26 **Abstract.** A stochastic deep convection parameterization is implemented into the U.S.
27 Department of Energy (DOE) Energy Exascale Earth System Model (E3SM) Atmosphere Model
28 version 1.0 (EAMv1). This study evaluates its performance on the precipitation simulation.
29 Compared to the default model, the probability distribution function (PDF) of rainfall intensity in
30 the new simulation is greatly improved. Especially, the well-known problem of “too much light
31 rain and too little heavy rain” is alleviated over the tropics. As a result, the contribution from
32 different rain rates to the total precipitation amount is shifted toward heavier rain. The less
33 frequent occurrence of convection contributes to the suppressed light rain, while both more
34 intense large-scale and convective precipitation contributes to the enhanced heavy total rain. The
35 synoptic and intraseasonal variabilities of precipitation are enhanced as well to be closer to
36 observations. The sensitivity of the rainfall intensity PDF to the model vertical resolution is
37 examined. The relationship between precipitation and dilute convective available potential
38 energy in the stochastic simulation agrees better with that in the Atmospheric Radiation
39 Measurement (ARM) observations compared with the standard model simulation. The annual
40 mean precipitation is largely unchanged with the use of the stochastic scheme except over the
41 tropical western Pacific, where a moderate increase in precipitation represents a slight
42 improvement. The responses of precipitation and its extremes to climate warming are similar
43 with or without the stochastic deep convection scheme.
44

45 **1. Introduction**

46 Precipitation plays a vital role in the Earth’s climate: the latent heat released during
47 precipitation formation is a major energy source that drives the atmospheric circulation, and
48 precipitation is an important part of the Earth’s hydrological cycle. The accurate simulation of
49 precipitation in global climate models (GCMs) is of great scientific and societal interest.
50 However, GCMs used for current climate simulation and future projections suffer from many
51 biases in the global distribution, frequency and intensity of simulated precipitation (Dai, 2006),
52 which have negatively impacted the model’s fidelity. Rainfall in nature is tightly associated with
53 many complex dynamic and physical processes in the atmosphere, including large-scale
54 circulation, convection, cloud microphysics, and planetary boundary layer (PBL) processes. The
55 deficiencies in representing these processes in GCMs are prime culprits for errors in simulated
56 rainfall (Watson et al., 2017).

57 Among the physical processes in GCMs, the parameterization of convection is responsible
58 for some well-known biases: the double Intertropical Convergence Zone (Zhang and Wang 2006;
59 Zhang et al., 2019), too weak synoptic and intraseasonal variabilities in the tropics (Zhang and
60 Mu, 2005a; Watson et al., 2017), the wrong diurnal cycle of rainfall (Xie et al., 2019), “too much
61 light rain and too little heavy rain” (Dai, 2006; Zhang and Mu, 2005b; O’Gorman and Schneider,
62 2009), to name a few. The conventional deterministic convective parameterization in GCMs
63 represents the ensemble effects of subgrid-scale convective clouds in a model grid box on
64 resolved scale variables. However, in reality, a given grid-scale state may lead to different
65 realizations of subgrid-scale convection (Davies et al., 2013; Peters et al., 2013) rather than to a
66 single “ensemble-mean” response. For instance, two model grid boxes, both in a similar
67 convective-equilibrium state, can have different numbers and/or sizes of convective clouds due
68 to stochasticity (Cohen and Craig, 2006). This stochasticity will appear more frequently as the
69 model grid-box size becomes smaller (Jones and Randall, 2011). Not including stochasticity in
70 convective schemes has been suggested to be at least partly responsible for the weak
71 intraseasonal variability and “too much light rain and too little heavy rain” in GCMs (Lin and
72 Neelin 2000, Wang et al., 2016; Watson et al., 2017; Peters et al., 2017).

73 As suggested in Palmer (2001, 2012), more realistic statistics of the impacts of subgrid
74 convective clouds should be derived by simulating them as random samples from probability
75 distributions conditioned on the grid-scale state, so that the influences of different individual
76 realizations are introduced in the convection parameterization. In this regard, much effort in the

77 past two decades has been made to develop stochastic convection schemes (e.g., Lin and Neelin,
78 2000, 2002; Plant and Craig, 2008; Khouider et al., 2010; Sakradzija et al., 2015). Among these
79 schemes, Plant and Craig (2008) (PC08 hereafter) developed a stochastic deep convection
80 parameterization under a framework based on statistical mechanics (Cohen and Craig, 2006;
81 Craig and Cohen, 2006) for noninteracting convective clouds in statistical equilibrium using
82 cloud-resolving model (CRM) simulations. This scheme was applied to numerical weather
83 prediction (NWP) models and to a GCM in an aquaplanet setting, resulting in some substantial
84 improvements in precipitation simulation (Groenemeijer and Craig, 2012; Keane et al., 2014,
85 2016).

86 Wang et al. (2016) incorporated the PC08 stochastic deep convection scheme into the
87 Zhang-McFarlane (ZM) deterministic deep convection scheme (Zhang and McFarlane, 1995) in
88 the National Center for Atmospheric Research (NCAR) Community Atmosphere Model version
89 5 (CAM5). They found that the introduction of the stochastic scheme improved the simulation of
90 precipitation intensity and intraseasonal variability over the tropics in CAM5 (Wang and Zhang
91 2016; Wang et al., 2017).

92 In this study, we implement the PC08 stochastic deep convection parameterization scheme
93 into the DOE Energy Exascale Earth System Model (E3SM) (Golaz et al. 2019) Atmosphere
94 Model version 1.0 (EAMv1) (Rasch et al. 2019; Xie et al. 2018) and examine its effect on
95 precipitation simulation. The EAMv1 is branched out from CAM5 and thus it inherits many
96 model deficiencies from CAM5 as well. Many modifications in physics parameterizations have
97 been made compared to CAM5 (Rasch et al. 2019; Xie et al. 2018). However, some model biases
98 such as weak precipitation intensity persist (Xie et al. 2019). Thus, besides the precipitation
99 metrics explored in our previous studies (Wang et al. 2016, 2017; Wang and Zhang 2016), this
100 study will evaluate precipitation simulation with more systematical metrics. In addition, the
101 responses of precipitation and its extremes to climate warming with the stochastic deep
102 convection scheme will be investigated.

103 The organization of the paper is as follows. Section 2 presents parameterization, model,
104 experimental design, and evaluation data. Section 3 describes results, including variability,
105 frequency, intensity, amounts, duration, mean state, and responses of precipitation and its
106 extremes to climate warming. The sensitivity of the rainfall intensity pdf to vertical resolution
107 and underlying mechanisms are also presented in this section. Summary is given in section 4.

108

109 **2. Parameterization, model, experimental design and evaluation data**

110 **2.1. Stochastic deep convection parameterization**

111 The stochastic convective parameterization scheme of PC08 is modified for climate models
112 when incorporating into the ZM deterministic deep convection scheme. The most essential part
113 of the PC08 scheme involves two probability distributions. One is the probability distribution of
114 mass flux of a cloud; it follows the exponential distribution:

115
$$p(m)dm = \frac{1}{\langle m \rangle} e^{-m/\langle m \rangle} dm \quad (1)$$

116 where $\langle m \rangle$ is the mean mass flux of a cloud and is a preset tuning parameter. The integral of the
117 probability density over all values of mass flux is 1, i.e., probability one that every cloud has a
118 mass flux between zero and infinity. The other is the probability of triggering n clouds for a
119 given cloud mass flux in the range between m and $m+dm$ at a given GCM grid box and time step;
120 it is drawn from a Poisson distribution:

121
$$P_{\langle N \rangle}(n) = \frac{\langle N \rangle^n e^{-\langle N \rangle}}{n!} \quad \text{for } n=0, 1, 2, 3, \dots \quad (2)$$

122 where $\langle N \rangle$ is the ensemble mean number of convective clouds in the grid box. Here the sum of
123 the probabilities over all n must equal one, i.e., probability one that some number between zero
124 and infinity of clouds will be triggered with mass flux in this interval. Thus, the average number
125 of clouds with mass flux between m and $m+dm$, $d\bar{n}(m)$, is:

126
$$d\bar{n}(m) = \langle N \rangle p(m)dm = \frac{\langle N \rangle}{\langle m \rangle} e^{-m/\langle m \rangle} dm \quad (3)$$

127 From eqs. (2) and (3), it follows then that for small $d\bar{n}(m)$ the probability of launching one
128 convective cloud with mass flux between m and $m+dm$ is given by:

129
$$p_{d\bar{n}(m)}(n = 1) = \frac{\langle N \rangle}{\langle m \rangle} e^{-m/\langle m \rangle} dm \quad (4)$$

130 Note that eq. (4) is not a probability density function, but rather the probability of triggering one
131 cloud for a given cloud mass flux interval ($m, m+dm$), knowing that the average number of
132 clouds within this mass flux interval is $d\bar{n}(m)$. $\langle N \rangle = \langle M \rangle / \langle m \rangle$, where $\langle M \rangle$ is the ensemble
133 mean total cloud mass flux given by the closure based on the convective quasi-equilibrium
134 assumption in the ZM deterministic parameterization. For each mass flux bin, whether to launch

135 a cloud is determined by comparing the probability $\frac{1}{\langle m \rangle} e^{-\frac{m}{\langle m \rangle}} dm$ with a random number
136 uniformly generated between zero and one. Then, the sum of mass fluxes generated this way is
137 multiplied by the factor $\langle N \rangle$ to rescale it to the mass flux of all clouds. The product of the total
138 mass flux and the temperature and moisture tendencies from the bulk plume model gives the
139 final temperature and moisture tendencies by the subgrid convective clouds.

140 There are two modifications to the original implementation in the NCAR CAM5. One is the
141 update frequency of random numbers which, unlike the update frequency of once a day in Wang
142 et al. (2016), is updated every 3 days in consideration of computational resources due to finer
143 vertical and horizontal resolutions in the EAMv1 (see section 2.2). For the same reason, the
144 spatial averaging of input quantities (i.e., vertical profiles of temperature and moisture) to the
145 closure over neighboring grid points used in the original design of PC08 is not performed
146 because it leads to an excessive communication load. One can argue that at a horizontal model
147 resolution of about 110 km in EAMv1, convective quasi-equilibrium approximately holds over
148 some timescale although at individual model timestep it does not. Thus, although spatial
149 averaging is not applied, the temporal trailing averaging over 3 h at each time step is retained in
150 the scheme. Other modifications to the PC08 scheme for incorporation into the ZM scheme in
151 climate models (Wang et al. 2016) are retained. These include:

152 1) The temporally averaged quantities are used to calculate the ensemble mean cloud mass
153 flux ($\langle M \rangle$), which is determined by the ZM scheme. The unsmoothed grid point quantities are
154 still used in the trigger function and the cloud model.

