Abstract

In this study, a new regional Earth system model is developed and applied to the Med-CORDEX region. The ENEA-REG system is made up of two interchangeable regional climate models as atmospheric components (RegCM and WRF), a river model (HD), and an ocean model (MITgcm); processes taking place at the land surface are represented within the atmospheric models with the possibility to use several land surface schemes of different complexity. The coupling between these components is performed through the RegESM driver.

Here, we present and describe our regional Earth system model and evaluate its components using a multidecadal hindcast simulation over the period 1980-2013 driven by ERA-Interim reanalysis. We show that the atmospheric components correctly reproduce both large-scale and local features of the Euro-Mediterranean climate, although we found some remarkable biases: in particular, WRF has a significant cold bias during winter over the North-Eastern bound of the domain and a warm bias in the whole continental Europe during summer, while RegCM overestimates the wind speed over the Mediterranean Sea.

Similarly, the ocean component correctly reproduces the analyzed ocean properties with performances comparable to the state-of-art coupled regional models contributing to Med-CORDEX initiative.

Our regional Earth system model allows studying the Euro-Mediterranean climate system and can be applied to both hindcast and scenario simulations.

1.   Introduction

The Mediterranean basin is a complex region characterized by pronounced topography and a complex land-sea distribution, including many islands and several straits. These features generate intense local atmosphere–sea interactions leading to the formation of intense local winds, like Mistral, Etesian and Bora, which, in turn, dramatically affect the Mediterranean ocean circulation (e.g. Artale et al., 2010; Lebeaupin-Brossier et al. 2015; Turuncoglu and Sannino, 2017). Given the relatively fine spatial scales at which these processes occur, the Mediterranean basin provides an excellent opportunity to study the regional climate, with a particular focus on the air-sea coupling (Sevault et al., 2014; Turuncoglu and Sannino, 2017). For these reasons, regional coupled models have been developed and used to study both present and future Mediterranean climate system (e.g. Dubois et al., 2012; Ruti et al., 2016; Darmaraki et al., 2019; Parras-Berrocal et al., 2020); these models, depending on their complexity, include several physical components of the climate system, like atmosphere, ocean, land surface, rivers and biogeochemistry (both for land and ocean) (e.g. Drobinski et al., 2012; Sevault et al., 2014; Reale et al., 2020). Since the last two decades, an increasing number of studies have been performed over the Mediterranean basin. Nowadays, there is a coordinated effort to produce hindcast and future simulations over this region using regional coupled climate models sharing some common protocols (Ruti et al., 2016). In particular, the Coordinated Regional Climate Downscaling Experiment (CORDEX) was designed to produce worldwide, high-resolution regional climate simulations through a coordinated experiment protocol ensuring that model simulations are carried out under similar conditions facilitating thus the analysis, intercomparison, and synthesis of different simulations (Giorgi et al., 2015 and 2016). In the framework of the CORDEX program, regional climate model simulations dedicated to the Mediterranean area belong to the Med-CORDEX initiative (Ruti et al., 2016; Somot et al., 2018; Soto-Navarro et al., 2020).

From an atmospheric point of view, the Mediterranean region is a transition zone between arid subtropics and temperate mid-latitudes, characterized by low annual precipitation totals and high interannual variability; during winter, rain is brought by mid-latitude westerlies, while warm and dry summer results from the influence of subtropical remote forcing triggered by the Indian monsoon (Tuel and Eltahir, 2020). A number of model studies have indicated that the

Mediterranean is expected to be one of the most prominent and vulnerable climate change "hotspots" in the world; in particular, a significant decline in the amount of precipitation is predicted by several models over the twenty-first century (Giorgi 2006; Tuel and Eltahir, 2020). Given the Mediterranean basin's complexity and the strong air-sea feedback, high-resolution regional Earth system models are an optimal tool for accurate simulation of past, present and future climate over this region. This paper aims to present and evaluate the newly developed regional Earth system model ENEA-REG; in particular, we evaluate the ability of the ENEA-REG system to represent the present climate of the Mediterranean adequately by making a hindcast simulation using the ERA-interim reanalysis as boundary conditions. The performances of individual model components are evaluated, comparing results with a wide range of observation-based datasets. Taking full advantage of the RegESM driver's potential (Turuncoglu 2019), which allows to build up in a modular way regional coupled models, the ENEA-REG is composed of two interchangeable regional climate models (RCMs) used as atmospheric components of the Earth system. Keeping fixed the ocean and rivers components, our model allows us to explore the sensitivity of the ocean model to different atmospheric forcings: specifically, with the direct comparison of simulations differing in the atmospheric component, we infer the impact of different modelling choices on both air-sea processes and, consequently, on the ocean dynamics.

Our results help to define possible future modelling strategies in the context of Med- CORDEX simulations. Besides, developing a modular regional Earth system model with interchangeable components allows defining the model to be used for a given application depending on the model's skills over the region of interest. This capability could be of particular interest for other CORDEX experiments, as it is well known that some parameterizations poorly perform locally or over some regions producing large local biases.

2.   Model description

2.1   The RegESM coupler

The ENEA-REG regional Earth system model can include several model components (atmosphere, river routing, ocean, wave) to allow different modelling applications. For each simulation, the modelling system components can be easily enabled or disabled via the driver's configuration file. The modelling framework also supports plugging new earth system sub-

93   components (e.g. atmospheric chemistry, sea ice, ocean biogeochemistry) with minimal code

94   changes through its simplified interface, which is called "cap". The National United Operational

95   Prediction Capability (NUOPC) cap is a Fortran module that serves as an interface to a model

96   when it is used in a NUOPC-based coupled system; it is a small software layer that sits on top of

97   a model code, making calls into it and exposing model data structures in a standard way

98   (Turuncoglu, 2019).

99   In this study, the modelling system is configured to include three components: a regional

100   atmospheric climate model, a regional ocean model and a hydrological model. The driver used to

101   regrid and exchange data among the three components of the ENEA-REG modelling system is

102   RegESM (Turuncoglu 2019). The driver employs the Earth System Modeling Framework

103   (ESMF) library (version 7.1) and the NUOPC layer to connect and synchronize each model

104   component and perform interpolation among different horizontal grids (Turuncoglu 2019). While

105   the ESMF library deals with interpolation and regridding of exchanged fields, the NUOPC layer

106   simplifies common tasks of model coupling like component synchronization and run sequence

107   by providing an additional wrapper layer between coupled model and ESMF framework

108   (Turuncoglu and Sannino, 2017; Turuncoglu 2019). It also allows defining different coupling

109   time intervals among the components to reproduce fast and slow interactions among the model

110   components (Turuncoglu and Sannino, 2017; Turuncoglu, 2019). In this study, the model

111   coupling time step between ocean and atmosphere is set to 3-hours, while the coupling with the

112   hydrological model is defined as 1-day. Also, the driver allows selecting the desired exchange

113   fields from a simple field database containing all available variables that can be exported or

114   imported by the different components. In this way, the coupled modelling system can be easily

115   adapted depending on the application and the particular configuration of the experiment without

116   any code customizations in both the driver and individual model components (Turuncoglu,

117   2019).

118   In the experiments presented here, the atmospheric model retrieves sea surface temperature

119   (SST) from the ocean model (where grids are overlapped), while the ocean model collects

120   surface pressure, wind components, freshwater (evaporation-precipitation, i.e. E-P) and heat

121   fluxes from the atmospheric component. Similarly, the hydrological model uses surface and sub-

122   surface runoff simulated by the atmospheric component to compute the river drainage and

123   exchanges this field with the ocean component to close the water cycle. Further details on the

124 ENEA-REG framework and the interaction among the components are schematically depicted in
125 **Figure 1**.

126 In the current work, we performed hindcast simulations covering the period 1st-October 1979-
127 31st-December 2013.

128
129 **2.2   The atmospheric components: WRF and RegCM**

130 The ENEA-REG regional Earth system model is made up of two interchangeable atmospheric
131 components: the Weather Research and Forecasting (WRF; Skamarock et al., 2008) model and
132 the REGional Climate Model (RegCM; Giorgi et al., 2012).

