Abstract.

Chemistry transport models (CTM) play an important role in understanding fluxes and atmospheric distribution of carbon dioxide (CO₂). They have been widely used for modeling CO₂ transport through forward simulations and inferring fluxes through inversion systems. With the increasing availability of high resolution observations, it has become possible to estimate CO₂ fluxes at higher spatial resolution. However the computational cost of high resolution global model simulation is so high that only major research and operation centers can afford it. In this paper, we implemented CO₂ transport in Model Prediction Across Scales-Atmosphere (MPAS-A). The objective is to use the variable-resolution capability of MPAS-A to enable high resolution CO₂ simulation at limited region with a global model. Treating CO₂ as an inert tracer, we implemented in MPAS-A (v6.3) the CO₂ transport processes, including advection, vertical mixing by boundary layer scheme, and convective transport. We evaluated the newly implemented model by running two sets of simulations over a 60-15 km variable-resolution global domain. The first set of simulations covers four Atmospheric Carbon and Transport-America (ACT-America) aircraft campaign seasons (2016-2018), and the simulated CO₂ is evaluated using the extensive airborne measurements from ACT. The simulation accuracy is also compared with a 27-km resolution WRF-Chem simulation and CarbonTracker (v2019) covering the same time periods. The second set of simulations covers the month of January and July of 2014, and the results are evaluated using near-surface hourly CO₂ measurements from 50 surface and tower sites across the globe. This simulation accuracy is compared with European Center for Medium-Range Weather Forecasts (ECMWF) Integrated Forecasting System (IFS) global simulation conducted during the same period. Overall, the evaluation using aircraft measurements indicates that MPAS CO₂ transport model is capable of representing the observed atmospheric CO₂ structures related with the mid-latitude synoptic weather system, including the warm/cold sector distinction, boundary layer to free troposphere difference, and CO₂ enhancements along frontal boundaries. The evaluation using hourly measurements shows that the MPAS CO₂ transport model is capable of achieving a same level of accuracy as the IFS 80-km resolution simulation.

1 Introduction

Carbon dioxide (CO₂) is the most important greenhouse gas, and our knowledge about its sources and sinks still have large gaps. Inversion systems are often used to infer CO₂ fluxes based on observations and chemistry transport models (CTM). Two

types of CTMs are commonly used: global models and regional models. Global models are commonly used for inferring CO₂ fluxes at coarse spatial scale (Patra et al., 2008; Schuh et al., 2019; Jacobson et al., 2007, 2020). With the fast increasing number of atmospheric CO₂ observations, including those acquired by ground based, airborne, and satellite instruments, regional inversion system have been developed and applied to estimate carbon fluxes at higher resolution (Gerbig et al., 2009; Pillai et al., 2012; Lauvaux et al., 2012; Hu et al., 2019; Zheng et al., 2018, 2019).

A major challenge of atmospheric CO₂ inversion modeling is how to partition the model-data mismatch (MDM) among the transport model error, observation error, and prior flux error. In the Bayesian inversion framework, the error covariance matrix \mathbf{R} is commonly used to represent the combined error of transport model and observations. While it is important to correctly represent the transport model error in an inversion system, it is also important to reduce the error in order to estimate the fluxes with less uncertainty. One approach to reduce transport model error is to increase simulation resolution. For instance, Feng et al. (2016) found high-resolution WRF-Chem simulation improved CO₂ model-data comparison because of better resolved planetary boundary layer and better representation of spatial variability of CO₂ fluxes. In a recent study, Agusti-Panareda et al. (2019) investigated the impacts of transport model's horizontal resolutions on simulated CO₂ accuracy, and they found that CO₂ variability are generally better represented by higher resolution simulations.

Global high resolution CO₂ simulations require large computational resources which may not be affordable outside major research and operational centers. Regional (limited area) models, which circumvent the high computational cost of global models, are often used for high resolution CO₂ transport (Feng et al., 2016; Diaz-Isaac et al., 2019, 2018) and inverse modeling (Sarrat et al., 2007; Gerbig et al., 2008; Lauvaux et al., 2012; Zheng et al., 2019). However a regional model requires CO₂ transported from outside its model domain to be prescribed. For a CO₂ inversion system, having lateral boundaries increase the size of the control vector to be optimized (Rayner et al., 2019). A number of approaches have been applied to the CO₂ lateral boundary problem, such as assuming the boundary inflow is perfectly known (Gockede et al., 2010), correcting the lateral boundary condition using observation prior to inversion (Lauvaux et al., 2012; Schuh et al., 2013), or jointly optimizing flux and lateral boundary condition (Zheng et al., 2018). When CO₂ lateral boundary is optimized, an inversion system adjusts its CO₂ fields at the boundary prescribed by a parent global model in addition to adjusting surface fluxes. This could be problematic for inversion systems that use satellite derived column averaged CO₂ measurements (XCO₂) because model-data mismatches in the free troposphere are often originated from outside a regional model's limited area domain (Feng et al., 2019; Lauvaux and Davis, 2014).