155 2) The root mean squared cloud radius information originally used in PC08 is not needed in
156 our implementation because the ZM scheme does not use cloud radius.

157 3) The ensemble mean mass flux of a cloud $\langle m \rangle$ is set to 1×10^7 kg s⁻¹ following
158 Groenemeijer and Craig (2012).

159 4) The cloud life cycle effect with a factor dt/T (dt is the model time step and T is the
160 constant lifetime parameter) in PC08 is not taken into account because the ZM deterministic
161 parameterization does not consider the life cycle of convection.

162

163 **2.2. EAMv1 model**

164 The standard configuration of the DOE EAMv1 uses a spectral element dynamical core at a
165 110-km horizontal resolution on a cubed sphere geometry and a vertical resolution of 72 layers
166 from the surface to 60 km (10 Pa) (Rasch et al. 2019, Xie et al. 2018). The treatment of PBL
167 turbulence, shallow convection, and cloud macrophysics are unified with a simplified third-order
168 turbulence closure parameterization CLUBB (Cloud Layers Unified by Binormals, Golaz et al.,
169 2002; Larson and Golaz, 2005). The deep convection is represented by the ZM scheme. The
170 Morrison and Gettelman (2008) (MG) microphysics scheme is updated to MG2 (Gettelman et
171 al., 2015) with the prediction of rain and changes to ice nucleation and ice microphysics (Wang
172 et al., 2014). A four-mode version of the modal aerosol module (MAM4) (Liu et a., 2016) is used
173 with improvements to aerosol resuspension, aerosol nucleation, scavenging, convective transport
174 and sea spray emissions for including the contribution of marine ecosystems to organic matter
175 (Rasch et al., 2019). A linearized ozone chemistry module (Hsu and Prather, 2009; McLinden et
176 al., 2000) is used to represent stratospheric ozone and its radiative impacts in the stratosphere.
177 Other modifications for model tuning are provided in detail in Xie et al. (2018).

178

179 **2.3. Experimental design**

180 Six Atmospheric Model Intercomparison Project (AMIP) type simulations are conducted.
181 Four 6-year simulations are forced by prescribed, seasonally varying climatological present-day
182 sea surface temperatures (SSTs) and sea ice extent, recycled yearly (Stone et al., 2018): two with
183 the default deterministic ZM scheme but having 72 and 30 vertical levels respectively (referred
184 to as EAMv1 and EAMv1-30L) and the other two with the stochastic deep convection scheme
185 (referred to as STOCH and STOCH-30L). The simulations with 30 vertical levels are conducted
186 to facilitate the comparison with Wang et al. (2016), in which the vertical resolution of CAM5 is
187 30 levels (see section 3.3). To explore the responses of precipitation and its extremes to climate
188 warming, similar to EAMv1 and STOCH runs, two 3-year simulations in a warmer climate are
189 conducted, in which a composite SST warming pattern derived from the Coupled Model
190 Intercomparison Project Phase 3 (CMIP3) coupled models (referred to as EAMv1-4K and
191 STOCH-4K respectively) is imposed for the boundary condition of the atmosphere. Following
192 Webb et al. (2017), it is a normalized multi-model mean of the sea surface temperature response
193 pattern from 13 CMIP3 atmosphere-ocean general circulation models, representing the change of
194 SST between years 0-20 and 140-160, the time of CO₂ quadrupling in the 1% runs. Before
195 calculating the multi-model ensemble mean, the SST response of each model was divided by its

196 global mean and multiplied by 4K. This guarantees that the pattern information from all models
197 is weighted equally and that the global mean SST forcing is +4K warming. The first year in all
198 simulations is discarded as a spin-up. Information for all experiments is summarized in Table 1.
199

200 **2.4. Evaluation data**

201 For model evaluation, the following datasets are used: The Clouds and the Earth's Radiant
202 Energy System Energy Balanced and Filled (CERES-EBAF) (Loeb et al., 2009) for evaluation of
203 shortwave and longwave cloud radiative forcing; the Interim European Centre for Medium-
204 Range Weather Forecasts Re-Analysis (ERA-Interim) (Simmons et al., 2007) for sea level pressure,
205 zonal wind, relative humidity, specific humidity, and temperature; the European Remote Sensing
206 Satellite Scatterometer (ERS-SCAT) (Bentamy et al., 1999) for surface wind stress; and the Willmott-
207 Matsuura (Willmott) (Willmott & Matsuura, 1995) data for land surface air temperature.

208 The rainfall mean state is evaluated against the Global Precipitation Climatology Project
209 (GPCP) monthly product (version 2.1) at a resolution of 2.5° (Adler et al., 2003; Huffman et al.,
210 2009) while a daily estimate of GPCP version 1.2 at 1° horizontal resolution (GPCP 1DD)
211 (Huffman et al., 2001, 2012) is used for evaluation of precipitation amount distribution. In
212 addition to GPCP, the Xie-Arkin pentad observations at 2.5° resolution (Xie and Arkin, 1996)
213 and the Tropical Rainfall Measuring Mission 3B42 version 7 (TRMM) daily observations at a
214 resolution of 0.25° over (50°S, 50°N) (Huffman et al., 2007) are applied to evaluate the
215 precipitation variance. The TRMM data are also used in the PDF of rainfall intensity and the
216 rainfall amount distribution. To estimate the uncertainty in the PDF of precipitation intensity in
217 observations, additional daily rainfall products are used. These include TAPEER v1.5, GSMAP-
218 NRT-gauges v6.0, PERSIANN CDR v1, CMORPH v1.0 CRT from the Frequent Rainfall
219 Observation on GridS (FROGS) database (Roca et al., 2019) and GPM IMERG v06b (Huffman
220 et al., 2017). For the rainfall duration evaluation, the TRMM 3B42 v7 3-hourly data is used. To
221 make the comparison consistent between observations and model simulations, the model data
222 with the same output frequency to that in the corresponding observations/reanalysis data are used
223 and all observations/reanalysis data are regridded to the same 1° lat-lon grids as EAMv1. The US
224 Department of Energy Atmospheric Radiation Measurement (ARM) multi-year observations for
225 daily precipitation and dilute convective available potential energy (CAPE) over the Southern
226 Great Plains (SGP) site for the time period of 2004-2018 (Xie et al. 2004) and Green Ocean

227 Amazon (GOAmazon) field campaign (Martin et al. 2016) site for 2014-2015 (Tang et al. 2016)
228 are used to evaluate the simulated CAPE vs. precipitation relationship.

229

230 **3. Results**

231 **3.1. Intraseasonal and synoptic variability**

232 The simulated variability of precipitation is an important aspect of model performance.
233 Here we focus on intraseasonal and synoptic-scale variability. The intraseasonal variability
234 associated with Madden-Julian oscillations (MJO) is problematic in many GCMs (Jiang et al.
235 2015; Zhang and Mu 2005). Figure 1 shows the tropical distribution of the 20-80 day
236 intraseasonal variance for the total precipitation in observations and simulations. The variance is
237 obtained with a Lanczos band-pass filter at each grid point. Both Xie-Arkin and TRMM
238 observations show large variance in the Indian Ocean and western Pacific as well as in the ITCZ
239 and the South Pacific Convergence Zone (SPCZ) regions. The intraseasonal variance in EAMv1
240 is much weaker, as in many other GCMs. Similar to the results in Wang et al. (2016), the
241 STOCH run with the stochastic deep convection scheme has a significantly enhanced
242 intraseasonal variance in these regions, making it much more comparable to observations
243 although there is excessive precipitation variance over central Africa, the Himalayas, the
244 Maritime Continent and the region near the Colombian coast. Compared with the EAMv1 run,
245 the STOCH run has more small-scale noise in the spatial structure of the precipitation variability.

246 Besides the intraseasonal variance, the synoptic variance (2-9 day Lanczos band pass-
247 filtered rainfall anomalies) is also investigated (Fig. 2). The synoptic-scale variance corresponds
248 to weather activities. In Fig. 2 only TRMM observations are shown to evaluate simulations
249 because the Xie-Arkin observations are pentad data. In TRMM, the geographical distribution of
250 the synoptic variance is similar to that of the intraseasonal variance, but with larger amplitudes
251 because synoptic-scale activities contain much more energy than intraseasonal disturbances.
252 Similar to the intraseasonal variance, the synoptic variance in the EAMv1 run is also much
253 weaker than that in observations. The synoptic-scale variance in the STOCH run is about twice
254 as strong as in EAMv1 although it is still underestimated compared to TRMM observations.
255 Over regions where the overestimated intraseasonal precipitation variance emerges, the STOCH
256 run has excessive synoptic precipitation variance as well. This result is consistent with Goswami
257 et al. (2017), which reported enhanced intraseasonal and synoptic variability of precipitation in

258 the National Centers for Environmental Predictions (NCEP) Climate Forecast System version 2
259 (CFSv2) using a stochastic multcloud model parameterization.

