QTP is thin, patchy, and short-lived
413 (Che et al., 2019), whose influence on soil temperature and permafrost state is usually
414 considered weak (Jin et al., 2008; Zou et al., 2017; Wu et al., 2018; Zhang et al., 2018;
415 Yao et al., 2019). However, our ensemble simulations showed that the surface albedo
416 is extremely overestimated in both magnitude and duration (Fig. 2), implying an
417 extreme overestimation of snow cover, which is consistent with the studies using Noah-
418 MP model (Jiang et al., 2020; Li et al., 2020; Wang et al., 2020) and widely found in
419 other state-of-the-art LSMs (Wei and Dong, 2015) on the QTP.

420 Great efforts to resolve the overestimation of snow cover in LSMs include
421 considering the vegetation effect (Park et al., 2016), the snow cover fraction (Jiang et
422 al., 2020), the blowing snow (Xie et al., 2019), and the fresh snow albedo (Wang et al.
423 2020). Our results illustrated the superiority of considering the snow sublimation from
424 wind (SUB(2)) and using semi-implicit snow/soil temperature time scheme (STC(1))
425 (Fig. 4, 6 and 9) when simulating snow cover on the QTP. It is consistent with previous
426 conclusions that accounting for the loss resulting from wind contributes to improve
427 snow cover days and depth (Yuan et al., 2016), and that STC(1) has a rapid snow

428 ablation than STC(2) (You et al., 2020a).

429 The impacts of snow cover on soil temperature in magnitude and vector (cooling or
430 warming) depend on its timing, duration, and depth (Zhang et al., 2005). In January and
431 February, the ground heat flux mainly goes upward, the warming effect of simulated
432 snow can be related to the overestimated snow depth that prevent heat loss from the
433 ground. During the spring and summer when snow melts, the cooling effects occurs,
434 mainly because considerable energy that used to heat the ground is reflected due to the
435 high albedo of snow. With the improvement of snow (STC(1)+SUB(2)), the originally
436 overestimated snow melts and infiltrated into the soil, resulting in improved SLWs (Fig.
437 3). And higher soil temperature also contributed to the SLWs according to the freezing-
438 point depression equation, in which SLW exponentially increase with soil temperature
439 for a given site (Niu and Yang, 2006).

440 **4.2 Discussions on the sensitivity of physical processes on soil hydrothermal
441 simulation**

442 **4.2.1 Canopy stomatal resistance (CRS) and soil moisture factor for stomatal
443 resistance (BTR)**

444 The biophysical process BTR and CRS directly affect the canopy stomatal
445 resistance and thus the plant transpiration (Niu et al., 2011). The transpiration of plants
446 could impact the ST/SLW through its cooling effect (Shen et al., 2015) and the water
447 balance of root zone (Chang et al., 2020). However, the annual transpiration of alpine
448 steppe is weak due to the shallow effective root zone and lower stomatal control in this
449 dry environment (Ma et al., 2015), which may explain the indistinctive or very small
450 difference among the schemes of the BTR and CRS processes for SCEs (Fig. 8), ST
451 (Fig. 7) and SLW (Fig. 8).

452 **4.2.2 Runoff and groundwater (RUN)**

453 In the warm season, different SLWs would result in the difference of the surface
454 energy partitioning and thus different soil temperatures. RUN(2) had the worst

455 performance for simulating ST and SLW (Fig. 7 and 8) among the four schemes, likely
456 due to its higher estimation of soil moisture (Fig. S1) and thus greater sensible heat and
457 smaller ST (Gao et al., 2015). Likewise, RUN(4) was on a par with RUN(1) in the
458 simulation of ST at most layers due to the very small difference in SLW of two schemes
459 (Fig. 8 and S1). For the whole soil column, RUN(4) surpassed RUN(1) and RUN(2) for
460 SLW simulation, both of which define surface/subsurface runoff as functions of
461 groundwater table depth (Niu et al., 2005; Niu et al., 2007). This is in keeping with the
462 study of Zheng et al. (2017) that soil water storage-based parameterizations outperform
463 the groundwater table-based parameterizations in simulating the total runoff in a
464 seasonally frozen and high-altitude Tibetan river. Besides, RUN(4) is designed based
465 on the infiltration-excess runoff (Yang and Dickinson, 1996) in spite of the saturation-
466 excess runoff in RUN(1) and RUN(2) (Gan et al., 2019), which is more common in arid
467 and semiarid areas like the permafrost regions of QTP (Pilgrim et al., 1988). In the cold
468 season, much of the liquid water freezes into ice, which would greatly influence the
469 thermal conductivity of frozen soil considering thermal conductivity of ice is nearly
470 four times that of the equivalent liquid water. Therefore, the impact of RUN is important
471 for the soil temperature simulations at both warm and cold seasons (Fig. 5 and 7).