The objective of the present paper is to provide an alternative high-resolution CO₂ transport modeling approach to regional transport models. This approach is to use a global variable-resolution model which allows for local grid refinement that enables high resolution simulation over interested region without incurring the prohibitively high computational cost or the lateral boundary condition. Variable-resolution through local grid refinement has been widely used in Numerical Weather Prediction (NWP) models, such as MPAS (Skamarock et al., 2012), Ocean-Land-Atmosphere Model (OLAM) (Walko and Avissar, 2008a,

b), Energy Exascale Earth System Model (E3SM) (Golaz et al., 2019), and Finite-Volume Cubed-Sphere model(FV3) (Putman and Lin, 2007). One benefit of local mesh refinement is enabling regional high-resolution modeling without incurring the lateral boundary condition and its associated problems, such as solution mismatches between the driving global model and the evolving regional model (Davies, 2014).

5

Model Prediction Across Scales-Atmosphere (MPAS-A) is a fully compressible non-hydrostatic global atmospheric model which uses finite-volume numeric solver discretized on centroidal Voronoi mesh with C-grid staggering of its prognostic variables (Skamarock et al., 2012; Thuburn, 2007; Ringler et al., 2010). The centroidal Voronoi mesh allows for local refinement and variable-resolution horizontal mesh which can be gradually changed from coarse to fine resolutions (Skamarock et al., 2012; Ringler et al., 2008).

10

To enable CO₂ transport modeling, we implemented in MPAS-A (v6.3) the CO₂ transport processes, including advection, vertical mixing by Planetary Boundary Layer (PBL) scheme, and convective transport. We used the newly developed model to conduct two sets of simulations over a 60-15 km variable-resolution global domain. Then the simulation results are evaluated using an extensive set of airborne observations over the eastern United States and near-surface observations from surface and tower stations across the globe. The simulation accuracy of MPAS is compared with three established CO₂ modeling systems based on the same observational data: WRF-Chem (Skamarock et al., 2008; Feng et al., 2019), Carbontracker (v2019, CT2019 hereafter) (Jacobson et al., 2020), and ECWMF IFS (Agusti-Panareda et al., 2014, 2019).

15

20

The remainder of the paper is organized as follows. Section 2 details the implementation of CO₂ transport in MPAS, Section 3 describes MPAS CO₂ simulation experiments and evaluation using airborne and near-surface observations, and comparison with WRF-Chem, CT2019, and IFS. Section 4 provides a summary of the model development and evaluations.

2 Implementation of CO₂ transport in MPAS

25

This section describes the major modifications to MPAS that we made to implement CO₂ tracer transport. We represent CO₂ by its dry air mixing ratio (q_{co_2}) and model its atmospheric transport by adding its continuity equation in MPAS following Eq. 7 of Skamarock et al. (2012).

$$\frac{\partial(\tilde{\rho} q_{co_2})}{\partial t} = -(\nabla \cdot \tilde{\rho} q_{co_2} \mathbf{V})_{\zeta} + F_{bl} + F_{cu} \quad (1)$$

30

where $\tilde{\rho} = \rho_d / (\partial\zeta / \partial z)$, ρ_d is dry air density, ζ is the vertical coordinate, z is geometric height, t is time, and \mathbf{V} is the velocity vector. The left hand side of the equation is the total CO₂ time tendency ($\partial(\tilde{\rho} q_{co_2}) / \partial t$), and the three terms on the right hand side represent the contributions from advection, vertical mixing, and convective transport respectively. CO₂ tendency

from advection is modeled in flux form (Section 2.1), while tendency from vertical mixing (F_{bl}) and convective transport (F_{cu}) are modeled in uncoupled form ($\partial q_{co_2}/\partial t$) which are coupled to $\tilde{\rho}$ before being added to the total tendency. Details of the three terms on the right hand side of Eq. 1 are described in the following sections. We note that because the monotonicity constraint in third-order scalar horizontal advection scheme (Skamarock and Gassmann, 2011) introduces dissipation MPAS does not use any explicit horizontal diffusion for scalar, and we did not include horizontal diffusion for CO₂ accordingly.