260

261 **3.2. Rainfall frequency, intensity, amount and duration**

262 Wang et al. (2016) showed that the most significant improvement with the use of the
263 stochastic deep convection scheme in CAM5 was in the simulated PDF of rainfall intensity over
264 the tropics, which became very close to TRMM observations. Since there are many
265 modifications in model configuration and physics parameterizations from CAM5 to EAMv1
266 (Rasch et al. 2019), such as a finer vertical resolution, an updated microphysics parameterization
267 (MG2), and the use of CLUBB in place of separate shallow convection and planetary boundary
268 layer turbulence parameterizations, it is not clear whether a similar degree of improvement in
269 precipitation intensity PDF can be achieved with a similar stochastic convection scheme. Using
270 an equal-interval rainfall intensity bin of 0.5 mm d^{-1} from 0 to 200 mm d^{-1} , Fig. 3 shows the
271 frequencies of the total precipitation intensity over the tropics (20°S - 20°N) from observations,
272 EAMv1 and STOCH, respectively. Also shown are the PDFs of large-scale and convective
273 precipitation intensity. The observational uncertainty is larger for intense precipitation than for
274 light precipitation (Fig. 3a), which is consistent with findings in Roca (2019). The GPCP
275 precipitation intensity distribution (the gray curve that even falls below the EAMv1 curve in Fig.
276 3a) has the lowest frequency for precipitation intensity greater than 30 mm d^{-1} . The GPCP
277 product is known to have underestimated precipitation intensities (Kooperman et al., 2016).
278 Despite the uncertainties in observations, the simulated frequencies in STOCH are more
279 consistent with those in the ensemble mean of all observations than those in the default EAMv1.
280 The stochastic convection parameterization in the STOCH run greatly mitigates the bias of “too
281 much light rain and too little heavy rain”, showing a decrease of the frequency of rainfall
282 intensity between 1 and 10 mm d^{-1} and an increase of that of rainfall intensity larger than 20 mm
283 d^{-1} compared to the EAMv1 run. Especially for light rain, the frequencies in STOCH fall in the
284 observational range while those in EAMv1 do not. A recent study finds that the decreased
285 frequency of light rain has a profound impact on simulated aerosol loading in the atmosphere
286 (Wang et al. 2021). Xie et al. (2019) indicated that the “too much light rain” in EAMv1 was a
287 result of too frequent convection. Consistent with this notion, Fig. 3b shows that the reduction of
288 the light rain frequency is entirely from convective precipitation. On the other hand, the increase
289 of intense precipitation frequency is from both convective and large-scale precipitation.

290 To understand why the use of stochastic convection scheme decreases the frequency of light
291 rain and increases the frequency of heavy rain, we conducted an additional simulation. In the
292 simulation, the setup is identical to the STOCH run except that the ZM scheme is called a second
293 time at each time step, with input (temperature, moisture, etc.) identical to that for the stochastic
294 scheme. However, the output is used for diagnostic purposes only and does not participate in
295 model integration. It is found that (figure not shown) two factors contribute to the decreased
296 frequency of light rain and increased frequency of heavy rain. First, for a given ensemble mean
297 convective mass flux (from the ZM scheme) the probability for cloud generation following the
298 Poisson distribution for a realization in the stochastic scheme can produce more intense
299 precipitation than obtained by the ZM scheme. Second, the probability distribution results in less
300 frequent convection in general. This allows the buildup of the atmospheric instability (also see
301 Fig. 9 below in section 3.3), which also leads to heavier convective rainfall (even with ZM
302 scheme alone without considering the stochastic part) as well as more large-scale condensation.
303 However, we note that the increase of the frequency in rainfall intensity ranges from 60 to 140
304 mm d⁻¹ in the STOCH run is not as much as that in Wang et al. (2016) for CAM5. This will be
305 elucidated through sensitivity experiments in the next subsection.

306 The frequencies of total precipitation intensity over selected regions also show qualitatively
307 similar degree of improvement. Fig. 4 shows six regions during their convectively active
308 seasons: Amazonia, tropical western Pacific, India for June-September, Maritime Continent,
309 SGP for May-August and eastern China for June-August in TRMM, EAMv1 and STOCH,
310 respectively. In all tropical regions, the EAMv1 simulation overestimates the occurrence
311 frequency for precipitation intensities less than 20 mm day⁻¹ and underestimates it for
312 precipitation intensities greater than 20 mm day⁻¹, similar to the distribution for the entire tropics.
313 In STOCH, the performance in the pdf over Amazonia and Maritime Continent is better than the
314 pdf over the entire tropics. Although the biases of “too much light rain” over India and tropical
315 western Pacific are alleviated by the stochastic deep convection scheme, the bias of “too little
316 heavy rain” remains, particularly over India where large-scale monsoonal dynamics regulate
317 heavy convective rain (Wang et al., 2018). For the two midlatitude convection regions (SGP and
318 eastern China), although there is also noticeable improvement across the precipitation intensity
319 spectrum, it is less significant compared to other regions, possibly because convection in
320 midlatitude land regions is not as prevalent as in the tropics.

321 Figure 5 shows the geographical distributions of precipitation frequency for all
322 precipitation, for precipitation intensities less than 20 mm d⁻¹, and more than 20 mm d⁻¹,
323 respectively, over the tropics in observations and simulations (days with precipitation intensity
324 less than 1 mm d⁻¹ are considered non-precipitating and thus excluded). In TRMM, the
325 occurrence frequency of rainy days ranges from 30 to 70% with the most frequent rain along the
326 ITCZ, the SPCZ and in the Indian Ocean, where the EAMv1 run has as high a frequency as 80-
327 90%, with up to 30% positive biases. In contrast, the STOCH run reduces the frequency to 50-
328 70% although it is still overestimated. When the total precipitation is broken down into
329 precipitation rates less than 20 mm d⁻¹ and precipitation rate above 20 mm d⁻¹, in both
330 observations and simulations the geographical distribution of the rainy days is dominated by that
331 of days with precipitation intensity less than 20 mm d⁻¹. In comparison with observations, again,
332 the STOCH run reduces the positive bias of the frequency of precipitation intensity less than 20
333 mm d⁻¹ in the EAMv1 run by up to 20%. For precipitation intensities greater than 20 mm d⁻¹, the
334 EAMv1 run underestimates their frequency compared to the TRMM observations. On the other
335 hand, the frequency of occurrence in the STOCH run is comparable to the TRMM observations.

336 Another metric for the precipitation pdf is the contribution of precipitation within a given
337 intensity bin to the total precipitation amount. It combines the information of precipitation
338 frequency distribution and precipitation intensity. While drizzle occurs much more frequently
339 than the more intense rain events, it may not contribute much to the total precipitation amount.
340 Following the approach of Kooperman et al. (2016, 2018), we divide the precipitation rate
341 ranging from 0.1 to 1000 mm d⁻¹ into equal bin intervals on a logarithmic scale, with a bin width
342 of $\Delta \ln(R) = \Delta R/R = 0.1$. If the frequency of rainfall rates falling into the i th bin is denoted f_i ,
343 then $f_i = n_i/N_t$, where N_t is the total number of days, n_i is the number of days with rainfall
344 rates falling into the i th bin. The mean precipitation rate in the i th bin is then:

$$345 \quad R_i = \frac{1}{n_i} \sum_{j=1}^{n_i} r_j, \quad (5)$$

346 where r_j is an individual precipitation rate within the i th bin. Thus, the contribution to the total
347 precipitation amount from the i th bin per unit bin width is given by:

$$348 \quad P_i = \frac{f_i R_i}{\Delta \ln(R)} = \frac{1}{\Delta \ln(R)} \frac{1}{N_t} \sum_{j=1}^{n_i} r_j \quad (6)$$

349 P_i has the units of mm d⁻¹. The total precipitation amount is then given by:

$$350 \quad P = \sum_i P_i \Delta \ln(R) = \sum_i f_i R_i \quad (7)$$

351 Accordingly, the amount distributions for total (P^T), convective (P^C) and large-scale (P^L)
 352 rainfall are given by:

$$353 \quad P_i^T = \frac{1}{\Delta \ln(R)} \frac{1}{N_t} \sum_{j=1}^{n_i} r_j^T \quad (8)$$

$$354 \quad P_i^C = \frac{1}{\Delta \ln(R)} \frac{1}{N_t} \sum_{j=1}^{n_i} r_j^C \quad (9)$$

$$355 \quad P_i^L = \frac{1}{\Delta \ln(R)} \frac{1}{N_t} \sum_{j=1}^{n_i} r_j^L \quad (10)$$

356 where r^T , r^C and r^L are the total, convective and large-scale rain rates.

357 Figure 6a shows the contribution to the total rainfall amount from each rainfall rate on a
 358 logarithmic scale for GPCP 1DD, TRMM, and the two simulations, respectively, over the
 359 tropics. The TRMM observations have larger contributions from intense rainfall rates than GPCP
 360 1DD, with the peak contribution rainfall rate of 28 mm d⁻¹, higher than the value of 22 mm d⁻¹ in
 361 GPCP 1DD. The EAMv1 run produces a much smaller peak contribution rainfall rate (15 mm d⁻¹)
 362 than the two observations while the STOCH run simulates it realistically (23 mm d⁻¹), falling
 363 in between the two observations. Note that precipitation from intensities less than 1 mm d⁻¹
 364 contributes about 0.05 mm d⁻¹ or less to the tropical mean total precipitation, thus justifying
 365 treating it as non-precipitating in Fig. 5. Fig. 6b shows the convective and large-scale
 366 contributions to the simulated total precipitation from EAMv1 and STOCH, respectively. The
 367 large-scale precipitation shows very similar contribution distributions in the two simulations,
 368 except for the largest rain rates which make only a small contribution to the total. For the most
 369 part, large-scale precipitation is not affected by how convection is treated in the model, with both
 370 simulations having a maximum contribution near 22 mm d⁻¹. On the other hand, the convective
 371 contribution is very different between the two simulations. Similar to the total precipitation, the
 372 peak contribution to convective precipitation is at a much smaller rainfall rate in EAMv1 than in
 373 STOCH.

374 Besides precipitation frequency and intensity, another important higher order statistic of
 375 precipitation is the duration of precipitation events; it measures the intermittency of precipitation
 376 (Trenberth et al. 2017). Using 3-hourly data, we calculate the duration of rainfall events as
 377 continuous number of hours of precipitation exceeding a threshold value of 1 mm d⁻¹. Figure 7
 378 shows the frequency of precipitation events for different durations over the tropics. 80% of
 379 TRMM observed precipitation events lasts for 3 hours or less, 18% lasts for 6 hours and 2% lasts
 380 for 9 hours. In contrast, both EAMv1 and STOCH produce very small proportions (~15%) of

381 precipitation events that last for 3 hours or less. The frequency of precipitation events lasting 9
382 hours or longer is extremely overestimated in the model simulations, with some lasting for as
383 long as 21 hours. This suggests that convection in the model lacks the observed intermittency
384 (Trenberth et al. 2017) and the use of the stochastic convection scheme does not improve this
385 aspect of the simulated convection.