133 WRF is a limited-area, non-hydrostatic, terrain-following eta-coordinate mesoscale model
134 developed by the NCAR/MMM (National Center for Atmospheric Research, Mesoscale and
135 Microscale Meteorology division). WRF offers multiple options for various physical
136 parameterizations; thus, it can be used for any region of the world for a wide range of
137 applications ranging from operational forecasts to realistic and idealized dynamical studies. In
138 this work, we use the dynamical core ARW (Advanced Research WRF, version 3.8.1)
139 (Skamarock et al., 2008), with a single-moment 5 class scheme to resolve the microphysics
140 (Hong et al., 2006) and the Rapid Radiative Transfer Model for GCMs (RRTMG) for the
141 shortwave and longwave radiation (Iacono et al., 2008). Convective precipitation and cumulus
142 parameterization are resolved via the Kain-Fritsch scheme (Kain 2004), the planetary boundary
143 layer (PBL) is represented through the Yongsei University scheme (Hong et al., 2006), while the
144 exchange of heat, water and momentum between soil-vegetation and atmosphere is simulated by
145 Noah–MP land surface model (Niu et al., 2011). The model domain is projected on a Lambert
146 conformal grid with a horizontal resolution of 15 km and with 35 vertical levels extending from
147 land surface up to 50 hPa (**Figure 2a**). The initial and boundary meteorological conditions are
148 provided by the European Centre for Medium-Range Weather Forecast (ECMWF) reanalysis
149 (Dee et al., 2011) with a horizontal resolution of 0.75° every 6 h. The lateral buffer zone has a
150 width of 10 grid points and uses an exponential relaxation to provide the model with lateral
151 boundary conditions. A synthesis of parameterizations and input data used in this study is given
152 in **Table 1**.

153 The other supported atmospheric component of the regional Earth system model is RegCM
154 (version 4.5) a hydrostatic, compressible, sigma-p vertical coordinate model initially developed

155 by Giorgi (1990) and Giorgi et al. (1993a, 1993b) and then modified as discussed by Giorgi et al.

156 (2012); RegCM is maintained by ICTP 's Earth System Physics (ESP) section. The dynamical

157 core of RegCM is based on the primitive equations, hydrostatic version of the National Centre

158 for Atmospheric Research (NCAR) and Pennsylvania State University mesoscale model MM5

159 (Grell et al., 1994). Similar to WRF, RegCM includes different physics and sub-grid

160 parameterization options. In this study, radiation is simulated with the radiative transfer scheme

161 of the global model CCM3 (Kiehl 1996), cumulus convection is resolved through the Grell

162 scheme (Grell 1993) with a Fritsch-Chappell scheme for unresolved convection, the planetary

163 boundary layer is represented via modified version of the Holtslag parameterization (Giorgi et al

164 2012), while the exchange of heat, water and momentum between soil-vegetation and

165 atmosphere is simulated by the Biosphere-Atmosphere Transfer Scheme (BATS) (Dickinson et

166 al., 1993). The resolved scale precipitation is modeled with the SUBEX parameterization (Pal et

167 al., 2000).

168 The model domain (**Figure 2b**) is projected on a Lambert conformal grid with a horizontal

169 resolution of 20 km and with 23 vertical levels extending from the land surface up to 50 hPa.

170 Similarly to WRF, we used ERA-Interim data to force RegCM and 6 grid-points in each side are

171 selected as relaxation zone with an exponentially decreasing relaxation coefficient (Giorgi et al.

172 1993) (**Table 1**).

173 A few modifications have been made both in WRF and RegCM to receive the oceanic surface

174 variables and send the atmospheric fields to the ocean component of the ENEA-REG system, as

175 described in **Figure 1**. Further details on the model's changes are described by Turuncoglu

176 (2019).

177

178 **2.3   The ocean component: MITgcm**

179 The ocean component of the ENEA-REG system is the Massachusetts Institute of Technology

180 General Circulation Model (MITgcm version c65; Marshall et al., 1997). The MITgcm solves

181 both the hydrostatic and non-hydrostatic Navier-Stokes equations under the Boussinesq

182 approximation for an incompressible fluid with a spatial finite-volume discretization on a

183 curvilinear computational grid using the z* rescaled height vertical coordinate (Adcroft and

184 Campin, 2004). MITgcm is designed to run on different platforms, from scalar to high-

185 performance computing (HPC) systems: it is parallelized via MPI through a horizontal domain

186 decomposition technique.

187 A broad community of researchers uses MITgcm for a wide range of applications at various

188 spatial and temporal scales ranging from local/regional (e.g. Sannino et al., 2009; Furue et al.,

189 2015; Rosso et al., 2015; Sannino et al., 2015; McKiver et al., 2016; Sannino et al., 2017; Llasses

190 et al 2018; Peng et al., 2019) to global ocean simulations (e.g. Stammer et al., 2003; Forget et al.,

191 2015; Breitkreuz et al., 2018; Forget and Ferreira, 2019). Moreover, MITgcm has also been used

192 for climate studies coupled to the atmosphere (e.g. Artale et al., 2010; Polkova et al., 2014; Sitz

193 et al., 2017; Sun et al., 2019; Turuncoglu et al., 2019).

194 In the configurations presented here, the MITgcm has been used in its hydrostatic, implicit free-

195 surface, partial step topography formulation (Adcroft et al., 1997) and has already been

196 customized and applied for simulating the Mediterranean circulation (Di Biagio et al 2019,

197 Cusinato et al. 2018). The model domain has a horizontal resolution of 1/12°, corresponding to

198 570x264 grid points, and covers the entire Mediterranean Sea with the boundary conditions in

199 the Atlantic Ocean (**Figure 2**). In the vertical, the model is discretized using 75 unevenly spaced

200 Z-levels going from 1 m at the surface to about 300 m in the deepest part of the basin. We use

201 lateral open boundary conditions prescribed by the MITgcm Open Boundary Conditions (OBCS)

202 package. Temperature and salinity boundary conditions in the Atlantic Ocean are interpolated

203 from the global LEVITUS94 climatological monthly 3D data.

204 To ensure numerical stability, a sponge layer is added to the open boundary of the domain. Each

205 variable is then relaxed toward the boundary values with a relaxation timescale that decreases

206 linearly with distance from the boundary. The thickness of the sponge layer in terms of grid

207 points is 18 and inner fields are relaxed toward boundary values using a 10 day period. Salinity

208 and temperature fields in the Mediterranean basin have been initialized using MEDATLAS/2002

209 climatology for the month of October. This month corresponds to a situation of stable vertical

210 stratification and can avoid sudden vertical mixing. A spin-up procedure for the ocean model has

211 not been adopted. Usually, for climate studies, long spin-up are desirable to avoid the models

212 drift considerably from the initial conditions and tend to converge toward a new state given by

213 the ocean physics (Sitz et al., 2017). However, since the main objective of this work is to

214 compare the air-sea interaction simulated by two coupled regional models that share the same

215 ocean model component, a long spin-up is not strictly necessary.

7

216   Similar to the atmospheric models, we have modified the MITgcm model in order to be forced
217   by meteorological conditions derived by the atmospheric components of the ENEA-REG system
218   (see Turuncoglu and Sannino 2017 for further details).

2.4   The river routing model: HD

220   The river discharge is a key variable in the Earth system modelling as it closes the water cycle
221   between the atmosphere and ocean. The ENEA-REG system uses the Hydrological Discharge
222   (HD, version 1.0.2) model, developed by the Max Planck Institute (Hagemann and Dümenil,
223   1998; Hagemann and Dümenil-Gates, 2001), to simulate freshwater fluxes over the land surface
224   and to provide a river discharge to the ocean model. The HD model uses a regular global grid
225   with a fixed horizontal resolution of $0.5°$, and it is forced by daily surface runoff and drainage
226   data. Similarly to other components, the HD model was slightly modified (Turuncoglu and
227   Sannino 2017) to retrieve surface runoff and drainage from the atmospheric components of the
228   regional coupled model and to provide the river discharge to the ocean component (**Figure 1**).
229   Although the HD model computes the discharge for each basin in the computational domain, a
230   selection of the 18 main rivers has been given to the ocean model as boundary conditions. For
231   instance, the Nile River has been prescribed as a climatological monthly mean because 1) the
232   whole catchment basin is not covered by the domain of atmospheric models and 2) the natural
233   discharge (which is the one computed by the model) is heavily modified by anthropic use and
234   regulation. The river discharge data for the Nile is provided by the Global Runoff Data Centre
235   (GRDC, Koblenz-Germany) as monthly means for the 1973–1984 periods. The same strategy
236   has been used for the contribution coming from the Black Sea, namely, the monthly values of net
237   flow have been taken from the study of the Black Sea water budget (Stanev et al. 2000).