2.1 CO₂ advection

Advection is the most significant component of CO₂ atmospheric transport. Following the example of other scalars in MPAS (Skamarock and Gassmann, 2011), we model CO₂ advection as:

$$10 \quad (\nabla \cdot \tilde{\rho} q_{co_2} \mathbf{V})_{\zeta} = \left[\frac{\partial(\tilde{\rho} u q_{co_2})}{\partial x} + \frac{\partial(\tilde{\rho} v q_{co_2})}{\partial y} \right]_{\zeta} + \frac{\partial(\tilde{\rho} w q_{co_2})}{\partial \zeta} \quad (2)$$

where $\mathbf{V} = (u, v, w)$, and u , v , and w is the zonal, meridional, and vertical wind respectively. The first item on the right hand side enclosed in the square bracket is the CO₂ horizontal flux divergence, and second item is the vertical flux divergence. The horizontal flux divergence is transformed via the divergence theorem into an integral of flux over each control volume, which is modeled as:

$$15 \quad \left[\frac{\partial(\tilde{\rho} u q_{co_2})}{\partial x} + \frac{\partial(\tilde{\rho} v q_{co_2})}{\partial y} \right]_{\zeta} = \frac{1}{A_i} \sum_e^{n_e} l_e F_e(\mathbf{V}_H, \tilde{\rho} q_{co_2}) \quad (3)$$

where e indexes the edges of a cell and n_e represents the number of edges the cell has, l_e is the length of an edge, A_i is the cell's areal size, $F_e(\mathbf{v}_H, \tilde{\rho} q_{co_2})$ is the instantaneous horizontal CO₂ flux that crosses the cell edge e , and $\mathbf{V}_H = (u, v)$ is the horizontal wind vector. The details of MPAS instantaneous horizontal flux calculation can found in Skamarock and Gassmann (2011). The vertical CO₂ flux divergence in Eq. 2 is calculated using finite difference

$$20 \quad \frac{\partial(\tilde{\rho} w q_{co_2})}{\partial \zeta} = \frac{1}{\Delta \zeta} \left[F(w, \tilde{\rho} q_{co_2})_{k+\frac{1}{2}} - F(w, \tilde{\rho} q_{co_2})_{k-\frac{1}{2}} \right] \quad (4)$$

where $F(w, \tilde{\rho} q_{co_2})$ is the vertical CO₂ flux that crosses a cell's vertical face, and k indexes the vertical coordinate.

2.2 CO₂ vertical mixing

Like in WRF (Skamarock et al., 2008), a planetary boundary layer (PBL) parameterization in MPAS treats the vertical mixing of momentum and scalars not only in the boundary layer but in the entire atmospheric column. Yonsei University (YSU) PBL scheme (Hong et al., 2006) is one of the PBL schemes available in MPAS 6.3. The present YSU scheme treats vertical mixing of momentum, potential temperature, and water species, but not atmospheric tracers. We modified the scheme to treat CO₂

vertical mixing.

In the YSU scheme, after the boundary layer (BL) top is determined, the vertical mixing of momentum, potential temperature, and water vapor are treated separately: above BL, local K-profile approach (Louis, 1979) is used for vertical diffusion of momentum and scalars (Noh et al., 2003; Hong et al., 2006). Within BL, an entrainment flux at the inversion layer is included for momentum and scalars diffusion. In addition, a countergradient mixing term is included for the diffusion of momentum and potential temperature to account for the convective-driven mixing (γ_c of Eq. 4 in Hong et al. (2006)), but this term is not used for water vapor.

Following the treatment of water vapor, we parameterize CO₂ vertical mixing in BL as

$$\frac{\partial q_{co_2}}{\partial t} = \frac{\partial}{\partial z} \left[K_h \left(\frac{\partial q_{co_2}}{\partial z} \right) - \overline{(w'q'_{co_2})}_h \left(\frac{z}{h} \right)^3 \right] \quad (5)$$

where z is the vertical distance to surface, h is BL top height, K_h is vertical eddy diffusivity. Note that this formulation does not include a countergradient mixing term following the treatment of water vapor in the original YSU (Hong et al., 2006). The second term in the square bracket of Eq. 5 represents the contribution from CO₂ entrainment flux at the inversion layer, which is parameterized as:

$$\overline{(w'q'_{co_2})}_h = w_e \Delta q_{co_2}|_h \quad (6)$$

where $\Delta q_{co_2}|_h$ is the CO₂ mixing ratio difference across the inversion layer, and w_e is the entrainment rate at the inversion layer calculated by Eq. A11 of Hong et al. (2006). Above BL top, vertical mixing of CO₂ is parameterized as:

$$\frac{\partial q_{co_2}}{\partial t} = \frac{\partial}{\partial z} \left[K_h \left(\frac{\partial q_{co_2}}{\partial z} \right) \right] \quad (7)$$