386

387 **3.3 Sensitivity of rainfall intensity PDF to vertical resolution**

388 A significant modification among several changes in EAMv1 from CAM5 is a much finer
389 vertical resolution, increasing from 30 levels in CAM5 to 72 levels in EAMv1. Within the PBL
390 alone EAMv1 has 17 layers compared to 5 layers in CAM5, and the thickness of approximately
391 20 m for the lowest model layer in EAMv1 is much thinner than that in CAM5, which is 100 m
392 (Xie et al., 2018). The increased resolution in the PBL in EAMv1 will likely affect the
393 convection behavior through PBL-convection interactions. In Fig. 3 we showed that the
394 precipitation intensity pdf is significantly improved with the introduction of the stochastic
395 convection scheme. However, the improvement was not as striking as that shown in Wang et al.
396 (2016) for CAM5. We suspect that this is primarily due to the enhanced vertical resolution in
397 EAMv1 rather than other changes in model physics parameterizations, tunings, or the model
398 dynamic core. To confirm this, EAMv1-30L and STOCH-30L runs with a vertical resolution of
399 30 layers are conducted and compared with the EAMv1 and STOCH runs with the default 72
400 vertical layers. As seen in Figure 8, when switching to a configuration of 30 vertical layers, the
401 performance of the STOCH-30L run is very similar to that in CAM5 (Wang et al., 2016). The
402 frequency distribution of rainfall intensity between 60 and 140 mm d⁻¹ almost falls on top of that
403 in TRMM. The PDF of rain intensity in the EAMv1-30L run is also closer to TRMM
404 observations compared to the EAMv1 run (Fig. 8a). For EAMv1, both convective and large-scale
405 precipitation becomes more intense in the 30-level configuration. The resolution-dependence of
406 large-scale precipitation is consistent with the scale analysis in Rauscher et al. (2016). In their
407 Equation (2), if the terms are rearranged to solve for vertical velocity (ω), it gives $\omega \propto \Delta p$, the
408 vertical grid-spacing in pressure coordinates. Stronger vertical velocity would lead to more
409 intense precipitation. In STOCH-30L, while the frequency of more intense convective
410 precipitation is increased, the frequency of more intense large-scale precipitation is decreased,
411 probably affected by the moisture depletion from strong convective precipitation (Fig. 8b&c).

412 The causes of the sensitivity of convective precipitation to vertical resolution are further
413 examined below. In the ZM convection scheme, the amount of convection is linked to dilute
414 CAPE (for convenience we will simply call it CAPE below with the understanding that it refers
415 to dilute CAPE). Thus, in Figure 9 we present the joint PDF of convective precipitation and
416 CAPE over the tropics in the four simulations. Note that all parameter settings are identical
417 between EAMv1 and EAMv1-30L except the vertical resolution. Both EAMv1 and EAMv1-30L
418 show an approximately linear relationship between CAPE and convective precipitation. The
419 CAPE values are generally smaller in EAMv1-30L than in EAMv1, as can be seen from the
420 frequency of occurrence of both large and medium CAPE values. However, the slope of the
421 maximum occurrence frequency is almost twice as large in EAMv1-30L as in EAMv1 (Fig.
422 9a&b), giving the higher frequency of larger convective precipitation as seen in Fig. 8. This is
423 because a coarser vertical resolution means stronger vertical mixing, which results in higher
424 precipitation for given CAPE values. For a given precipitation rate that the model produces, there
425 is in general a large range of CAPE values and the CAPE values in EAMv1 are predominantly
426 larger than in EAMv1-30L as can be seen from the pdf distribution in Fig. 9a and b. Compared to
427 EAMv1, the smaller CAPE values in EAMv1-30L are caused by higher parcel launching levels
428 due to thicker model layers near the surface, where the most unstable air is often found (figure
429 not shown). There is also a bifurcation for medium to large CAPE values. This is likely related to
430 atmospheric moisture conditions in the atmosphere: for the same CAPE values there is less
431 precipitation when the atmosphere is dry, and vice versa. With the introduction of the stochastic
432 deep convection scheme, there are no longer approximately linear relations between CAPE and
433 convective precipitation (Fig. 9c&d) in spite of the fact that the CAPE-based closure is still used
434 to determine the cloud base mass flux (the ensemble mean). This is surprising; it implies that for
435 a given convectively unstable atmospheric thermodynamic condition, the use of the stochastic
436 scheme often inhibits the triggering of convection, thereby allowing for the buildup of CAPE for
437 (the less frequently occurring) stronger convection. Similar to EAMv1, smaller (larger) CAPE
438 values occur more (less) frequently in STOCH-30L due to higher parcel launching levels. Also,
439 the small and moderate values of CAPE have larger probabilities to precipitate more in STOCH-
440 30L compared to STOCH.

441 Over the ARM SGP and GOAmazon sites, no linear relationship is seen between the total
442 precipitation and CAPE in observations (Fig. 10). At the SGP site, high CAPE values generally
443 correspond to low precipitation. At the GOAmazon site, high precipitation values correspond to

444 medium values of CAPE, somewhat resembling the STOCH simulation, although the observed
445 CAPE values at the GOAmazon site are much smaller than those in the simulations.

446

447 **3.4 Mean state**

448 So far, we have shown that the introduction of a stochastic convection scheme into the
449 E3SM atmospheric model can significantly improve the simulation of short-term variability and
450 intensity pdf of precipitation. In climate model development efforts, it is important that an
451 improvement in some aspects of the model does not lead to degradation of other aspects, at least
452 not to outweigh the improvement. Thus, it is imperative that we examine the climate mean fields
453 as well. Fig. 11 shows the global distribution of annual mean precipitation in GPCP observations
454 and simulations, as well as the differences of total, convective, and large-scale precipitation
455 between the STOCH and EAMv1 runs. Overall, the geographical distributions of precipitation in
456 the two simulations are similar to those in observations, but both overestimate the tropical
457 precipitation (Fig. 11a-c). There is a slight increase of rainfall over the tropical western Pacific,
458 equatorial Indian Ocean and Africa and a slight decrease over India and Amazonia in the
459 STOCH simulation (Fig. 11d). Most of these changes are from convective precipitation except
460 over equatorial Africa where the changes are from large-scale precipitation (Fig. 11e&f).

461 The zonal mean of temperature and specific humidity from ERAI and the model biases are
462 shown in Figure 12. For temperature, EAMv1 produces mostly negative biases in the entire
463 troposphere over the tropics and subtropics and positive biases in the lower troposphere in high
464 latitudes. With the stochastic deep convection scheme used, the temperature changes in STOCH
465 are very minor, increasing slightly from EAMv1. In the simulation of specific humidity, there are
466 positive biases in the lower troposphere across all latitudes and negative biases above 900 hPa
467 over the tropics and subtropics in EAMv1. In comparison with EAMv1, the negative biases are
468 alleviated but the positive biases are increased slightly in STOCH.

469 The overall difference in model performance as measured by the commonly used mean
470 climate metrics between EAMv1 and STOCH runs is summarized in the Taylor diagram (Fig.
471 13). Most metrics are comparable between the two simulations except precipitation, especially
472 over land where STOCH shows a larger standard deviation than both GPCP and EAMv1. In
473 short, the mean climate does not change much after the incorporation of the stochastic
474 convection scheme in EAMv1. This is practically desirable since one does not need to heavily re-

475 tune the model, a task that is often time-consuming and more of engineering than scientific
476 interest.

477

478 **3.5. Response to climate warming**

479 Another aspect of interest concerns the model’s response to climate change. It is well
480 known that the estimated climate sensitivity for future climate projections is sensitive to changes
481 in model physics parameterizations (Golaz et al. 2019). With the stochastic deep convection
482 parameterization, it is necessary to check if the response of precipitation and associated extremes
483 to climate warming differs. As seen in Fig. 14, relative to the current climate simulations, the
484 geographical patterns and magnitudes of annual mean precipitation changes normalized by the
485 global-mean surface air warming (ΔT_{sa}) in the +4K SST warming simulations (i.e., $(P_{+4k} -$
486 $P)/P/\Delta T_{sa}$, units: %/K) with and without the stochastic deep convection scheme are very
487 similar, both showing maximum increases over the ITCZ, the western Pacific and the Indian
488 Ocean. Pendergrass et al., (2019) found that the response of extreme precipitation to warming
489 follows a nonlinear relation:

$$490 \quad \frac{dr_x}{dT_{sa}} = aT_{sa} \quad (11)$$

491 or

$$492 \quad r_x = \frac{1}{2} aT_{sa}^2 + b \quad (12)$$

493 where r_x is a rainfall extreme index (here using R95p, the total rainfall from the days with daily
494 rainfall intensity exceeding 95th percentile of the daily precipitation distribution), T_{sa} is the
495 global-mean surface air temperature in a warmer world, and a is the slope of dr_x/dT_{sa} versus
496 T_{sa} measuring the strength of the nonlinear response of extreme rainfall to warming. At each
497 grid point, $dr_x \approx \Delta r_x$ is equal to R95p in a warmer world minus that under the current climate
498 and normalized by the global-mean surface air warming ($dT_{sa} \approx \Delta T_{sa}$). With T_{sa} in the +4K
499 SSTs warming simulations and the calculated dr_x/dT_{sa} , the global distributions of the slope, a
500 (units: %/K²), with and without the stochastic deep convection scheme are displayed in Fig.
501 14c&d. Although the stochastic deep convection parameterization introduces stochasticity into
502 convection and significantly improves the underestimated frequency of intense precipitation
503 under the current climate (Wang et al., 2017), it does not lead to a different nonlinear response of
504 precipitation extremes in a warmer world. The resemblance of the coefficient a between the two
505 simulations results from the similar response of the fractional change in r_x to global warming

506 (Fig. 14e&f). Increasing circulation strength as the climate warms is considered to be the main
507 driver for the nonlinear relationship between tropical precipitation extremes and global-mean
508 surface air temperature (Pendergrass et al., 2019), and it is possible that the circulation changes
509 with and without the stochastic deep convection scheme are similar. Relative to their respective
510 current climate states, the responses of the EAMv1-4K and STOCH-4K runs show similar
511 geographical distributions with comparable maximum nonlinearity over the tropical Pacific and
512 Atlantic and the Indian Ocean which bears some resemblance to that in Pendergrass et al. (2019).

513

514 **4. Summary**

515 In this study, we implemented the stochastic deep convection scheme (Plant and Craig,
516 2008; Wang et al., 2016) into the DOE EAMv1 and investigated its impact on the simulation of
517 precipitation. Several improvements are observed with the use of the stochastic convection
518 scheme: (1) the weak intraseasonal and synoptic-scale variabilities in EAMv1 are enhanced to
519 levels much closer to those in observations; (2) the “too much light rain and too little heavy rain”
520 bias over the tropics is significantly alleviated due to less frequent occurrence of drizzling
521 convection and more frequent occurrence of intense large-scale and convective precipitation
522 contributing to enhanced heavy rain; (3) the simulated peak precipitation rates (the amount
523 mode) in the precipitation amount distribution, which contribute the most to the total amount of
524 precipitation, are larger and are in better agreement with those in TRMM and GPCP
525 observations.