238

3.   Experiment design and observational datasets

240   In this work, we present Med-CORDEX hindcast climate simulations performed with the ENEA-
241   REG model using both the atmospheric components of the system (i.e. WRF and RegCM). We
242   perform the model validation over the period 1982-2013, using the first two years of simulation
243   as spin-up to initialize all the fields of the different components of the coupled system. The
244   validation of the coupled model focuses on sea surface temperature, sea surface salinity and
245   mixed layer depth for the ocean, and 2m temperature, wind speed and freshwater and heat fluxes

246   for the atmosphere. We also compare river discharge from the Po river as it influences the

247   Adriatic Sea circulation and deep waters formation.

248   The simulated SST data are validated against the Objectively Interpolated Sea Surface

249   Temperatures (OISST v2, Reynolds et al., 2002 and 2007), developed and distributed by the

250   National Oceanic and Atmospheric Administration (NOAA). The OISST composites

251   observations from different platforms (satellites, ships, buoys) on a 1/4° global grid and the gaps

252   are filled by interpolation (Reynolds et al., 2007).

253   Salinity data for the Mediterranean Sea are obtained from MEDHYMAP (Jordà et al., 2017). For

254   the mixed layer depth, we use a global climatology computed from more than one million Argo

255   profiles collected from 2000 to the present (Holte et al., 2017); this climatology provides

256   estimates of monthly mixed layer depth on a global 1° gridded map.

257   As a reference dataset to evaluate the performances of the atmospheric components of the

258   ENEA-REG system, we use ERA5: this allows to test model's ability to reliably reproduce their

259   parent data (Mooney et al., 2013) and because, unlike other observational data, this dataset

260   provides information on both over land and ocean. However, it should be considered that ERA5

261   has some weakness over the ocean and should be used cautiously (Belmonte Rivas and Stoffelen

262   2019) to validate the wind speed over the Mediterranean Sea.

263   The observed river discharge of the Po river has been extracted from the series of measures at the

264   Ponte Lagoscuro station from the RivDIS dataset (Vorosmarty et al., 1998).

265

266   **4.   Results**

267   **4.1   Evaluation of atmospheric models**

268   The general ability of the atmospheric components of the ENEA-REG system to reproduce

269   realistic spatio-temporal patterns of the most relevant physical variables is assessed by

270   comparing model simulations with ERA5 during winter (DJF) and summer (JJA) seasons

271   averaged over the reference period 1982-2013. In the present analysis, in addition to spatial

272   patterns and anomalies maps, we also compute uncentered correlation patterns and domain-

273   averaged bias to provide a measure of the model's skills.

274   Looking at the surface air temperature (**Figure 3**), consistent with ERA5 data, during winter,

275   both WRF and RegCM show a typical eastward gradient with temperature decreasing with

276   increasing continentally, while during summer, the models correctly reproduce the decreasing

south-north gradient with colder areas localized over mountainous regions (i.e. Alps and Pyrenees). Looking at the anomalies, WRF shows a remarkable cold bias during DJF over northeastern Europe, with magnitudes larger than 4°C. Such a cold bias over this region was already described in several studies, and it mainly depends on the poor representation of the snow-atmosphere interaction, amplified by the albedo feedback (e.g. Mooney et al., 2013; Kotlarski et al., 2014; García-Díez et al., 2015; Katragkou et al., 2015). Despite, when setting up WRF, we were aware of both the need to carefully select parameterization combinations and the issues associated with some of the selected parameterizations, we chose the present settings as they well reproduce wind fields over the Mediterranean region, which is relevant when running WRF coupled with an ocean model. Besides, as demonstrated by Mooney et al. (2013) in a sensitivity study, where different WRF physical parameterizations schemes were used to represent radiation, microphysics, convection, PBL and land surface over a large domain, no single combination of parameterizations yields optimal results. Unlike WRF, RegCM does not show any remarkable bias during winter and, in general, it shows a cold bias ranging between 1 and 2°C over the whole Mediterranean region. The good spatial agreement found during DJF between the simulated surface air temperature and the reference data is confirmed by the high spatial correlation varying between 0.97 in the case of WRF to 0.99 for RegCM, while the domain-averaged bias ranges from -1.4°C for WRF to -0.15°C for RegCM.

During summer, both WRF and RegCM show a similar bias pattern over land, with a warm bias extending from France to Eastern Europe and reaching magnitudes of up to 4 °C in the case of WRF. In contrast, over the Mediterranean sea, the two configurations show an opposite bias pattern, with WRF exhibiting a warm bias over the sea and RegCM a cold bias. In case of WRF, the warm bias over land was already described by Mooney et al. (2013), who showed how the selection of the land surface model mostly controls the simulated summer surface air temperature. Considering RegCM, our results are consistent with Turuncoglu and Sannino (2017), who described a similar behaviour running RegCM both standalone and coupled to ROMS ocean model, with a temperature overestimation up to 2.0–2.5 °C during the summer season in central and eastern Europe. Overall, our regional models well reproduce the observed spatial pattern, being the spatial correlation larger than 0.99 for both WRF and RegCM. Because of compensation between warm bias over land and cold bias over the sea, during JJA, the configuration using RegCM shows a lower bias (0.14 °C) than WRF (0.85 °C).

308 Looking at precipitation, during winter, both the ENEA-REG configurations agree with ERA5
309 data, namely the atmospheric components can reproduce the major precipitation maxima over
310 the Alps, Balkans and western Norway with only a substantial local dry bias in the areas around
311 the coastlines of the eastern Mediterranean. In contrast, during summer, WRF and RegCM
312 systematically simulate less precipitation over most continental Europe, with RegCM showing
313 the largest dry bias (**Figure 4**). Interestingly, considering WRF, these results are not consistent
314 with Mooney et al. (2013), who reported a positive bias in mean daily precipitation over Europe
315 during summer and related this wet bias to the land surface scheme used and partially to the
316 microphysics scheme. However, Kotlarski et al. (2014) comparing three WRF experiments
317 showed a different sensitivity, with two simulations overestimating mean summer precipitation
318 and one underestimating it; they conclude that this result depends on the choice of different
319 microphysics schemes. On the other side, Turuncoglu and Sannino (2017) found a similar bias
320 pattern for RegCM during summer.

321 In general, the spatial performances of the ENEA-REG system are better when WRF is used as
322 the atmospheric component: the spatial correlation ranges between 0.97 during DJF to 0.92
323 during JJA, while the configuration with RegCM exhibits a slightly lower pattern correlation
324 (0.95 for DJF, 0.92 during JJA). Similarly, WRF has a smaller bias both during winter (-0.18 vs -
325 0.24 mm/day) and summer (-0.32 vs -0.54 mm/day).

326 Despite the weak summer dry bias, the two atmospheric models well reproduce precipitation
327 over the sea, enhancing the reliability of freshwater flux exchanged with the ocean component of
328 the ENEA-REG system. Nevertheless, it should be noted that in the framework of coupled
329 ocean-atmosphere models, rather than precipitation, the water budget, defined as evaporation–
330 precipitation (E–P), plays a pivotal role in the dynamics of the ocean component. For this reason,
331 in **Figure 5** we show both the simulated inter-annual variability and mean seasonal cycle of the
332 area-averaged Mediterranean Sea precipitation, evaporation along with their difference (i.e. E-P).
333 Looking at precipitation, WRF shows a systematic dry bias over the Mediterranean Sea with
334 respect to ERA5, while RegCM is in good agreement with the reference value. The mean annual
335 cycles suggest that WRF underestimates rainfall during colder months (from October to April),
336 while RegCM well reproduces the observed seasonal cycle, with a weak overestimation between
337 August and October. Overall, the two configurations of the ENEA-REG system well reproduce

338   the seasonal cycle, characterized by maximum values during fall and winter and minimum in

339   summer.

340   The total simulated precipitation over the Mediterranean Sea is 372±47 mm/yr using WRF and

341   496±48 mm/yr in case of RegCM, while ERA5 predicts 469±50 mm/yr. In general, these

342   estimates agree with previous studies: in particular, in a different experiment, where WRF was

343   coupled with NEMO ocean model, Lebeaupin-Brossier et al. (2015) found a precipitation budget

344   of 482±53 mm/yr over the period 1989–2008, concluding that this value is in the upper part of

345   the range given in the literature [290–510 mm/yr] (Mariotti et al., 2002; Pettenuzzo et al., 2010;

346   Romanou et al., 2010; Criado-Aldeanueva et al., 2012). Similarly, in a regional climate system

347   model developed over the Mediterranean Sea, where RegCM was coupled with ROMS ocean

348   model, Turuncoglu and Sannino (2017) found mean annual precipitation of 561 mm/yr during

349   the period 1988–2006. In a different configuration, where ALADIN climate model was coupled

350   with NEMO ocean model, Sevault et al. (2014) found precipitation of 510 mm/yr over the period

351   1980-2012, while Sanchez-Gomez et al. (2011) compared 12 regional climate models finding a

352   large spread among models with mean annual precipitation estimates ranging between 347 and

353   606 mm/yr with a mean value of 442±84 mm/yr.