We use the same value for CO₂ eddy diffusivity as water vapor. The details of K_h calculation can be found in the appendix of Hong et al. (2006). The term $\partial q_{co_2} / \partial t$ from Eqs. 5 is coupled with dry air density before being applied to the continuity equation (Eq. 1).

2.3 CO₂ convective transport

For convective transport, we modified the Kain-Fritsch scheme (hereafter KF) (Kain, 2004) to include the CO₂ treatment. KF is a mass-flux convection scheme which rearranges mass in an air column using convective updrafts, downdrafts, and environmental mass fluxes. Both the updraft and downdraft entrain from and detrain to the environment, thus altering the vertical profile of an air column's thermodynamic properties. We added the CO₂ convective transport as:

$$\frac{\partial q_{co_2}}{\partial t} = \frac{(M_u + M_d)}{\rho A} \frac{\partial q_{co_2}}{\partial z} + \frac{M_{ud}}{M} (q_{co_2}^u - q_{co_2}) + \frac{M_{dd}}{M} (q_{co_2}^d - q_{co_2}) \quad (8)$$

where q_{CO_2} , $q_{CO_2}^u$, and $q_{CO_2}^d$ are the CO_2 mixing ratio in the environment, updraft, and downdraft respectively, M_u and M_d are the updraft and downdraft mass respectively, ρ is the environment air density, A is the horizontal area of a cell, $M = \rho A \delta z$ is the mass of environmental air in a grid box, and M_{ud} and M_{dd} are the detrainment from the updraft and downdraft respectively.

- 5 In KF, the updraft and downdraft mass and the rates for the entrainment and detrainment are determined by a steady-state plume model and a convective available potential energy (CAPE) closure assumption: 90% of the existing CAPE should be removed by the convection parameterization (Kain and Fritsch, 1990; Fritsch and Chappell, 1980; Kain, 2004). The updraft source layers are determined by a search from the model's lowest vertical level for a group of consecutive layers that is buoyant and at least 50 hPa deep (Kain, 2004). The initial value of CO_2 mixing ratio in the updraft is modeled as a pressure weighted
- 10 average of the source layers:

$$q_{CO_2}^u = \sum_k \frac{\delta q_{CO_2,k} \delta p_k}{\delta p_k} \quad (9)$$

where δp_k is layer's pressure depth, and $q_{CO_2,k}$ is the layer's CO_2 mixing ratio. Carbon dioxide mixing ratio of the updraft is modified by the entrainment of the environmental air through its ascent from its starting level to the cloud top.

$$q_{CO_2}^u = \frac{q_{CO_2}^u M_u + q_{CO_2} M_{ue}}{M_u + M_{ue}} \quad (10)$$

- 15 where M_{ue} is the updraft entrainment. The initial CO_2 mixing ratio of a downdraft ($q_{CO_2}^d$) is the same as that of the environment (q_{CO_2}) at the downdraft starting level and it is modified by entrainment through the downdraft descent:

$$q_{CO_2}^d = \frac{q_{CO_2}^d M_d + q_{CO_2} M_{de}}{M_d + M_{de}} \quad (11)$$

where M_{de} is the downdraft entrainment.

3 Model evaluation

- 20 In this section we evaluate the newly developed MPAS CO_2 transport model through simulation experiments using airborne and near-surface observations. After describing the simulation configuration (Sect. 3.1), we assess the model's global CO_2 mass conservation property (Sect. 3.2), then we evaluate the model accuracy by comparing MPAS simulated CO_2 with high-resolution airborne measurements (Sect. 3.3) and near-surface hourly measurements (Sect. 3.4). Two sets of MPAS simulations are conducted: the first set simulations covers four ACT campaign seasons (2016-2018) for evaluation using high-resolution
- 25 airborne measurements; the second set covers January and July of 2014 for evaluation using near-surface CO_2 measurements and comparison with the IFS simulation results reported in Agusti-Panareda et al. (2019). In the following model evaluation,

we use root mean square error (RMSE), bias (μ), and random error (STDE) as the model accuracy metrics:

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^N (m_i - o_i)^2} \quad (12)$$

$$\mu = \frac{1}{N} \sum_{i=1}^N (m_i - o_i) \quad (13)$$

5

$$\text{STDE} = \sqrt{\frac{1}{N} \sum_{i=1}^N (m_i - o_i - \mu)^2} \quad (14)$$

where o_i and m_i represent the observed and modeled values respectively.