526 While the improvement in the simulated PDF of rainfall intensity is significant, it is less
527 than what we had expected based on our earlier work with the NCAR CAM5 (Wang et al.,
528 2016). Since there are many changes from CAM5 to EAMv1, including vertical resolution,
529 model dynamic core and physics parameterizations, it is not clear which changes are related to
530 the difference in the improvement of the simulated rainfall pdf. Two sensitivity tests were
531 performed to elucidate this, both with a coarser vertical resolution configuration of 30 layers
532 (i.e., EAMv1-30L and SOTC-30L) as in CAM5. The STOCH-30L run successfully reproduces
533 the frequency distribution of rainfall intensity found by Wang et al. (2016) with an increased
534 frequency of convective precipitation intensities between 60 and 140 mm d⁻¹. This increase is
535 explained by the fact that small and moderate values of CAPE generate more convective
536 precipitation from the altered relation between them compared to the 72-level configuration due
537 to fewer model layers in the 30-level resolution. Since vertical velocity in general increases with

538 the vertical grid spacing, the increase of large-scale precipitation also contributes to the increased
539 frequency of total precipitation intensities in the 30-level configuration.

540 For any changes in model physics parameterization that improve some aspects of the model
541 performance, it is important that other aspects are not degraded. It is known in the climate
542 modeling community that improved intraseasonal variability is often accompanied by a
543 degradation of the mean state (e.g., Kim et al. 2011; Klingaman and Demott, 2020). We showed
544 that the mean states in tropospheric temperature, moisture as well as precipitation are not much
545 different with or without the use of the stochastic convection scheme, and neither are the
546 responses of mean precipitation and precipitation extremes to climate warming. This is
547 encouraging and desirable for model development efforts. However, we note that for higher
548 horizontal resolutions (Caldwell et al., 2019) or a regionally refined mesh version of EAMv1
549 (Tang et al., 2019), spatial averaging of the input fields of the stochastic scheme would be
550 needed to make use of convective quasi-equilibrium over a larger domain. This could be
551 challenging for computational efficiency and it requires further research in the future.

552

553 **Code and data availability.** The E3SMv1 source code can be downloaded from the E3SM
554 official website <https://e3sm.org/>. The GPCP 1DD data is available from NASA GSFC RSD
555 (<https://psl.noaa.gov/data/gridded/data.gpcp.html>). TRMM and GPM data are available from
556 <https://gpm.nasa.gov/data/directory>. The availability of daily precipitation observations from the
557 FROGS database is described in Roca et al. (2019). The ARM observations over the SGP and
558 GOAmazon sites are available from <https://www.arm.gov/data>. The EAMv1 simulation output is
559 provided in an open repository Zenodo (<http://doi.org/10.5281/zenodo.3902998>).

560

561 **Author contributions.** GJZ conceived the idea. YW developed the model code. YW and WYL
562 conducted the model simulations. YW performed the analysis. YW and GJZ interpreted the
563 results and wrote the paper. All authors participated in the revision and editing of the paper.

564

814

815 **Table captions:**

816

817 **Table 1.** List of simulations.

Simulation	Years	Vertical Levels	Description
EAMv1	6	72	Standard EAMv1 with the default deterministic ZM deep convection scheme for simulating the current climate ¹
STOCH	6	72	Same as EAMv1, but coupling with the PC stochastic deep convection scheme with the deterministic ZM deep convection scheme
EAMv1-30L	6	30	Same as EAMv1, but using a vertical resolution configuration of 30 layers
STOCH-30L	6	30	Same as STOCH, but using a vertical resolution configuration of 30 layers
EAMv1-4K	3	72	Same as EAMv1, but for simulating a warmer world ²
STOCH-4K	3	72	Same as STOCH, but for simulating a warmer world

818 ¹Atmosphere-only simulations, using fully prognostic atmosphere and land models with
 819 prescribed, seasonally varying climatological present-day sea surface temperatures (SSTs) and
 820 sea ice extent, recycled yearly.

821 ²For simulating a warmer world, the atmosphere-only simulations are subjected to a composite
 822 SST warming pattern derived from the Coupled Model Intercomparison Project Phase 3
 823 (CMIP3) coupled models.

824

825 **Figure captions**

826 **Figure 1.** Spatial distributions of the 20–80 day variance of rainfall from (a) the Xie-Arkin
827 observations, (b) TRMM, (c) EAMv1, and (d) STOCH, respectively (units: $\text{mm}^2 \text{d}^{-2}$).

828 **Figure 2.** Spatial distributions of the synoptic variance of rainfall from (a) TRMM, (b) EAMv1,
829 and (c) STOCH, respectively (units: $\text{mm}^2 \text{d}^{-2}$).

830 **Figure 3.** Frequency distributions of (a) total (solid line), (b) convective (solid line) and large-
831 scale (dashed line) precipitation intensity over the tropics (20°S , 20°N) for EAMv1 (blue) and
832 STOCH (red) respectively. For total precipitation, the TRMM observations (black) and ensemble
833 mean of multiple observations (Obs_ens, purple) where each observation is denoted by the gray
834 line are included for evaluation.

835 **Figure 4.** Frequency distributions of total precipitation intensity over Amazon (20°S - 5°N , 40°W -
836 80°W), tropical western Pacific (TWP) (0°N - 15°N , 130°E - 170°E), India (14°N - 26.5°N , 74.5°E -
837 94°E ; for June-September), Maritime Continent (MC) (10°S - 10°N , 90°E - 160°E), Southern Great
838 Plains (SGP) (37°N - 42°N , 90°W - 110°W ; for May-August) and eastern China (25°N - 35°N ,
839 100°E - 120°E ; for June-August) for TRMM (black), EAMv1 (blue) and STOCH (red)
840 respectively.

841 **Figure 5.** Spatial distributions of frequencies of total rainfall intensity larger than (top row) 1
842 mm d^{-1} , (middle row) between 1 and 20 mm d^{-1} and (bottom row) larger than 20 mm d^{-1} for
843 TRMM, EAMv1 and STOCH, respectively.

844 **Figure 6.** Annual mean rainfall amount distributions of (a) total precipitation (solid line) over the
845 tropics (20°S , 20°N) for GPCP 1DD (grey), TRMM (black), EAMv1 (blue) and STOCH (red),
846 respectively. Individual distributions of (b) convective (solid line) and large-scale (dashed line)
847 precipitation in EAMv1 (blue) and STOCH (red) are also shown. The rainfall intensity on the x-
848 axis is on a logarithmic scale with bin intervals of $\Delta \ln(R) = \Delta R/R = 0.1$.

849 **Figure 7.** Histogram of percentage frequency of total rainy events as a function of their duration
850 using 3-hourly data (conditional probability of rainfall, given rainfall the previous times) from
851 TRMM (black), EAMv1 (blue) and STOCH (red) for the threshold rainfall rate of 1 mm d^{-1} over
852 the tropics.

853 **Figure 8.** Same as Fig. 3, but including PDFs for EAMv1-30L and STOCH-30L (both dashed
854 lines).

855 **Figure 9.** Joint PDFs of CAPE versus convective precipitation over the tropics (20°S , 20°N)
856 from (a) EAMv1, (b) EAMv1-30L, (c) STOCH, and (d) STOCH-30L, respectively.

857 **Figure 10.** Scatterplots of total precipitation versus CAPE at the ARM (a-c) SGP and (d-f)
858 Amazon sites for (a & d) observations calculated from multi-year sounding data (2014-2015 for
859 Amazon and 2004-2018 for SGP), (b & e) EAMv1 and (c & f) STOCH.

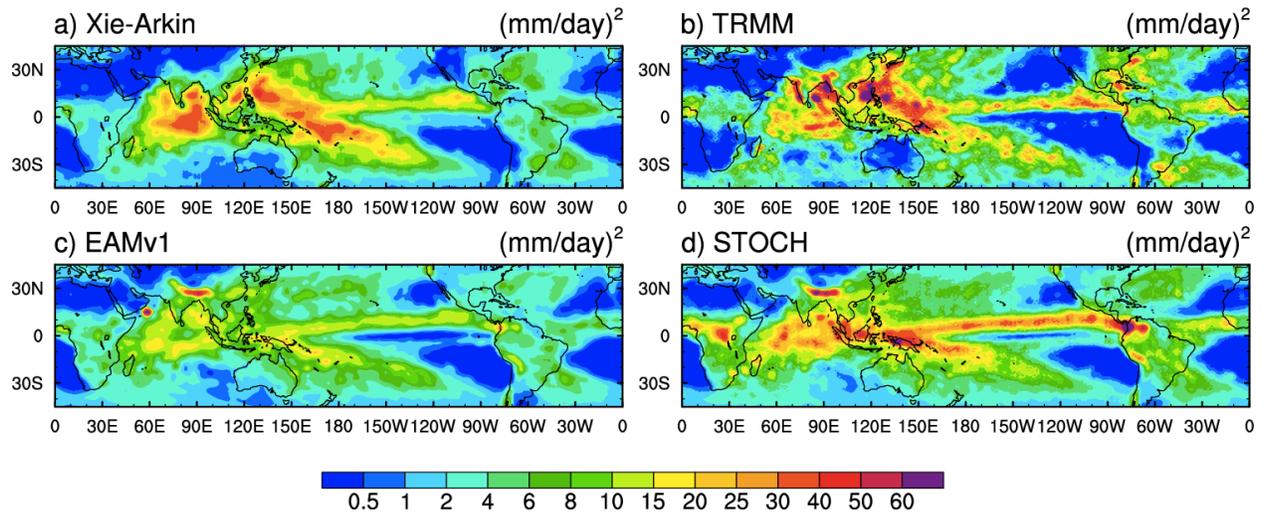

860 **Figure 11.** Global distributions of total precipitation for (a) GPCP, (b) EAMv1, and (c) STOCH,
861 and differences of (d) total, (e) convective and (f) large-scale precipitation between STOCH and
862 EAMv1. Differences with a confidence level greater than 95% in (d-f) are stippled.