472 **4.2.3 Surface layer drag coefficient (SFC and CMB)**

473 SFC defines the calculations of the surface exchange coefficient for heat and water
474 vapor (CH), which greatly impact the energy and water balance and thus the
475 temperature and moisture of soil (Zeng et al., 2012; Zheng et al., 2012). SFC(1) adopts
476 the Monin-Obukhov similarity theory (MOST) with a general form, while the SFC(2)
477 uses the improved MOST modified by Chen et al. (1997). In SFC(1), the roughness
478 length for heat (Z_{0h}) is taken as the same with the roughness length for momentum (Z_{0m} ,
479 Niu et al., 2011). SFC(2) adopts the Zilitinkevitch approach for Z_{0h} calculation
480 (Zilitinkevitch, 1995). The difference between SFC(1) and SFC(2) has a great impact
481 on the CH value. Several studies have reported that SFC(2) has a better performance
482 for the simulation of sensible and latent heat on the QTP (Zhang et al., 2016; Gan et al.,
483 2019). The results of T-test in this study showed remarkable distinctions between the

484 two schemes, where SFC(2) was dramatically superior to SFC(1) (Fig. 7 and 8). SFC(2)
485 produces lower CH than SFC(1) (Zhang et al., 2014), resulting in less efficient
486 ventilation and greater heating of the land surface (Yang et al., 2011b), and substantial
487 improvement of the cold bias of Noah-MP in this study (Fig. 7 and 10).

488 Both SFC(1) and SFC(2) couldn't produce the diurnal variation of $Z_{0,h}$ (Chen et al.,
489 2010). CMB offers a scheme that considered the diurnal variation of $Z_{0,h}$ in bare ground
490 and under-canopy turbulent exchange in sparse vegetated surfaces (Li et al., 2020).
491 Consistent with previous studies in the QTP (Chen et al., 2010; Guo et al., 2011; Zheng
492 et al., 2015; Li et al., 2020), the simulated ST generally followed SFC(2)+CMB(2) >
493 SFC(2) > SFC(1)+CMB(2) > SFC(1) with/without removing the overestimation of
494 snow (Fig. 10), indicating that CMB(2) contributes to resolve the cold bias of LSMs.
495 However, none of the four combinations could well reproduce the shallow and deep
496 STs simultaneously. When the snow is well-simulated, SFC(2)+CMB(2) performed the
497 best at deep layers at the cost of overestimating shallow STs. Meanwhile,
498 SFC(1)+CMB(1) showed the best agreements at shallow layers with considerable cold
499 bias at deep layers, which can be related to the overestimated frozen soil thermal
500 conductivity (Luo et al., 2009; Chen et al., 2012; Li et al., 2019).

501 **4.2.4 Super-cooled liquid water (FRZ) and frozen soil permeability (INF)**

502 FRZ and INF describe the unfrozen water and permeability of frozen soil, and had
503 a larger influence on ST/SLW during the cold season than warm season as expected
504 (Fig. 5). Specifically, FRZ treats liquid water in frozen soil (super-cooled liquid water)
505 using two forms of freezing-point depression equation. FRZ(1) takes a general form
506 (Niu and Yang, 2006), while FRZ(2) exhibits a variant form that considers the increased
507 surface area of icy soil particles (Koren et al., 1999). FRZ(2) generally yields more
508 liquid water in comparison of FRZ(1) (Fig. S2). INF(1) uses soil moisture (Niu and
509 Yang, 2006) while INF(2) employs only the liquid water (Koren et al., 1999) to
510 parameterize soil hydraulic properties. INF(2) generally produces more impermeable
511 frozen soil than INF(1), which is also found in this study (Fig. S3). For the whole year,
512 INF(1) surpassed INF(2) in simulating STs, which may be related to the more realistic

513 SLWs produced by INF(1) for the whole soil column (Fig. S3).

514 **4.2.5 Canopy gap for radiation transfer (RAD)**

515 RAD treats the radiation transfer process within the vegetation, and adopts three
516 methods to calculate the canopy gap. RAD(1) defines canopy gap as a function of the
517 3D vegetation structure and the solar zenith angle, RAD(2) employs no gap within
518 canopy, and RAD(3) treat the canopy gap from unity minus the FVEG (Niu and Yang,
519 2004). The RAD(3) scheme penetrates the most solar radiation to the ground, followed
520 by the RAD(1) and RAD(2) schemes. As an alpine grassland, there is a relative low
521 LAI at TGL site, and thus a quite high canopy gap. So, schemes with a larger canopy
522 gap could realistically reflect the environment. Consequently, the performance
523 decreased in the order of RAD(3) > RAD(1) > RAD(2) for ST/SLW simulation.