354   Compared to ERA5, the evaporation is systematically overestimated by both RegCM and WRF

355   during our study period, although the year-to-year variability is well reproduced and the

356   mismatch decreases with time (**Figure 5**). Nevertheless, the two configurations correctly

357   reproduce the seasonal cycle, characterized by evaporation minimum in May and maxima during

358   late summer and winter months, when the gradient between air-sea temperature is high, and the

359   wind speed is strong. The total evaporation over the Mediterranean Sea is 1312±34 mm/yr and

360   1405±38 for WRF and RegCM, respectively, while ERA5 has lower evaporation of 1198±59

361   mm/yr. Consistent with precipitation, our estimates well agree with previous studies: Lebeaupin-

362   Brossier et al. (2015) using WRF coupled to NEMO found total evaporation of 1442±45 mm/yr

363   during the 1989–2008 period, while Turuncoglu and Sannino (2017) using RegCM coupled to

364   ROMS reported a value of 1388 mm/yr during the 1988–2006 period. Sevault et al. (2014)

365   estimated a mean annual evaporation of 1390 mm/yr, while Sanchez-Gomez et al. (2011)

366   displayed a large variability among 12 regional climate models, with annual mean estimates

367   ranging between 1066 mm/year and 1618 mm/year, this latter using RegCM offline forced by

368   ERA40 data. The comparison with previous studies highlights a general tendency of RegCM to

369 overestimate the evaporation over the Mediterranean Sea, irrespective of the forcing data and

370 parameterizations selected; this could be likely caused by an overestimation of wind speed

371 (discussed later).

372 Interestingly, because of bias compensation WRF and RegCM show a similar E-P estimate

373 (**Figure 5**); however, we found in both the configurations of the ENEA-REG system a

374 remarkable bias in E-P, with values larger than 100 mm/year, which could significantly affect the

375 ocean component. Anyhow, the monthly distribution of E–P shows, in both the ENEA-REG

376 configurations, a similar monthly distribution compared to ERA5 dataset with a peak in the late

377 summer caused by sparse precipitation and high evaporation. The total E-P estimated simulated

378 using WRF is 940±48 mm/yr while with RegCM we obtain a mean annual estimate of 909±45

379 mm/yr; in contrast, ERA5 data has a lower E-P of 729±56 mm/yr.

380 In addition to freshwater flux, wind speed is also a key variable for ocean models as it controls

381 the evaporation over the sea surface and affects the ocean circulation through drag stress. **Figure**

382 **6** shows the near-surface wind speed as simulated by the ENEA-REG system and ERA5

383 reanalysis. The comparison with the observationally-based dataset indicates that both WRF and

384 RegCM overestimate the wind speed over land during the two analyzed seasons, while over sea

385 the atmospheric models are able to correctly simulate the wind speed, especially over the Gulf of

386 Lion and the Aegean sea, where the structure and magnitude of dominant Mistral and Etesian

387 winds are well reproduced by the models, although they produce too weak Etesian during

388 summer.

389 It should also be noted that the large bias found over mountainous regions is an artefact due to

390 the spatial resolution differences, with ERA5 reanalysis reproducing lower wind speed than both

391 WRF and RegCM because of its coarser resolution. In general, the two atmospheric models have

392 comparable performances in reproducing the observed spatial pattern; we find a correlation of

393 0.98 for both models and seasons, except for RegCM during summer (0.97). In contrast, WRF

394 has a lower bias (0.7 m/s for DJF and 0.47 m/s for JJA) than RegCM (0.9 m/s for DJF and 0.7

395 m/s for JJA).

396 Besides freshwater flux and wind components, the surface net heat flux is used to drive the ocean

397 model of the ENEA-REG system (**Figure 1**); this variable represents the energy that the ocean

398 surface receives from the atmosphere and is computed from net longwave, net shortwave, latent

399 heat and sensible heat fluxes. In **Figure 7**, we compare the simulated net energy flux with ERA5

13

data; overall, the two atmospheric models are in good agreement with the reference dataset during the analyzed seasons, albeit large biases are evident in both the atmospheric components. The models show similar skills in reproducing the ERA5 spatial patterns, both having a correlation of 0.96 during DJF, while in JJA RegCM (0.97) is slightly better than WRF (0.96). Similarly, RegCM also exhibits the lowest bias during both DJF (-1.3 W/m2 vs 5.7 W/m2) and JJA (3.1 W/m2 vs 13.8 W/m2). Looking at the spatial bias in more details, WRF shows a systematic positive bias over the land surface up to 15 W/m2 during winter and 20 W/m2 in summer, while RegCM well matches ERA5 data in DJF with bias lower than 5 W/m2 but with a systematic negative bias (-10 W/ m2) over the land during JJA.

Figure 8 compares the monthly climatology of energy flux components averaged over the whole Mediterranean Sea with ERA5 data. The analysis of model results suggests that the atmospheric components systematically overestimate the latent heat during the whole year (**Figure 8a**). The annual mean estimates are 104±2.7 W/m2 from WRF and 112±2.9 W/m2 from RegCM, with ERA5 showing a slightly smaller flux (95±4.7 W/m2). This result is consistent with previous findings, namely, the too intense wind speed simulated by WRF and RegCM over sea surface leads to large latent heat flux and consequently an overproduction of evaporative flux. We stress that our results are also consistent with previous studies; in particular, Turuncoglu and Sannino (2017) reported a value of 110.52 W/m2 from RegCM coupled to ROMS, whilst Sanchez-Gomez et al. (2011) showed a value of 128±5 W/m2; in this latter study, RegCM showed the at largest overestimation of latent heat flux among 12 regional climate models.

The sensible heat flux shows similar behaviour to that observed for the latent heat, namely, RegCM systematically overestimates this variable during the whole year, whilst WRF is closer to the reference data (**Figure 8b**). The annual mean estimates are 12.9±1.3 W/m2 from WRF, 17.6±1.2 W/m2 from RegCM, while ERA5 has a slighter lower flux of 11.9±1.1 W/m2. Interestingly, using RegCM coupled to ROMS, Turuncoglu and Sannino (2017) found a smaller sensible heat flux of 9.85 W/m2, while Sanchez-Gomez et al. (2011) running RegCM offline reported a value closer to our estimate (22±2 W/m2); as the sensible heat strictly depends on the gradient between SST and air temperature the lower value of Turuncoglu and Sannino (2017) could be explained by a large discrepancy between the SSTs simulated by the MITgcm and the ROMS ocean models.

430   The mean annual cycle of net shortwave radiation is well simulated by the atmospheric models,

431   with WRF showing an almost perfect match compared to ERA5, while RegCM underestimates

432   the summer peak of about 25 W/m2 and slightly overestimates the amount of radiation received

433   by the ocean from January to April (**Figure 8c**). The mean annual estimates are 200±1.1 W/m2

434   form WRF, 201±1.2 W/m2 form RegCM and 198±1.1 W/m2 form ERA5; for both the ENEA-

435   REG configurations, these estimates are in agreement with other studies (Sanchez-Gomez et al.,

436   2011; Turuncoglu and Sannino, 2017).

437   Comparison between simulated net longwave radiation and ERA5 shows that RegCM

438   underestimates the thermal radiation during the whole year, while WRF generally agrees with

439   ERA5 during cold months but largely underestimates the longwave radiation between March and

440   October (**Figure 8d**). In addition, the amplitude of seasonal variation is well captured by

441   RegCM; in contrast, WRF shows a stronger month-to-month variability. The mean annual net

442   longwave radiation simulated by RegCM and WRF is -77.6±1.3 W/m2 and -79.9±1.2 W/m2,

443   respectively, while ERA5 dataset predicts -84.8±1.2 W/m2.