863 **Figure 12.** Annual and zonal mean cross sections of (a-c) temperature and (d-f) specific
864 humidity for (a & d) ERAI and differences for (b & e) EAMv1-ERAI and (c & f) STOCH-
865 EAMv1. Differences with a confidence level greater than 95% in between STOCH and EAMv1
866 are stippled.

867 **Figure 13.** Taylor diagram with metrics for STOCH, compared with EAMv1.

868 **Figure 14.** Geographical distributions of responses of (a & b) annual mean precipitation, (c & d)
869 the coefficient a , and (e & f) the fractional change in precipitation extremes (R95p) to climate
870 warming from +4K experiments. Differences with a confidence level greater than 95% are
871 stippled.
872

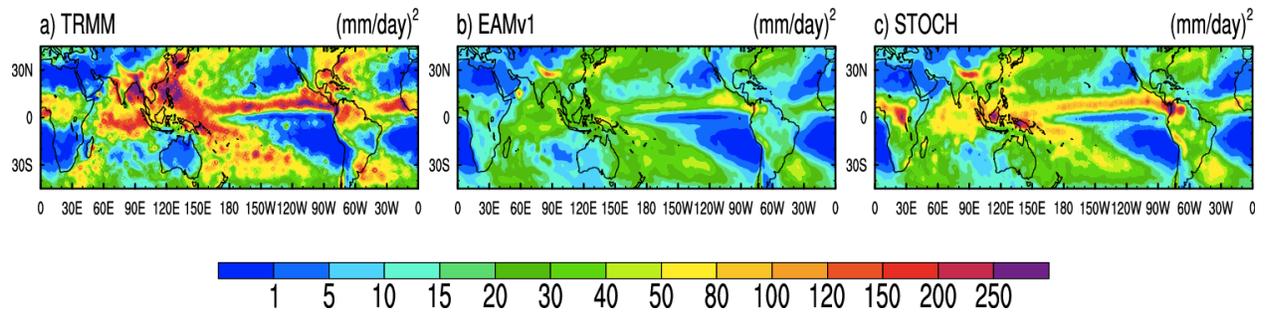

873 **Figures**

874

875 **Figure 1.** Spatial distributions of the 20–80 day variance of rainfall from (a) the Xie-Arkin
876 observations, (b) TRMM, (c) EAMv1, and (d) STOCH, respectively (units: $\text{mm}^2 \text{d}^{-2}$).

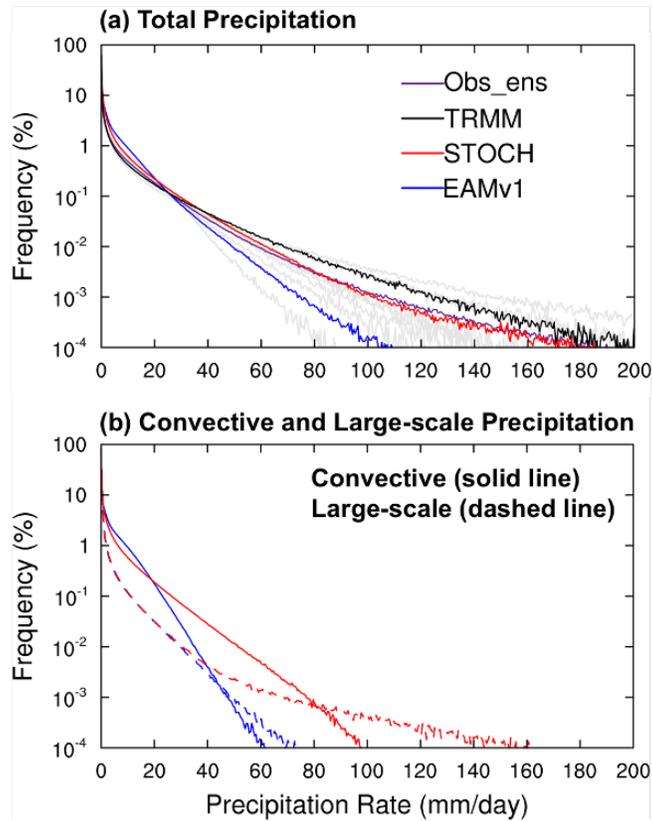

877

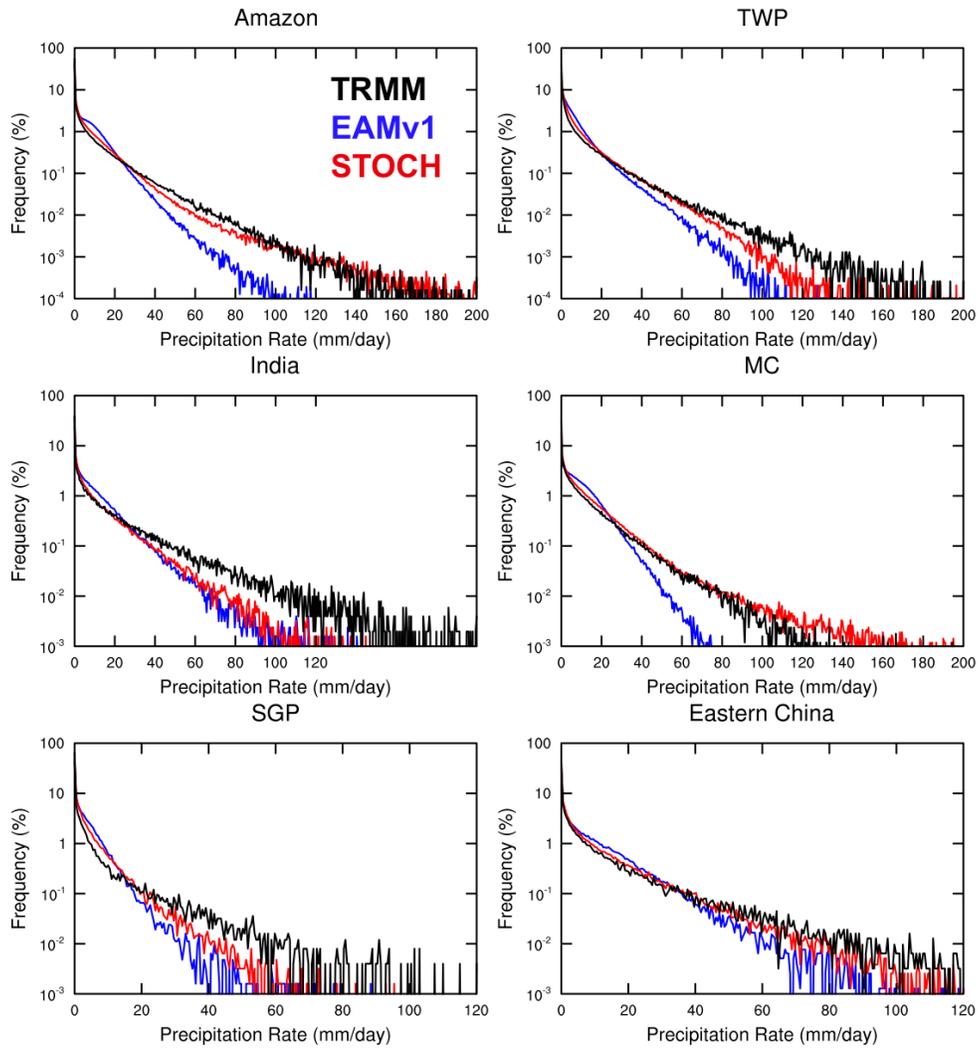

878

879 **Figure 2.** Spatial distributions of the synoptic variance of rainfall from (a) TRMM, (b) EAMv1,
 880 and (c) STOCH, respectively (units: $\text{mm}^2 \text{d}^{-2}$).

881

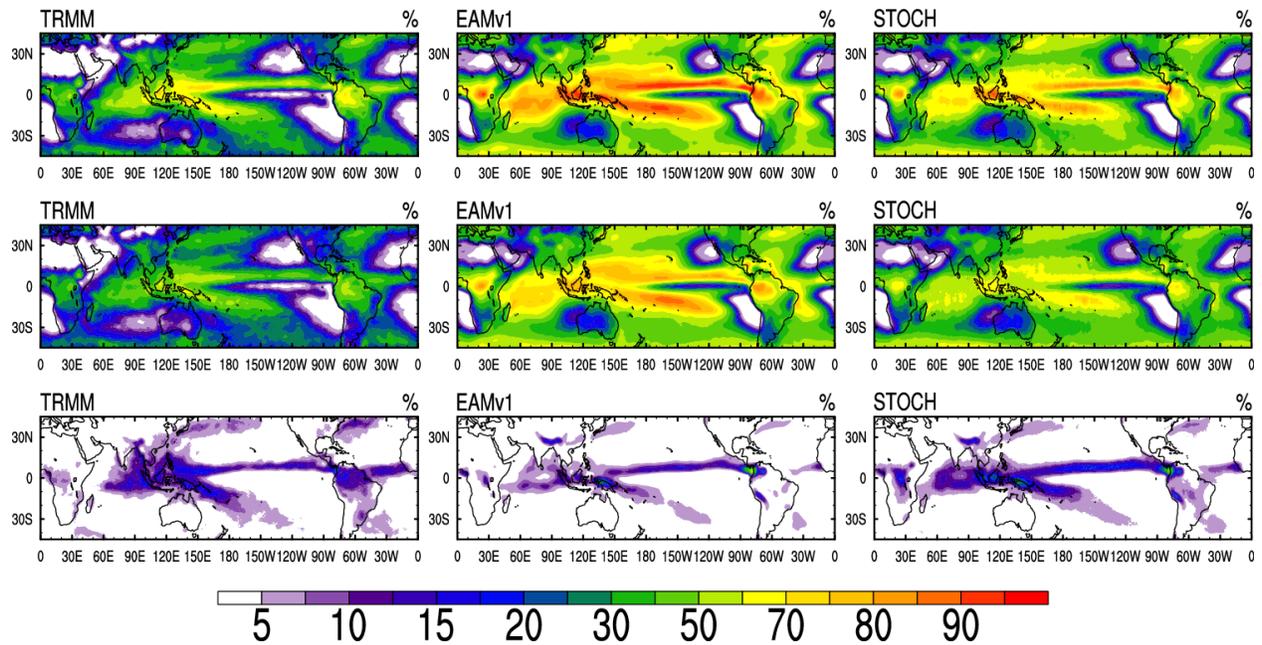

882
 883 **Figure 3.** Frequency distributions of (a) total (solid line), (b) convective (solid line) and large-
 884 scale (dashed line) precipitation intensity over the tropics (20°S, 20°N) for EAMv1 (blue) and
 885 STOCH (red) respectively. For total precipitation, the TRMM observations (black) and ensemble
 886 mean of multiple observations (Obs_ens, purple) where each observation is denoted by the gray
 887 line are included for evaluation.
 888

889

890 **Figure 4.** Frequency distributions of total precipitation intensity over Amazon (20°S-5°N, 40°W-
 891 80°W), tropical western Pacific (TWP) (0°N-15°N, 130°E-170°E), India (14°N-26.5°N, 74.5°E-
 892 94°E; for June-September), Maritime Continent (MC) (10°S-10°N, 90°E-160°E), Southern Great
 893 Plains (SGP) (37°N-42°N, 90°W-110°W; for May-August) and eastern China (25°N-35°N,
 894 100°E-120°E; for June-August) for TRMM (black), EAMv1 (blue) and STOCH (red)
 895 respectively.