3.1 Simulation experiment configuration

For all subsequent simulations, MPAS uses a 60-15km variable-resolution global mesh. Fig. 1 shows the cell size (in km²) of
10 the simulation domain, where the highest resolution (15 km) over North America has cell size smaller than 250 km² which
gradually increases to about 3,600 km² for the rest of the global domain. On the vertical direction, there are 55 levels span-
ning from surface to 30 km above the mean sea level. Model time step is 90 seconds in accordance with the highest (15km)
horizontal resolution. For physical parameterizations, in addition to the modified YSU PBL (Hong et al., 2004) and Kain-
Fristch cumulus schemes (Kain, 2004) described in Sect. 2, we use RRTMG for longwave and shortwave radiation (?), Noah
15 land scheme (Chen and Dudhia, 2001), Monin-Obukhov surface layer scheme, and WRF single-moment 6-class microphysics
scheme (Hong and Lim, 2006). The third-order advection is used for all scalars and CO₂ tracer. A summary of the physics
parameterizations used in the simulations is given in Table 1.

Meteorology initial conditions are generated from the ERA-Interim analysis (Dee et al., 2011). To keep model meteorolo-
20 gical fields close to the analysis, MPAS meteorological fields are re-initialized using the analysis at 00:00 UTC each day
throughout a simulation period. Carbon dioxide mixing ratio is kept unchanged during the meteorology re-initializations, thus
a free-running simulation. This configuration is the same as that used by Agusti-Panareda et al. (2014, 2019) in their IFS global
CO₂ simulations. The first CO₂ initial condition for a simulation is from CT2019 3° × 2° posterior dry mole fraction product
and CO₂ fluxes are prepared by interpolating the CT2019 3-hourly 1° × 1° posterior flux product (Jacobson et al., 2020). The
25 four fluxes from CT2019 (biosphere, ocean, fossil fuel, and fire) are interpolated to MPAS model grid and ingested at 3-hour
intervals throughout a simulation.

3.2 CO₂ mass conservation

For a transport model, it is very important to maintain the global CO₂ mass conservation (Agusti-Panareda et al., 2017; Polavarapu et al., 2016). To evaluate the mass conservation property of MPAS, we run a 120-hour continuous simulation and examine the change of total mass of CO₂ in the model domain. The simulation starts at 2016-08-01 00:00 UTC and ends at 2016-08-06 00:00 UTC. It uses the physics parameterizations and domain setup described in Sect. 3.1. The CO₂ dry air mixing ratio field in the model is initialized using CT2019 dry mole fraction, but fluxes ingestion is turned off. Because the meteorology re-initiation will introduce dry air mass change which in turn will impact the total CO₂ mass, we run the simulation without applying the meteorology re-initialization. The impact of meteorological re-initialization and its treatment are considered in Section 3.2.2.

3.2.1 Mass conservation without meteorology re-initialization

Through the 120-hour simulation, model outputs are saved at 1-hour intervals using double-precision. The total mass of dry air (m_{air}) and CO₂ (m_{co_2}) is then calculated from these hourly outputs using Eqs. 15 and 16 respectively.

$$m_{air} = \sum_k^L \left(\sum_i^N A_i h_{i,k} \rho_{i,k} \right) \quad (15)$$

$$m_{co_2} = \sum_k^L \left(\sum_i^N A_i h_{i,k} \rho_{i,k} q_{i,k} \right) \quad (16)$$

In Eqs. 15 and 16, subscript i indexes the horizontal cell, ranging from 1 to $N=535,554$; subscript j indexes the vertical level, ranging from 1 to $L=55$. MPAS hexagon cell base areal size is A_i (cell size is constant within a given column at different vertical levels), and the height of the cell is represented by $h_{i,j}$ (heights at different columns of a same vertical level maybe different due to the terrain-following vertical coordinate). The volume of a grid box is $V_{i,k} = A_i h_{i,k}$, its dry air density (kg/m^3) is $\rho_{i,j}$, and its CO₂ dry air mixing ratio (kg/kg) is $q_{i,j}$.