444

4.2   Evaluation of ocean model

4.2.1. Surface processes

447   The correct representation of physical processes taking place at the air-sea interface is crucial for

448   the success of a coupled climate simulation. A first evaluation of the goodness with which these

449   processes are simulated is given by the analysis of the ocean surface variables like Sea Surface

450   Temperature (SST) and Sea Surface Salinity (SSS).

451   **Figure 9** shows the comparison of simulated SST with OISST reference data. We recall that

452   SST, in a coupled simulation, is actually the same variable for ocean and atmosphere

453   components (where grids overlap), and guides the thermal exchange providing an active

454   feedback among the two components: the higher is the difference among SST and atmosphere

455   temperature, the larger will be the heat exchange at the interface that tends to lower such

456   difference. Looking at **Figure 9**, the coupled model well reproduces the OISST spatial pattern

457   for both the configurations and seasons: WRF-MITgcm shows a mean bias of -0.5°C during

458   winter and of 0.7°C during summer, while RegCM-MITgcm has a general negative bias in

459   winter with a mean value of -0.9°C and a small positive bias in summer of 0.25°C. The large

460   winter bias of the RegCM simulation is due to an important bias located in the Levantine Sea,

461 while, during summer, WRF shows a large bias covering all the Western basin and part of the
462 Ionian Sea.

463 In spite of some large local bias, the MITgcm, in both its configurations, well reproduces the
464 observed interannual variability, although it has a too marked year-to-year variability (**Figure**
465 **10a**). The SST seasonal cycle closely follows the reference dataset, although both WRF-MITgcm
466 and RegCM-MITgcm show a notable SST underestimation between October and April and a
467 slight overestimation during summer months (**Figure 10b**). Compared to similar modelling
468 experiments, we note that an overall cold bias is not unusual in coupled simulations of the
469 Mediterranean Sea and the magnitude of the biases obtained in the present study is comparable
470 to the literature (Sevault et al., 2014, Turuncoglu and Sannino, 2017, Reale et al.2020). In
471 particular, the seasonal spatial patterns in winter and summer closely resemble those shown in
472 Turuncoglu and Sannino (2017), although they used the ROMS model to simulate the
473 Mediterranean Sea. More recently, Reale et al. (2020) obtained a reduced cold bias with respect
474 to both the available literature and the present experiment performed with RegCM-MITgcm;
475 however a direct comparison is not straightforward as their simulation period was limited to the
476 years 1994-2006.

477 Considering the SSS, compared to the reference data, both the simulations show very similar
478 spatial patterns and biases (**Figure 11**); the ocean model, in both its configurations, is saltier than
479 the reference dataset, especially in the Adriatic Sea during summer. This is due to the fact that
480 the Adriatic Sea is a dilution basin, mainly because of the important freshwater supply provided
481 by rivers. In both the simulations the freshwater input from river runoff is heavily
482 underestimated by the interactive river routing model (**Figure 12**); this underestimation is
483 slightly more evident in RegCM, which shows a lower river baseline with respect to WRF
484 (**Figure 12**).

485 Looking at the monthly SSS anomalies (**Figure 13a**) we found a similar temporal variability
486 compared to the reference data. Besides, the two configurations of the coupled model fairly
487 agree, with the exception of 1996, when WRF has a remarkable drop in SSS due to the minimum
488 in the freshwater flux (**Figure 5**) caused by exceptional precipitation and river runoff during that
489 year; interestingly, such a drop is also evident in other observational datasets (Sevault et al.,
490 2014).

491 The seasonal cycle of SSS for the two simulations is very close during all the months (**Figure**

492 **13b**). Compared to other studies, the mean bias of both WRF-MITgcm and RegCM-MITgcm is

493 lower than that of similar simulations for the Mediterranean Sea as it does not exceed 0.1 g/km

494 on a basin mean (e.g. Sevault et al., 2014, Turuncoglu and Sannino, 2017).

495

496 **4.2.2 Sea surface height and circulation**

497 The Strait of Gibraltar is the only connection between the Mediterranean basin and the Atlantic

498 Ocean. In general, the two-way exchange at the strait is constituted by an upper inflow of

499 Atlantic water and a lower outflow of relatively colder and saltier Mediterranean water.

500 However, the semidiurnal tidal effect is strong enough to reverse the direction of the flows

501 during part of the tidal cycle. As this exchange represents the main driver of the circulation in the

502 basin, the challenge of estimating its value has been faced for decades.

503 The inflow transport derived from the two coupled simulations is about 1 Sv (**Table 2**);

504 similarly, the models predict a net transport of 0.06 Sv. Unfortunately, the estimate of the

505 transport obtained from the direct measurements of velocities is affected by the limited number

506 of moorings used to this purpose that cannot resolve the structure of the entire section. Therefore,

507 some numerical models have also been used to reproduce and quantify the two way-exchange.

508 Estimates of mean inflow range from about 0.72 Sv of Bryden et al. (1994) to 1.68 Sv of

509 Bethoux (1979). Sannino et al. (2009) computed an inflow of 1.03 Sv using a three-dimensional

510 numerical model characterized by a very high resolution in the strait. Similarly, the long-term net

511 transport that balances the excess of evaporation over precipitation and river runoff in the

512 Mediterranean has a value of about 0.05 Sv (Bryden et al. 1994; Sannino et al., 2009);

513 noteworthy, our results well agree with these estimates (**Table 2**).

514 The mean annual current velocity at 30 m depth and the mean annual Sea Surface Height (SSH)

515 are analyzed in **Figure 14** for WRF-MITgcm (a) and RegCM-MITgcm (b), respectively. The

516 two simulations depict a similar mean annual circulation, with similar large-scale features.

517 The Atlantic Water (AW) circulation is in good agreement with those described by Millot and

518 Taupier-Letage (2005) and Pinardi et al. (2013), the first being mainly based on both in situ and

519 remotely sensed datasets, the latter resulting from a reanalysis performed with a model having an

520 horizontal resolution of 1/16° x 1/16°. In particular, Atlantic surface waters enter at Gibraltar, are

521 trapped into gyres in the Alboran Sea and then exit, dividing into two branches: one sticking to
522 the North-African coast, forming the Algerian current and the other in the direction of the
523 Balearic Islands. This latter detaches from the coast and flows south of Ibiza Island generating an
524 intense jet flowing eastward. This current receives the contribution of the Southern edge of the
525 Lion cyclonic gyre after the Balearic Sea and generates the Southern Sardinian Current flowing
526 along the west coast of Sardinia and merging with the Algerian current. The Southern Sardinian
527 Current branches in three parts (Béranger et al., 2004; Pinardi et al., 2006): the southernmost
528 branch produces the Sicily Strait Tunisian current, the central one forms the Atlantic Ionian
529 Stream (Robinson et al., 1999; Onken et al., 2003; Lermusiaux and Robinson, 2001) and the
530 northernmost one enters in the Tyrrhenian Sea giving rise to the South-Western Tyrrhenian gyre.
531 Finally, the Atlantic waters penetrate into the eastern basin through the Sicily Strait. Noticeably,
532 all these structures are very well defined in both the configurations of the regional Earth system
533 model (**Figure 14**). The two model's versions show the wide cyclonic gyre in the Gulf of Lion,
534 that includes the liguro-provencal current, which is one of the main features of the Western
535 Mediterranean circulation.

536 The mean circulation in the Eastern basin is characterized by several features common to both
537 simulations. It is possible to appreciate how the surface water penetrates into the Adriatic Sea
538 with a cyclonic circulation, and it is possible to notice the presence of a counterclockwise
539 circulation in the Aegean Sea in both simulations.

540 Moreover, the simulations reproduce quite clearly the places where deep water formation takes
541 place: the three cyclonic gyres located in the Gulf of Lion, southern Adriatic Sea and in the
542 Levantine Sea. These cyclonic gyres concur with negative SSH values, which highlight the
543 sinking of surface waters.

544

545 **4.2.3 Heat and salt contents**

546 Mean annual temperature and salinity averaged over the entire Mediterranean basin and the
547 Western and Eastern sub-basins are shown in **Table 3**; here we present estimates from the
548 MEDHYMAP data, while for the two simulations we show the anomalies with respect to the
549 reference data. The average content of heat and salt has been computed over different vertical
550 layers: the entire column, the surface layer (0 -150m) corresponding approximately to the
551 Atlantic Water, the intermediate layer (150-600m) representing mainly the Levantine

552 Intermediate Water, and the deep layer (600-3500m) containing the Eastern and Western
553 Mediterranean Deep Waters.

554 The average temperature of the whole water column, for each sub-basin, is in good agreement
555 with observations in both coupled runs, being the difference between modeled values and
556 observations not exceeding 0.2°C. Major discrepancies are concentrated in the upper layer of the
557 Eastern basin, where both models result colder than observation, with WRF-MITgcm showing an
558 underestimation of 0.78°C, while RegCM-MITgcm has a bias exceeding 1°C. Such discrepancy
559 reduces within the intermediate layer and deep layer in case of WRF-MITgcm, while MITgcm
560 forced by RegCM shows a slight overestimation in the deep layer, that quite compensates for the
561 error in the uppermost layer. In the western basin the two models remain much closer to the
562 observations, with RegCM-MITgcm showing a systematic cold bias and WRF-MITgcm is closer
563 to observations. Notwithstanding some biases, we point out that the mean values of the
564 temperature within the different layers are compatible with those obtained in analogous
565 simulations and are within the ensemble spread computed from the series of Med-CORDEX
566 simulations analyzed by Llasses et al. (2018).