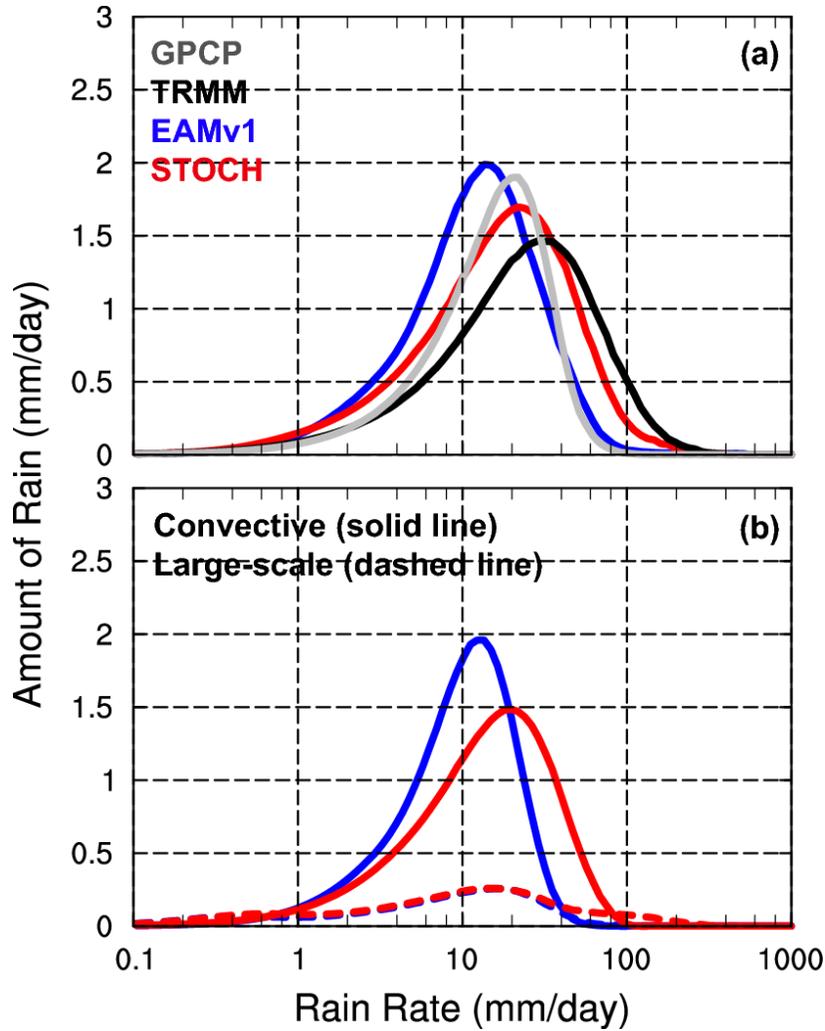

896

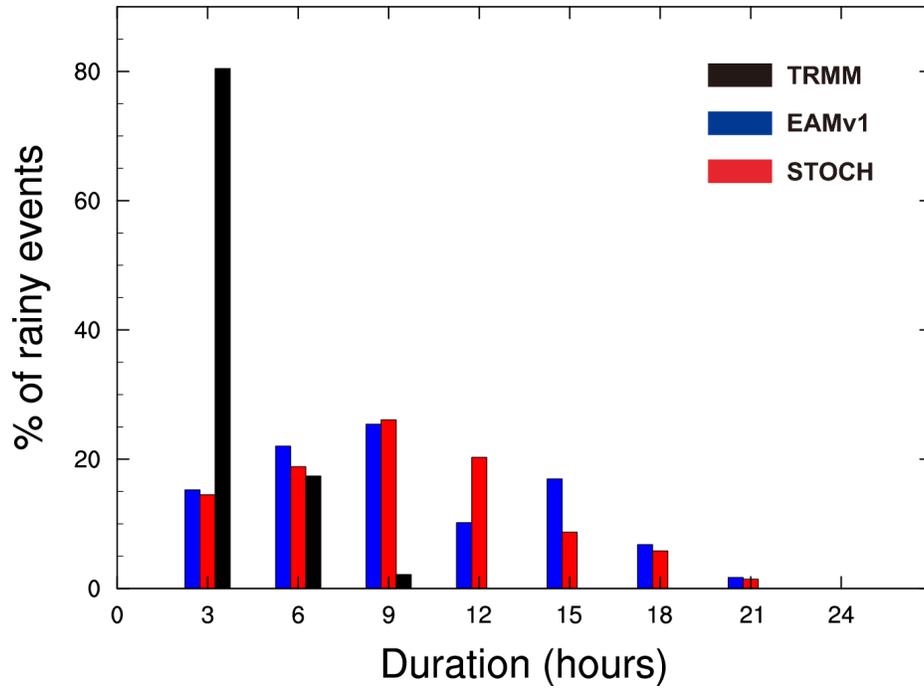

897

898 **Figure 5.** Spatial distributions of frequencies of total rainfall intensity larger than (top row) 1
 899 mm d⁻¹, (middle row) between 1 and 20 mm d⁻¹ and (bottom row) larger than 20 mm d⁻¹ for
 900 TRMM, EAMv1 and STOCH, respectively.

901

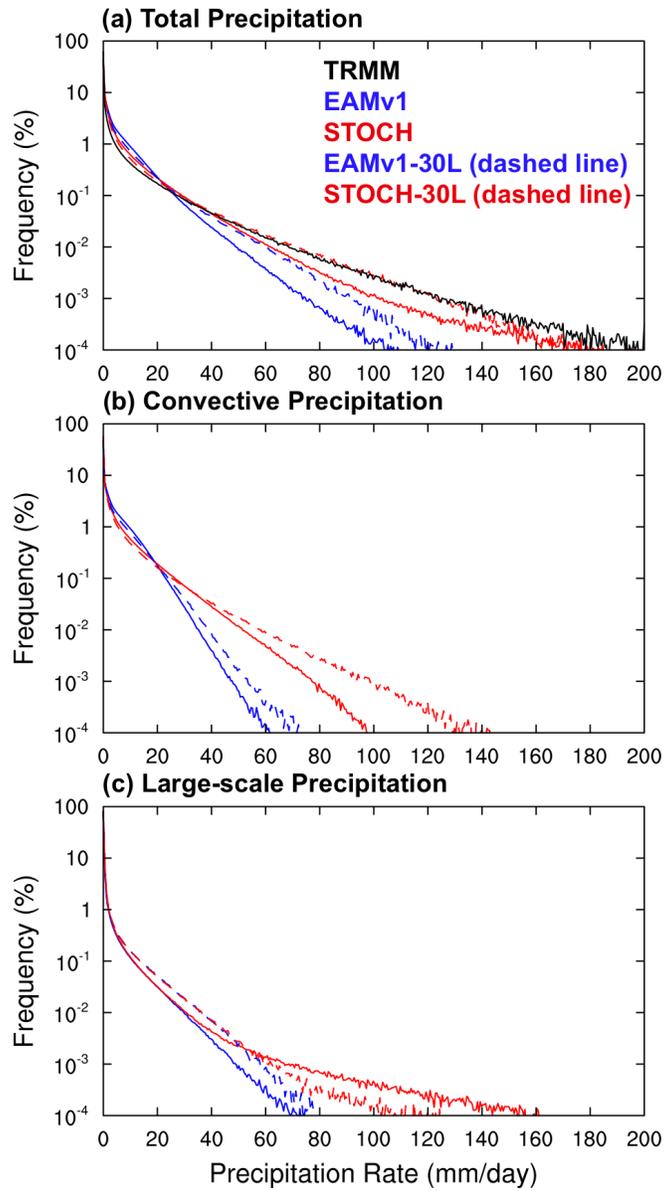

902
 903 **Figure 6.** Annual mean rainfall amount distributions of (a) total precipitation (solid line) over the
 904 tropics (20°S, 20°N) for GPCP 1DD (grey), TRMM (black), EAMv1 (blue) and STOCH (red),
 905 respectively. Individual distributions of (b) convective (solid line) and large-scale (dashed line)
 906 precipitation in EAMv1 (blue) and STOCH (red) are also shown. The rainfall intensity on the x-
 907 axis is on a logarithmic scale with bin intervals of $\Delta \ln(R) = \Delta R/R = 0.1$.
 908

909

910 **Figure 7.** Histograms of percentage frequency of total rainy events as a function of their duration
 911 using 3-hourly data (conditional probability of rainfall, given rainfall the previous times) from
 912 TRMM (black), EAMv1 (blue) and STOCH (red) for the threshold rainfall rate of 1 mm d⁻¹ over
 913 the tropics.