524 **4.2.6 Snow surface albedo (ALB) and precipitation partition (SNF)**

525 The ALB describe two ways for calculating snow surface albedo, in which the
526 ALB(1) and ALB(2) adopt the scheme from BATS and CLASS LSM, respectively.
527 ALB(2) generally produce lower albedo than ALB(1), especially when the ground
528 covered by snow (Fig. S4). As a result, higher net radiation absorbed by the land surface
529 and more heat is available for heating the soil in ALB(2), which is beneficial for
530 counteracting the cooling effect of overestimated snow on ST (Fig. S5). Along with the
531 higher ST, ALB(2) outperformed ALB(1) for SLW simulation, likely due to more snow
532 melt water offset the dry bias in Noah-MP (Fig. S5).

533 The SNF defines the snowfall fraction of precipitation as a function of surface air
534 temperature. SNF(1) is the most complicated of the three schemes, in which the
535 precipitation is considered rain/snow when the surface air temperature is greater/less
536 than or equal to 2.5/0.5 °C, otherwise, it is recognized as sleet. While SNF(2) and
537 SNF(3) simply distinguish rain or snow by judging whether the air temperature is above
538 2.2 °C and 0 °C or not. The significant difference between three schemes for SCEs
539 simulation during the warm season is consistent with the large difference of snowfall
540 fraction in this period (Fig. 6 and S6). SNF(3) is the most rigorous scheme and produce
541 the minimum amount of snow, followed by SNF(1) and SNF(2) with limited difference

542 (Fig. S6). This exactly explains superiority of SNF(3) for ST and SLW simulation (Fig.
543 7 and 8).

544 **4.2.7 Lower boundary of soil temperature (TBOT) and snow/soil temperature time
545 scheme (STC)**

546 TBOT process adopts two schemes to describe the soil temperature boundary
547 conditions. TBOT (1) assumes zero heat flux at the bottom of the model, while TBOT(2)
548 adopts the soil temperature at the 8 m depth (Yang et al., 2011a). In general, TBOT(1)
549 is expected to accumulate heat in the deep soil and produce higher ST than TBOT(2).
550 In this study, the two assumptions performed significantly different, especially at the
551 deep soils and during the cold season. Although TBOT(2) is more representative of the
552 realistic condition, TBOT(1) surpassed TBOT(2) in this study. It can be related to the
553 overall underestimation of the model, which can be alleviated by TBOT(1) because of
554 heat accumulation (Fig. S7).

555 Two time discretization strategies are implemented in the STC process, where
556 STC(1) adopts the semi-implicit scheme while STC(2) uses the full implicit scheme, to
557 solve the thermal diffusion equation in first soil or snow layers (Yang et al., 2011a).
558 STC(1) and STC(2) are not strictly a physical processes but different upper boundary
559 conditions of soil column (You et al., 2020a). The differences between STC(1) and
560 STC(2) were significant (Fig. 7). The impacts of the two options on ST is remarkable
561 (Fig. 6), particularly in the shallow layers and during the warm season (Fig. 5). In
562 addition, STC(1) outperformed STC(2) in the ensemble simulated ST (Fig. 7), because
563 STC(1) greatly alleviated the cold bias in Noah-MP (Fig. S8) by producing the higher
564 OA of SCEs (Fig. 6)

565 **4.3 Perspectives**

566 This study analyzed the characteristics and general behaviors of each
567 parameterization scheme of Noah-MP at a typical permafrost site on the QTP, hoping
568 to provide a reference for simulating permafrost state on the QTP. We identified the

569 systematic overestimation of snow cover, cold bias and dry bias in Noah-MP, and
570 discussed the role of snow and surface drag coefficient on soil hydrothermal dynamics.
571 Further tests at another permafrost site (BLH site, 34.82° N, 92.92° E, Alt.: 4,659 m
572 a.s.l) basically showed consistent conclusions with that at TGL site (see Supplementary
573 files for details), indicating that relevant results and methodologies can be practical
574 guidelines for improving the parameterizations of physical processes and testing their
575 uncertainties towards soil hydrothermal modeling in the permafrost regions of the
576 plateau. Although the site we selected may be representative for the typical environment
577 on the plateau, continued investigation with a broad spectrum of climate and
578 environmental conditions is required to make a general conclusion at regional scale.