567 **Figure 15** shows the time series of mean annual temperature anomalies computed over the 1982-
568 2013 period for the surface and intermediate layers in the whole basin and in the Western and
569 Eastern sub-basins. Generally, the interannual variability of the whole basin is well captured by
570 the two simulations in both the surface layer and in the intermediate level with the two
571 configurations showing similar variability and performances. However, the observations show a
572 slight increasing trend, mainly in the Eastern basin, that the simulations do not capture. In any
573 case, both simulations well capture the surface positive anomaly in 1990 in the western basin, as
574 well as the sequence of negative anomalies in the eastern basin (1983,1987, and 1993). In the
575 intermediate layer, the sudden drop of temperature during 1993 is the signature of the Eastern
576 Mediterranean Transient (EMT) phenomenon (discussed in paragraph **4.2.4**).

577 The mean annual salinity averaged over the whole column (**Table 3**) is slightly underestimated
578 by WRF-MITgcm (-0.07 psu) and overestimated by RegCM-MITgcm (0.06 psu). In the Eastern
579 basin the maximum of salinity is correctly found in the intermediate layer (150-600m), in
580 correspondence of the LIW, although the RegCM-MITgcm simulation shows a too slight
581 decrease of the salinity from the intermediate to the deep layer. Such behaviour is consistent with

582 the higher values reached by the Mixed Layer Depth (MLD) in the same area with respect to the

583 MLD of the WRF-MITgcm simulation (discussed in paragraph **4.2.4**).

584 Similarly, in the western basin saltier intermediate water is clearly identified in the WRF run

585 with respect to RegCM, due to the combined effect of the advection of a saltier LIW and a less

586 intense deep convection, that in the western basin is mostly concentrated in the Gulf of Lion

587 area. The comparison of the MLD in the Gulf of Lion area (see paragraph **4.2.4**) supports this

588 hypothesis.

589 **Figure 16** shows the time series of mean annual salinity anomalies computed over the 1982-

590 2013 period for the surface and intermediate layers in the whole basin and in the Western and

591 Eastern sub-basins. While the entire basin variability is generally well reproduced, the behaviour

592 of models in the two sub-basins deserves some comment. In particular, in the western basin the

593 MITgcm, in its two configurations, simulation fails in reproducing the drop in salinity of the

594 uppermost layer during the years 1990-1995. This is probably due to a too low freshwater flux

595 simulated by the atmospheric components in those years, confirmed by high values of the MLD.

596 On the other hand, in the eastern basin the WRF-MITgcm shows a large freshwater anomaly in

597 the 0-150m layer during the years 1995-1997 that is not detectable in the reference data.

598 However, it should be noted that the same anomaly has also been observed in the SSS time series

599 and is caused by exceptional precipitation and river runoff as already reported by Sevault et al.

600 (2014). Anyhow, such a drop seems to affect mainly SSS and the surface layer, while it is

601 scarcely transferred below 200 m. In the intermediate layer both simulations show a steady

602 increase in the salinity anomaly. RegCM-MITgcm has almost a linear increase throughout the

603 entire simulation period, due to the excess of surface salinity and anomalous deep convection in

604 the Levantine Sea, while WRF-MITgcm is quite stable during the first half of the simulations

605 and then shows a steep linear increase from 2000 onward.

606

607 **4.2.4 Deep water formation**

608 The formation of intermediate and deep waters due to sinking of dense water is one of the

609 fundamental processes taking place in the Mediterranean Sea, in both the Eastern and Western

610 sub-basins. Typical regions interested in this process are the Gulf of Lion, the South Adriatic

611 Sea, the Cretan Sea and the Rhode Gyre. Such a process, mainly driven by the strong air-sea

612 interactions, takes place during the winter season, and is more effective during February. The

613   most active regions for deep water formation are the Gulf of Lion and the Adriatic Sea, while

614   intermediate waters are usually formed in the Levantine Sea.

615   The MLD is related to thermodynamic properties of seawater and is a pivotal variable helping in

616   the identification of deep-water formation events. High MLD values are related to strong air-sea

617   processes taking place at the surface or to preexisting stratification of the whole water column.

618   **Figure 17** compares the simulated monthly maximum MLD computed over the most important

619   convective areas, i.e. the Levantine Sea, the Gulf of Lion, and the Adriatic Sea. In general,

620   RegCM-MITgcm shows a more intense convection activity with respect to WRF-MITgcm, often

621   reaching the deepest levels in all the analyzed regions. Looking at the Levantine region (**Figure**

622   **17a**), during almost the entire simulation, the MLD simulated by RegCM-MITgcm exceeds

623   1000m depth, while in case of WRF-MITgcm there are few events where the MLD is confined to

624   the intermediate level (400-500 m). The strong events of 1983,1987 and 1989 are clearly

625   detectable in both simulations, and correspond to intense atmospheric fluxes, that have favoured

626   the preconditioning of the eastern basin leading to the well-known phenomenon of the EMT. In

627   the Gulf of Lion, both simulations show an intense convection activity that often reaches the

628   bottom of the column in at least one of the two models, with the exception of the years

629   1989,1990 and 2007. The other site of deep water formation is the South Adriatic zone, where

630   the two models are remarkably in good agreement one with each other.

631   In addition to the temporal evolution of MLD, in **Figure 18** we compare the mean spatial pattern

632   of the MLD with ARGO data (Holte et al., 2017). Results suggest that the downwelling regions

633   of both simulations are much more extended compared to ARGO data, and in RegCM-MITgcm

634   the convective area is slightly wider than in the WRF-MITgcm simulation.

635   The steady-state picture of the Mediterranean thermohaline circulation, in which the Eastern

636   Mediterranean Deep Water (EMDW) is only of Adriatic origin, has been called into question by

637   the discovery of the EMT. As described by many authors, there is observational evidence that

638   during the '90s the main source of EMDW migrated to the Aegean Sea (Lascaratos et al., 1993;

639   Malanotte et al., 1999; Wu et al., 2000; Roether et al., 2007; Beuvier et al., 2010). The common

640   understanding is that the EMT has been the effect of many concurrent causes that make this

641   process difficult to be simulated: the large heat loss from surface in the Levantine, the shifting

642   from cyclonic to anticyclonic circulation in the Ionian that prevents the entering of freshwater in

643   the Levantine basin, and the lower than usual freshwater flux from the Black Sea. Waters formed

in the Aegean are warmer and saltier than that of the Eastern Mediterranean at the same levels, and they are found at intermediate levels between LIW and EMWD of Adriatic origin. During the EMT period, instead, bottom levels were filled with newly formed waters of Aegean origin, while the less dense Adriatic waters were uplifted (Roether et al., 2007). All the studies agree on a massive dense-water formation in the Aegean Sea during the period 1987-1994 (e.g. Theocharis et al., 2002); as described by Theocharis et al. (1999), during the period 1986-1987, the Cretan Sea was characterized by a weak stratification. In the following years, water with densities higher than 29.2 was found at progressively upper layers in the Cretan Sea, with a significant formation rate in particular during 1989, due to an intrusion of deep waters from the central Aegean through the Myconos-Ikaria strait (Vervatis et al., 2013). Starting from 1989 dense water outflowed from the Cretan Arcs and was found in the Eastern Mediterranean Sea at levels between 700 and 1600 m. Then, dense water formation in the Cretan Sea increased during 1991 and 1992, the new water reached the upper layer of the Cretan basin, and the entire basin was filled with young water with density up to 29.3.

This phenomenon is remarkably well reproduced by the two configurations of the model, both considering the timing of events and the density and volumes of newly formed waters, as shown in **Figure 19.** Here the volumes occupied by water with density higher than 29.2 kg/m3 and 29.3 kg/m3 in the Cretan Sea are shown; it can be seen that the period between 1983 and 1993 is characterized by an increase of the volume with three most significant peaks in 1984, 1989, and the highest in 1993, in both the simulations.

5.   Summary and conclusions

We presented a newly designed regional Earth system model to study the climate variability over the Euro-Mediterranean region. The performances of individual model components were evaluated comparing results from the simulations with a wide range of observation-based datasets.