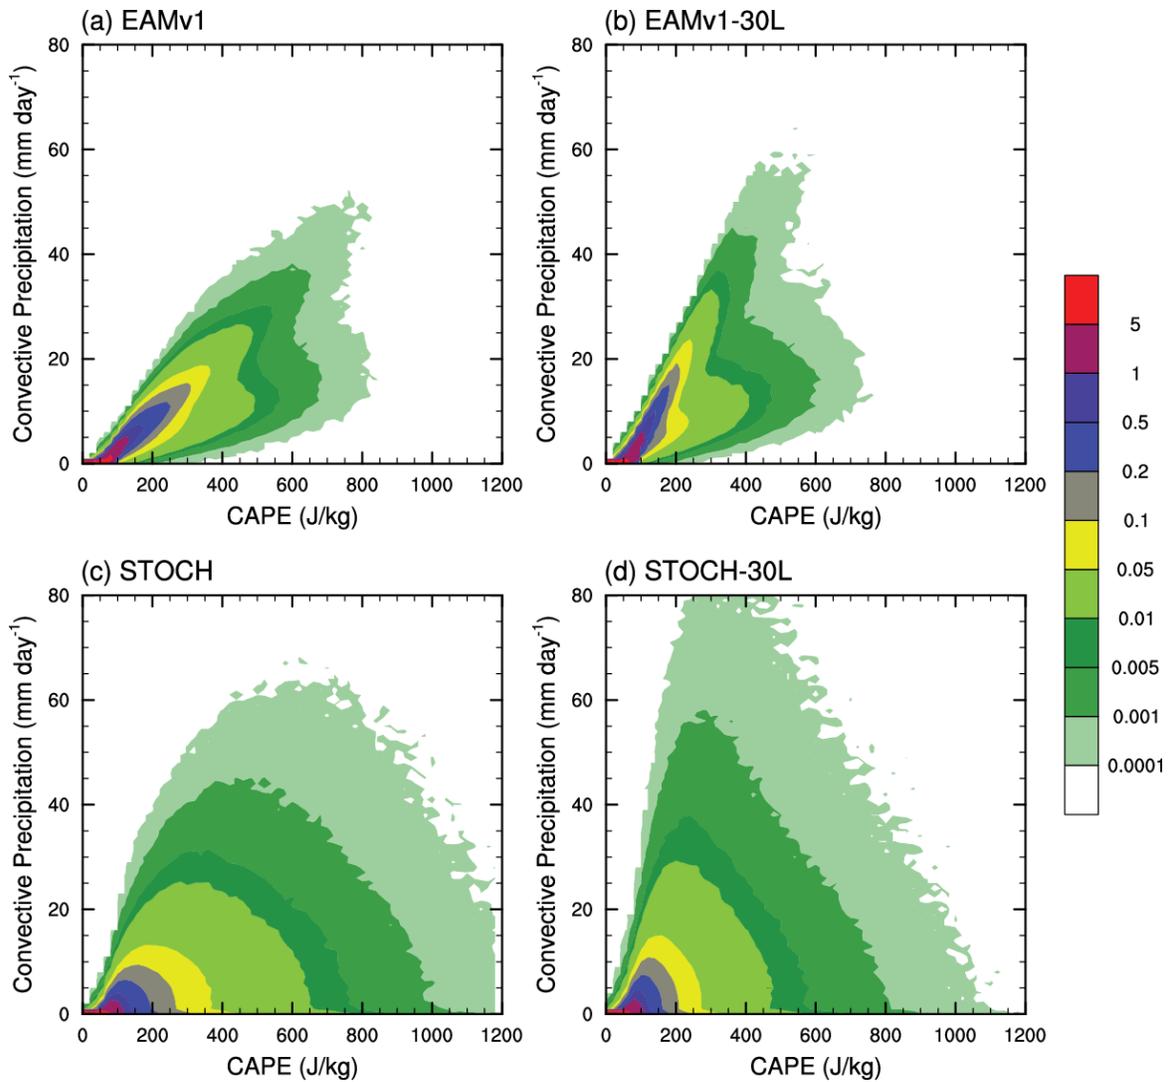

914

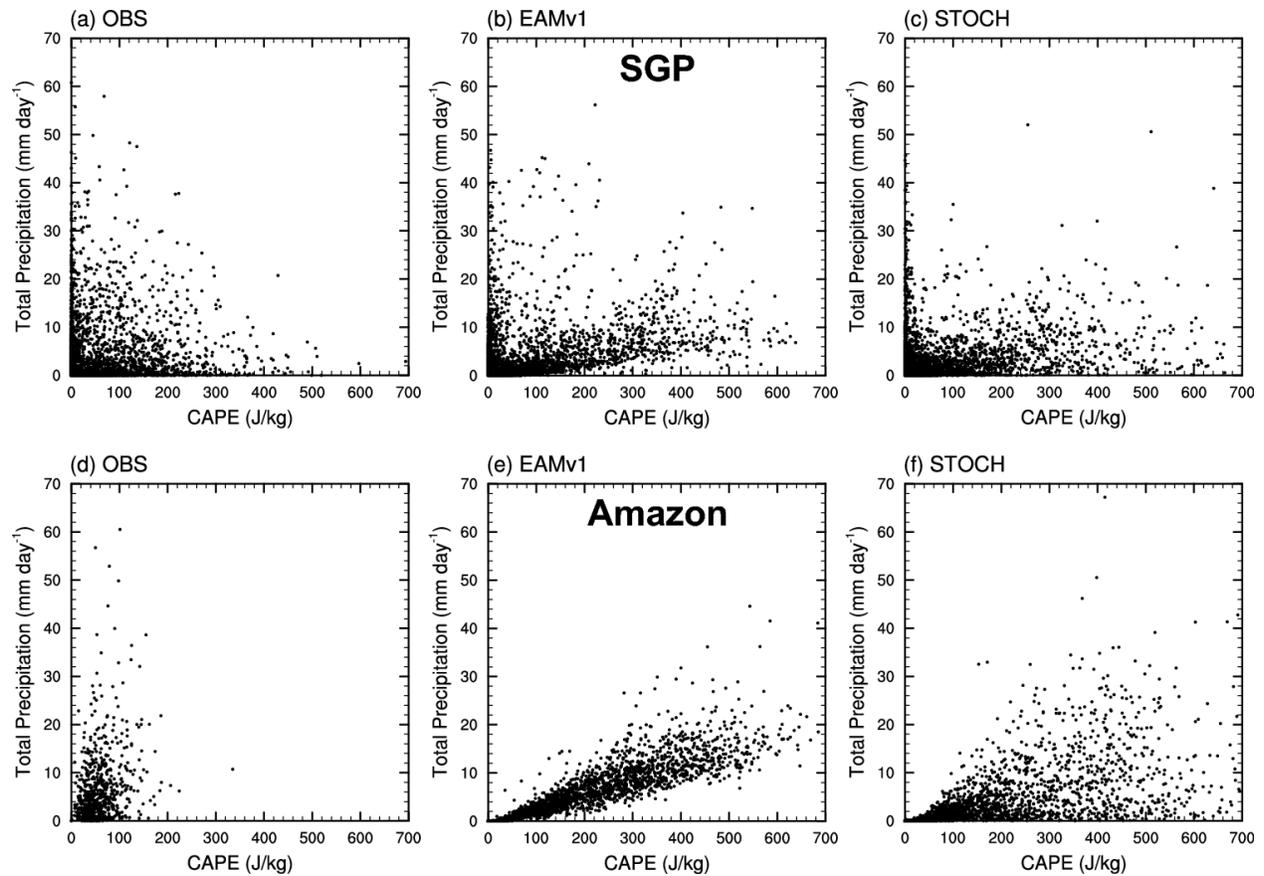

915

916 **Figure 8.** Same as Fig. 3, but including PDFs for EAMv1-30L and STOCH-30L (both dashed
 917 lines).

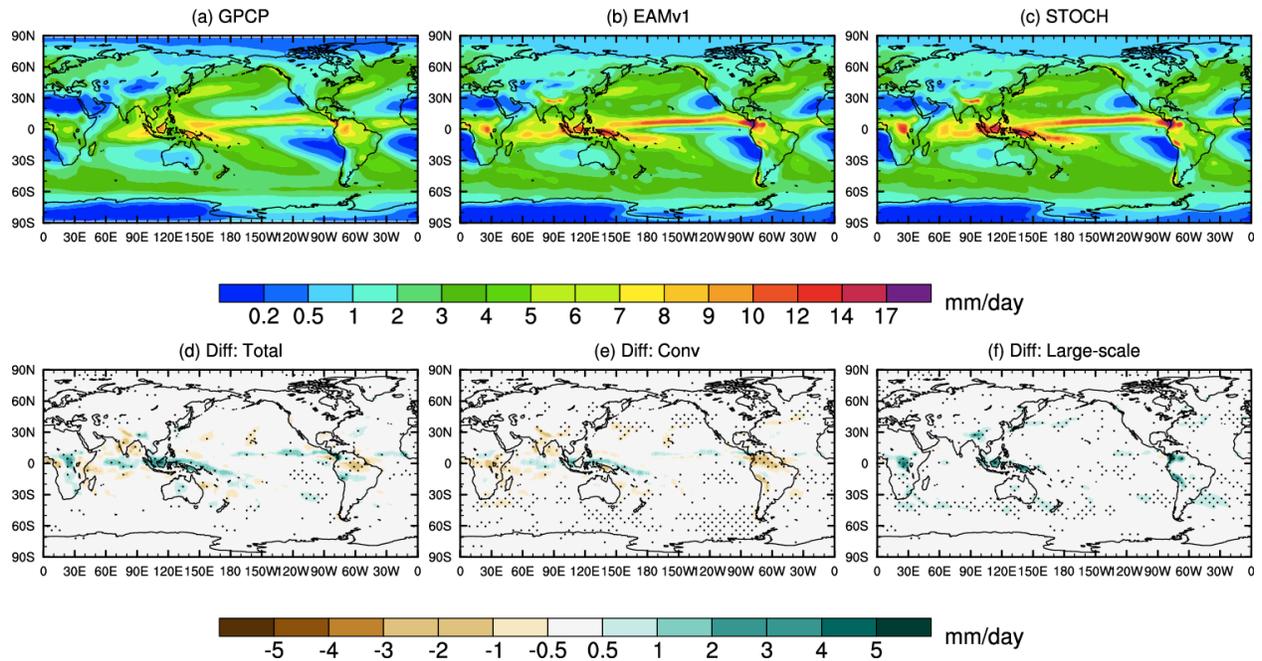

918

919
 920 **Figure 9.** Joint PDFs of CAPE versus convective precipitation over the tropics (20°S, 20°N)
 921 from (a) EAMv1, (b) EAMv1-30L, (c) STOCH, and (d) STOCH-30L, respectively.
 922

923
 924 **Figure 10.** Scatterplots of total precipitation versus CAPE at the ARM (a-c) SGP and (d-f)
 925 Amazon sites for (a & d) observations calculated from multi-year sounding data (2014-2015 for
 926 Amazon and 2004-2018 for SGP), (b & e) EAMv1 and (c & f) STOCH.
 927