The calculation shows that the total volume of the MPAS model domain is $1.5184682921961 \times 10^{19} m^3$, which is a constant through the simulation because of the model's height based vertical coordinate. At the start of the simulation, the total dry air mass is $5.053906341880670208 \times 10^{18} kg$ and total CO₂ mass is $3.079178060337270 \times 10^{15} kg$. The total mass of dry air and CO₂ at each subsequent hour is normalized by their respective starting values and resulting variations are shown in Fig. 2. The maximal variation of the total dry air mass from its starting value during the 120-hour simulation is 29,660,160 kg, which when divided by the total air volume represents a variation of mean dry air density approximately $1.95310^{-12} kg/m^3$. The maximal variation of total CO₂ mass from its starting value is 18,980 kg, which represents a variation in mean CO₂ mixing

ratio of 1.0416×10^{-15} kg/kg (equivalent to 6.839×10^{-10} ppm) for a mean dry air density of 1.2 kg/m^3 .

In MPAS dry air density and CO_2 dry air mixing ratio are prognostic variables and their precision is limited by the round-off error of the model's Fortran double-precision code. Fig.2 shows that the maximal variation in dry air density is 1.95310^{-12} kg/m³) and maximal variation in CO_2 dry air mixing ratio is 1.0416×10^{-15} kg/kg during the simulation period. Given that the double precision float number calculation of MPAS Fortran code is capable of having 14 decimal places of precision, we consider the MPAS CO_2 transport maintains the global mass conservation to the level allowed by the machine precision.

3.2.2 CO_2 mass conservation during meteorology re-initialization

The last section has demonstrated that MPAS is capable of maintaining global CO_2 mass conservation. However when meteorology re-initialization is applied, dry air density fields in the model are replaced by values from the initialization files generated from the ERA-Interim analysis (Dee et al., 2011). In most cases, this will cause dry air density change which in turn will introduce CO_2 mass change because CO_2 dry air mixing ratios are kept unchanged during the re-initializations.

To assess this possible change in global CO_2 mass, we conducted a 48-day MPAS simulation starting 00:00 UTC 15 July 2016 with meteorology re-initialization at 24-hour interval but without CO_2 fluxes ingestion. The global CO_2 mass is calculated using Eq. 16 at the end of each 24-hour period which is then compared with its initial value at the start of the simulation. The resulting global CO_2 mass variation is shown in the top panel of Fig. 3. The figure shows that during the 48-day simulation, the maximal variation of total CO_2 mass can reach approximately $\pm 0.05\%$, which is 7 to 8 magnitudes larger than that without re-initialization (Fig. 2). To restore the CO_2 mass conservation, we calculate the total CO_2 mass difference caused by a meteorology re-initialization using

$$r = \frac{\sum_k^L (\sum_i^N A_i h_{i,k} \rho_{i,k} q_{i,k})}{\sum_k^L (\sum_i^N A_i h_{i,k} \rho'_{i,k} q_{i,k})} \quad (17)$$

where notations are the same as in Eq. 16 except that $\rho'_{i,k}$ is the dry air density after a meteorology re-initialization and $\rho_{i,k}$ is the value before the re-initialization. Then CO_2 mixing ratio at each grid box is scaled by

$$q'_{i,k} = r \times q_{i,k} \quad (18)$$

where $q'_{i,k}$ is the CO_2 mixing ratio that will be used as the initial value for the next 24-hour simulation period.

To test the effectiveness of this scaling method, the 48-day simulation is conducted again but with the CO_2 mixing ratio scaling after each re-initialization using Eqs. 17 and 18. The resulting variation in total CO_2 mass is plotted at the lower panel of Fig. 3. The figure shows that maximal variation is less than $\pm 0.001\%$, which is small enough to be acceptable for most CO_2

transport simulations. We note that an alternative approach is to scale CO₂ mixing ratio at each grid box individually by

$$q'_{i,k} = \frac{\rho_{i,k}}{\rho'_{i,k}} \times q_{i,k} \quad (19)$$

where notation is the same as Eq. 17. This scaling approach can maintain total CO₂ mass conservation as allowed by machine precision but it will introduce artificial spatial variations in CO₂ mixing ratio. In the simulations in the following sections, we chose to use the first scaling approach to avoid the artificial CO₂ mixing ratio variation by accepting the small change in total CO₂ mass.