Unlike other existing regional coupled atmosphere–ocean models, our system is made up of two interchangeable atmospheric components (i.e. RegCM and WRF), offering the capability to select the regional atmospheric model to be used depending on the region of interest and the model's performances over the selected region. We performed a hindcast simulation for each

atmospheric configuration over the period 1980-2013 using ERA-Interim reanalysis as lateral boundary conditions.

Overall, results indicate that the two atmospheric components of the regional Earth system model (i.e. WRF and RegCM) correctly reproduce both large-scale and local features of the Euro-Mediterranean climate, although we found some remarkable biases for some variables. While WRF shows a significant cold bias during winter over the North-Eastern area of the domain and a large warm bias during summer, RegCM overestimates the wind speed over the Mediterranean Sea.

The ocean component correctly reproduces the analyzed surface ocean properties (along with their interannual variability) and the observed circulation in both the coupled model configurations. Anyhow, because of the wind speed overestimation by RegCM, we found a cold bias in the SST during the winter months.

A possible approach aimed to reduce the biases is the adoption of nudging techniques, recently introduced into some RCMs (Liu et al., 2012). This method allows the passing of the driving model information not only onto the lateral boundaries but also into the interior of the regional model domain (Waldron et al.1996; Heikkilä et al., 2011); this is achieved by relaxing the model state towards the large-scale driving fields by adding a non-physical term to the model equation (Omrani et al., 2015). Clearly, the nudging allows a stronger control by the driving forcing and thus a greater consistency between the regional model and large-scale climate coming from the driving model. However, nowadays, there is still some controversy on the use of indiscriminate nudging in regional climate models (e.g. Omrani et al., 2015). Some studies agree that nudging does not allow the regional model to deviate much from the driving fields limiting the internal physics of the regional climate model (e.g. Sevault et al. 2014; Giorgi 2019). Considering the atmosphere-ocean coupling, Sevault et al. (2014) conclude that the use of spectral nudging strongly constrains the synoptic chronology of the atmospheric flow and thus the chronology of the air-sea fluxes and the ocean response; they also found that this facilitates day-to-day and interannual evaluation with respect to observations, but nudging also limits the internal variability of the atmospheric component of the coupled model. Conversely, in a different study on extreme events in the Mediterranean Sea performed with a coupled atmosphere-ocean model, Lebeaupin-Brossier et al. (2015) found that nudging does not inhibit small scale processes; thus, potential air-sea feedbacks are correctly simulated. This result is consistent with Omrani et al.

706 (2015), who suggested that the spectral nudging technique does not affect the small-scale fields
707 since only the large scales are relaxed.

708 Not all RCMs offer the possibility to use nudging; for example, WRF can be used with spectral
709 or grid nudging (Liu et al., 2012), while RegCM does not. To assess the impact of nudging on
710 the performance of a coupled model, we performed an additional coupled simulation with WRF-
711 MITgcm using the spectral nudging; the overall performances of the regional model in its three
712 versions are summarized for the relevant variables over the Mediterranean Sea with a Taylor
713 diagram (**Figure 20**). Results indicate that WRF with nudging performs better than the
714 simulation without nudging in most analyzed meteorological variables. However, the most
715 interesting result is that the ocean physical processes are much better represented and agree with
716 observation-based data when nudging is used in the atmospheric component. In particular,
717 intermediate and deep water formation are much better represented. **Figure 21** shows the
718 intercomparison between the WRF-MITgcm with nudging and the RegCM-MITgcm simulation
719 as representative of the simulations performed without nudging. While in the Levantine Sea, the
720 MLD simulated by RegCM-MITgcm exceeds 1000m depth, WRF-MITgcm MLD is more
721 variable in time. The latter reaches the entire water depth during a few events, which are well
722 known and documented with in-situ observations (Lascaratos et al. 1999; Malanotte et al., 1999;
723 Roether et al., 2007). Therefore, we can conclude, as expected, that the LIW formation is better
724 reproduced when the nudging is applied. Several MLD observation-based estimates are available
725 in the Gulf of Lion for the period covered by our simulations (e.g. Martens and Schott 1998;
726 Schroeder et al., 2008; Somot et al., 2016). Compared to these estimates, we observe that WRF-
727 MITgcm simulation closely follows the timing of deep water formation in the Western
728 Mediterranean, in particular the deep convection events of 1987 and 2005, with the exception of
729 1991 and 1992, identified by Somot et al. (2016) as years of intense mixing, while RegCM-
730 MITgcm systematically presents a deeper MLD (**Figure 21b**). The deep convection in the
731 Adriatic does not change significantly due to the nudging, always involving the entire column
732 depth.

733 This analysis reveals that spectral nudging helps to keep the large scale circulation of the
734 regional model closer to the driving model; however, we remark that nudging does not avoid the
735 model to develop the small scale processes such as those relevant in the Gulf of Lion. This is a
736 crucial point for the entire thermohaline circulation of the Mediterranean Sea. The striking

737 correspondence with observed data in this region depends on the good representation of the local
738 wind, the Mistral, and the correct stratification of the whole column water, with the Levantine
739 Intermediate Water coming from the Eastern basin playing a crucial preconditioning role.
740 Notwithstanding the added-value of nudging proved by the better performance of the WRF-
741 MITgcm configuration, nudging has also to be used with caution: strong inconsistencies between
742 regional model and large-scale driving fields may lead to unrealistic compensations within the
743 model, for example, anomalous heat fluxes compensating for temperature biases (Brune and
744 Baehr, 2020).

745 This study presented two different configurations of the same regional Earth-system model,
746 differing for the atmospheric component and using the same version of the ocean model. Our
747 main result is that the two configurations are comparable and consistent with the previous results
748 available in the literature. Thus they can be used to realize future climate scenario simulations,
749 contributing to the realization of regional ensembles. On the other hand, we can perform hindcast
750 simulations very close to observations, once switching to an atmospheric model that offers the
751 opportunity to use the spectral nudging technique.

752

753 **Code availability**

754 The source code of the RegESM driver is distributed through the public code repository hosted
755 by GitHub (https://github.com/uturuncoglu/RegESM, last access: 24 December 2020). The
756 version that is used in this study is permanently archived on Zenodo and accessible under the
757 digital object identifier https://doi.org/10.5281/zenodo.4386712. The user guide and detailed
758 information about the modelling system and how to compile it are also distributed along with the
759 source code in the same code repository.
760 The standard version of WRF model is publicly available online at
761 https://github.com/NCAR/WRFV3/releases/tag/V3.8.1 (last access: 24 December 2020) but the
762 customized version that allow to couple with RegESM modelling system is permanently
763 archived on Zenodo and accessible under the digital object identifier
764 https://doi.org/10.5281/zenodo.4392230. The MITgcm model can be freely downloaded from its
765 web page (http://mitgcm.org/source-code/ (last access: 24 December 2020) but the substantially
766 modified version to allow coupling with RegESM modelling system can be accessible at
767 https://github.com/uturuncoglu/MITgcm and it is permanently archived on Zenodo and
768 accessible under the digital object identifier https://doi.org/10.5281/zenodo.4392260. The
769 RegCM model can be downloaded from public GitHub repository (https://github.com/ictp-
770 esp/RegCM, last access: 24 December 2020), while the HD model is available at
771 https://wiki.coast.hzg.de/display/HYD/The+HD+Model (last access: 24 December 2020) but

slightly customized version that enables coupling with RegESM modelling system can be accessed from the public GitHub repository (https://github.com/uturuncoglu/HD) and it is permanently archived on Zenodo and accessible under the digital object identifier https://doi.org/10.5281/zenodo.4390527. For each model, the coupling support is provided contacting the authors (alessandro.anav@enea.it; turuncu@ucar.edu; gianmaria.sannino@enea.it).

The initial and boundary meteorological conditions, provided by the European Centre for Medium-Range Weather Forecast (ECMWF), can be freely downloaded from the ECMWF web page (https://apps.ecmwf.int/datasets/data/) after registration.

The LEVITUS94 monthly climatology for temperature and salinity is available at the web page https://iridl.ldeo.columbia.edu/SOURCES/.LEVITUS94/.MONTHLY/ (last access: 24 December 2020). The Mediterranean and Black Sea database of temperature and salinity (MEDATLAS/2002) is available at http://www.ifremer.fr/medar/.

Author contributions

UT wrote the RegESM driver, while all the authors worked on the coding tasks to couple the model components through RegESM. AA and MS performed the simulations. All authors discussed the results and contributed to the writing of the article.

Competing interests

The authors declare that they have no conflict of interest.