579 **5 Conclusions**

580 An ensemble simulation using multi-parameterizations was conducted using the
581 Noah-MP model at the TGL site, aiming to present a reference for simulating soil
582 hydrothermal dynamics in the permafrost regions of QTP using LSMs. The model was
583 modified to consider the vertical heterogeneity in the soil and the simulation depth was
584 extended to cover the whole active layer. The ensemble simulation consists of 55296
585 experiments, combining thirteen physical processes (CRS, BTR, RUN, SFC, FRZ, INF,
586 RAD, ALB, SNF, TBOT, STC, SUB, and CMB) each with multiple optional schemes.
587 On this basis, the general performance of Noah-MP was assessed by comparing
588 simulation results with in situ observations, and the sensitivity of snow cover event, soil
589 temperature and moisture at different depths of active layer to parameterization
590 schemes was explored. The main conclusions are as follows:

591 (1) Noah-MP model tends to overestimate snow cover, which is most influenced by the
592 STC and SUB processes. Such overestimation can be greatly resolved by
593 considering the snow sublimation from wind (SUB(2)) and semi-implicit snow/soil
594 temperature time scheme (STC(1)).

595 (2) Soil temperature is largely underestimated by the overestimated snow cover and
596 thus dominated by the STC and SUB processes. Systematic cold bias and large

597 uncertainties of soil temperature still exist after eliminating the effects of snow,
598 particularly at the deep layers and during the cold season. The combination of Y08
599 and UCT contributes to resolve the cold bias of soil temperature.

600 (3) Noah-MP tend to underestimate soil liquid water content. Most physical processes
601 have limited influence on soil liquid water content, among which the RUN process
602 plays a dominant role during the whole year. The STC and SUB process have a
603 considerable influence on topsoil liquid water during the warm season.

604

605 *Code availability.* The original source code of the offline 1D Noah-MP LSM v1.1 is
606 available at

607 [https://ral.ucar.edu/solutions/products/noah-multiparameterization-land-surface-](https://ral.ucar.edu/solutions/products/noah-multiparameterization-land-surface-model-noah-mp-lsm)
608 model-noah-mp-lsm (last access: 23 February 2021). The modified Noah-MP with the
609 consideration of vertical heterogeneity in soil profile, snow sublimation from wind and
610 the combination of roughness length for heat and under-canopy aerodynamic resistance
611 can be downloaded at <http://doi.org/10.5281/zenodo.4555449>.

612

613 *Data availability.* The 1-hourly forcing data, daily soil temperature and liquid water
614 content at the TGL and BLH sites are available at
615 <https://doi.org/10.17632/h7hbd69nnr.2>. Soil texture data can be obtained at
616 <https://doi.org/10.1016/j.catena.2017.04.011> (Hu et al., 2017). The AVHRR LAI data
617 can be downloaded from <https://www.ncei.noaa.gov/data/> (Claverie et al., 2016).

618

619 *Author contributions.* TW and XL conceived the idea and designed the model
620 experiments. XL performed the simulations, analyzed the output, and wrote the paper.
621 JC helped to compile the model in a GNU/Linux (CentOS 7.0) environment. XW, XZ,
622 GH, RL contributed to the conduction of the simulation and interpretation of the results.
623 YQ provided the observations of atmospheric forcing and soil temperature. CY and JH
624 helped in downloading and processing the AVHRR LAI data. JN and WM provide
625 guidelines for the visualization. Everyone revised and polished the paper.

626

627 *Competing interests.* The authors declare that they have no conflict of interest.

628

629 *Acknowledgements.* This work has been supported by the CAS "Light of West China" 630 Program, the National Natural Science Foundation of China (41690142; 41771076; 631 41961144021; 42071093), the CAS "Hundred Talents" Program (Sizhong Yang), and 632 the National Cryosphere Desert Data Center Program (E0510104). The authors thank 633 Cryosphere Research Station on the Qinghai-Tibet Plateau, CAS for providing field 634 observation data and Mr. Guohui Zhao for awarding us access to supercomputing 635 resources. We would like to thank Dr. Sizhong Yang and two anonymous reviewers for 636 their insightful and constructive comments and suggestions, which greatly improved 637 the quality of the manuscript.