3.3 Model valuation using airborne measurements

In this section, we evaluate the MPAS CO₂ simulation accuracy using an extensive high resolution CO₂ observation data acquired through the Atmospheric Carbon and Transport-America project (ACT-America, henceforth, referred to as ACT). ACT is a National Aeronautics and Space Administration (NASA) Earth Venture Suborbital 2 (EVS-2) mission, and its goal is to improve atmospheric inversion estimates of CO₂ and CH₄ through extensive airborne measurements over the eastern United States during multiple seasons (Davis et al., 2018a). Through four campaign seasons from Summer 2016 to Spring 2018 with two research aircraft (C130 and B200), the ACT project has collected an extensive dataset of highly resolved CO₂ measurements in both boundary layer and free troposphere. To use ACT airborne CO₂ measurements for model evaluation, we ran four sets of MPAS simulations each covering one ACT campaign season. The duration of the ACT campaign seasons and the corresponding MPAS simulation periods is given in Table 2. All simulations use the same domain and configurations as described in Sect. 3.1, and model outputs are saved at 1-hourly interval for subsequent evaluation.

3.3.1 Evaluation of modeled horizontal wind fields

Accurate meteorological fields are critical for an accurate CO₂ transport simulation. Michaelis et al. (2019) has assessed MPAS simulated meteorology accuracy using extensive observation data. Before evaluating the simulated CO₂, we first evaluate the MPAS simulated horizontal wind fields considering their importance in CO₂ advection. We compare MPAS simulated horizontal wind fields at 00:00 and 12:00 UTC each day of the simulation period with radiosonde observations from 457 stations located around the globe at four pressure levels (1,000, 850, 500, 850, and 200 hPa). The locations of the 457 radiosonde stations are shown in Fig. S3 of the supplement material. The horizontal wind fields evaluation results for each of the four ACT seasons are summarized in Table 6. For instance, the RMSE of vector wind at the 1000, 850, 500, and 200 hPa are 3.31, 3.87, 3.78, and 5.46 m/s for the Summer 2016 season. These values are comparable to but higher than the vector wind RMSE of the month of July 2014 from the IFS 9km and 80km horizontal resolution global simulations reported in Agusti-Panareda et al. (2019). For the winter 2017 season, RMSE of vector wind is 3.70, 4.44, 4.56, and 5.40 m/s respectively at the four pressure levels, and they are slightly higher than the January 2014 vector wind RMSE reported in Agusti-Panareda et al. (2019). The

error statistics from the other two seasons are of similar magnitude as the summer 2016 and winter 2017 seasons.

3.3.2 Overall accuracy of MPAS modeled CO₂

We use the ACT airborne measurements to evaluate MPAS CO₂ simulation regarding its overall accuracy and its performance
5 measured by three model evaluation metrics proposed by Pal et al. (2020). To provide an objective reference, we also compare
MPAS performance with two established CO₂ model systems: WRF-Chem (Skamarock et al., 2008) and CT2019 (Jacobson
et al., 2020) using the same set of airborne measurements.

WRF-Chem is an online chemistry transport model based on the regional NWP WRF (Grell et al., 2011; Skamarock et al.,
10 2008). WRF-Chem simulations have been carried out at 27 km horizontal grid over North America as a part of the ACT
project (Feng et al., 2020). The WRF-Chem simulations use ERA5 reanalysis (Hersbach et al.) for meteorological initial and
boundary conditions, CarbonTracker (Jacobson et al., 2007) posterior mole fraction for CO₂ initial and boundary conditions,
and CarbonTracker posterior fluxes for CO₂ fluxes. The WRF-Chem simulations use meteorological nudging and 120-hour
meteorological re-initialization to keep meteorological fields close to the analysis. CarbonTracker (Jacobson et al., 2007, 2020)
15 is an operational carbon data-assimilation system which uses Transport Model 5 (TM5) (Krol et al., 2005) for atmosphere
transport. TM5 is an offline global chemical transport model which includes CO₂ advection, deep and shallow convection, and
vertical diffusion in both the planetary boundary layer and free troposphere (Krol et al., 2005). In producing CT2019 CO₂
mole fraction (Jacobson et al., 2020), TM5 simulation ran over a 3° × 2° global domain and an nested 1° × 1° North America
domain driven by ERA-interim reanalysis (Dee et al., 2011).