1159 **Figure 1.** Schematic description of the ENEA-REG regional coupled model. The green block
1160 represents the atmosphere with the two components that can be selected and used (i.e. WRF and
1161 RegCM), the blue block is the ocean component (i.e. MITgcm), the red block represents the river
1162 routing component while the grey block is the ESMF/NUOPC coupler which collects, regrids
1163 and exchanges variables between the different components of the system.
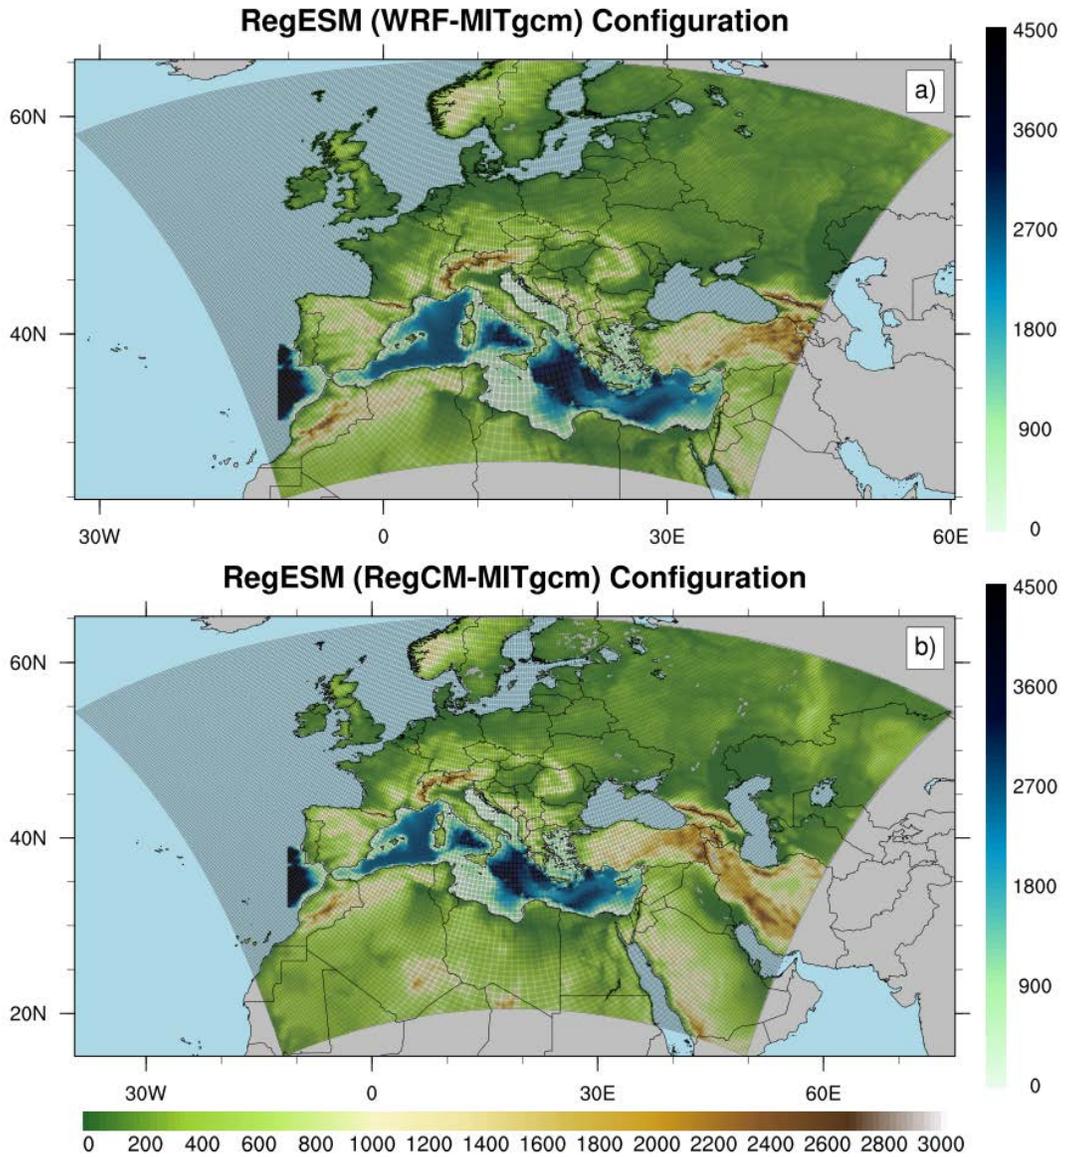

Figure 2. Different domains of the ENEA-REG system, with green shading representing the topography of the atmospheric models (i.e. WRF and RegCM, solid grey lines indicate the computational domain) and blue shading the bathymetry of the ocean component.
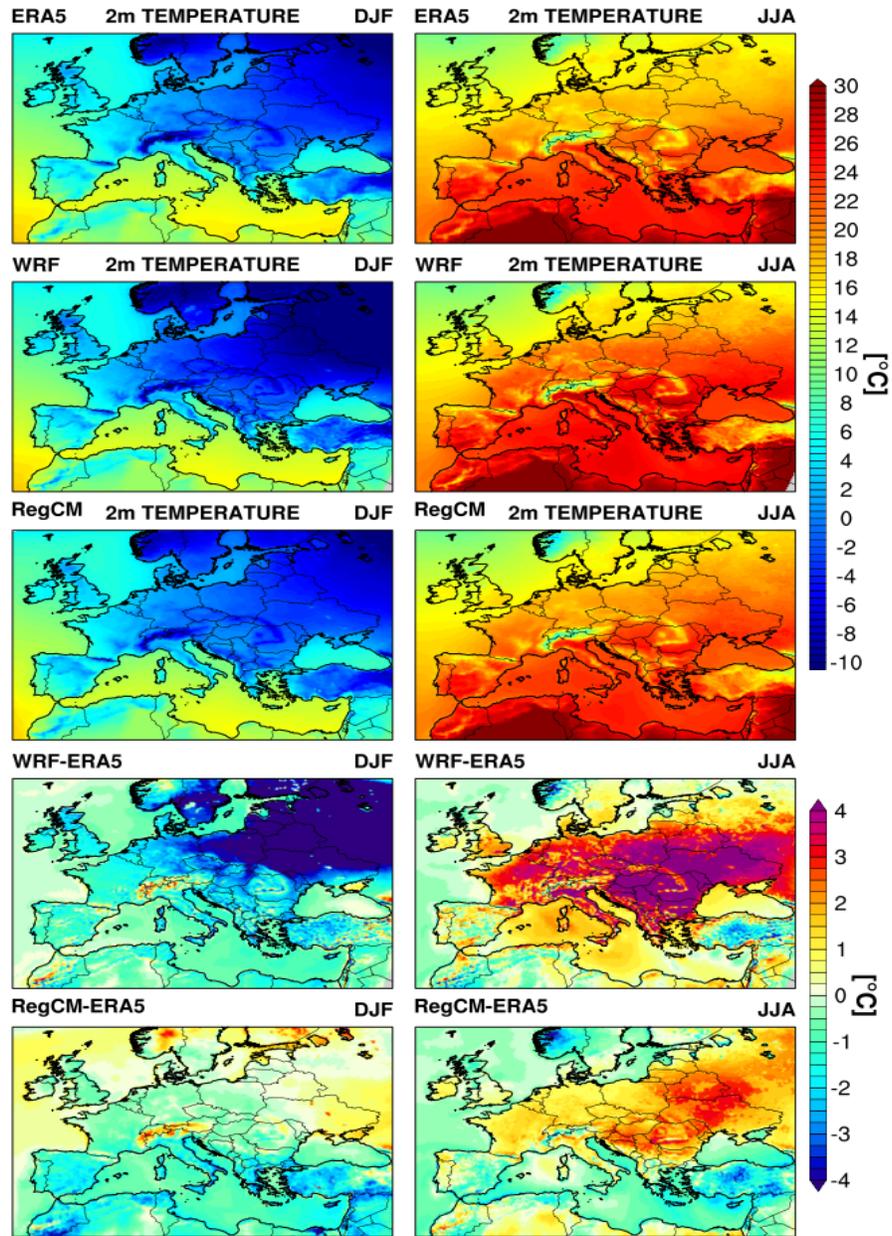

1168

Figure 3. Seasonal winter (DJF) and summer (JJA) spatial pattern (upper three panels) and bias (lower two panels) of 2m air temperature as simulated by the coupled model using the two atmospheric components (i.e. WRF and RegCM) and ERA5 dataset between 1982 and 2013. Note that in the bias panels ERA5 data are interpolated into the atmospheric model grid. Mind also the differences in colour scales between DJF and JJA climatologies.