20

We use the ACT 5-second averaged CO₂ measurement dataset (Davis et al., 2018b), which has a horizontal resolution ap-
proximately 500 m given the average aircraft velocity. MPAS simulated CO₂ fields are interpolated in time and space to match
each 5-second airborne data points. WRF-Chem simulated CO₂ fields are also interpolated to match the ACT 5-second data
point using the same approach as MPAS. CarbonTrack CO₂ used for the evaluation is obtained from CarbonTrack ObsPack
25 ((Masarie et al., 2014)), which is the CT2019 posterior mole fraction interpolated to the ACT 5-second data points.

For each ACT flight day, CO₂ measurements from the two aircraft are combined if both are available, and their corresponding
modeled CO₂ values from MPAS, WRF-Chem, and CT2019 are combined in the same way. With the four seasons combined,
there are a total of 97 flight days (Pal and Davis, 2020), each one presented by an observation-model dataset consisted of
30 observed CO₂, modeled CO₂ from the three models, along with the time, latitude, longitude, and altitude of each observation
data point. Using the ACT maneuver flag dataset Pal et al. (2020), we further divide each flight day's data into two groups:
one for the boundary layer (BL) and another for the free troposphere (FT). RMSE and bias of the modeled CO₂ from the three
models (MPAS, WRF-Chem, and CT2019) are then calculated for each flight day, with the calculations for the BL and FT
carried out separately. In addition to the RMSE and bias, standard deviation is also calculated for the observed and modeled

CO₂ for assessing each model's representation of CO₂ spatial variability.

Using RMSE as an accuracy metric, we compare MPAS CO₂ simulation with WRF-Chem and CT2019 in Fig. 4. The figure shows that all three models have higher accuracy (lower RMSE) in FT than BL, which is most likely because flux errors impact simulated CO₂ in BL more than in FT. The figure also shows that compared with WRF-Chem, MPAS has a similar magnitude of RMSE overall in both BL and FT, with some exception where substantial differences exist between the two models. Averaged over the 97 flight days, the mean RMSE is 4.49/1.85 ppm (BL/FT) for MPAS, and 4.91/1.71 ppm for WRF-Chem, indicating MPAS achieved a slightly higher accuracy than WRF-Chem in BL which maybe partially because the former has a higher horizontal resolution (15 km) than the latter (27 km). In free troposphere, WRF-Chem resulted in a slightly higher accuracy than MPAS maybe because that it applied meteorological nudging while MPAS did not. Compared with CT2019, MPAS simulations resulted in larger RMSE in the majority of flight days, and the differences in RMSE between the two models are large in BL than FT. Averaged over the 97 flight days, the mean RMSE for CT2019 is 3.36 ppm and 1.42 ppm in BL and FT respectively, which are substantially lower than MPAS (4.49 ppm/1.85 ppm in BL/FT).

Next we examine how well each model represents the CO₂ spatial variability (as measured by standard deviation). Fig. 5 shows the comparison of the standard deviation (σ) of the modeled and aircraft observed CO₂. The figure shows that the observed CO₂ has higher variability (σ) in BL than in FT (note that different scales are used for BL and FT plots). The figure also shows that the MPAS simulated CO₂ has larger σ than the observations in most of the flight days (Fig. 5(a) and (d)). In comparison, CT2019 CO₂ has substantially lower variability than the observations in the majority of the flight days (Fig. 5(c) and (f)), especially in the boundary layer. Averaged over the 97 flight days, ACT airborne CO₂ observations has a mean σ of 3.53 ppm in BL, comparing to 4.27 ppm of MPAS, 4.63 ppm of WRF-Chem, and 2.23 ppm of CT2019.

The above model evaluation using airborne observations shows that the MPAS CO₂ transport model is capable of achieving a similar level of accuracy as 27 km resolution WRF-Chem simulation. Compared with the global inversion system CT2019, although MPAS resulted in higher RMSEs, it achieved better estimations of the observed CO₂ spatial variability.

3.3.3 Model representation of CO₂ difference between warm and cold sectors

Through analyzing the ACT Summer 2016 campaign data, Pal et al. (2020) identified three consistent features in CO₂ mole fraction and proposed to use these features as transport model assessment metrics. The three features are the differences between the warm and cold sectors, the difference between the boundary layer and free troposphere, and the CO₂ enhancement bands in the vicinity of frontal boundaries. Here and in next two sections, we evaluate how MPAS simulated CO₂ represents the three features.

Using the ACT maneuver flag dataset (Pal et al., 2020), we identified flights that crossed a weather front and their associated warm and cold sectors. The CO₂ mole fraction statistics for the warm and cold sectors are calculated from the aircraft measurements and the modeled CO₂ by MPAS, WRF-Chem, and CT2019, respectively. The results are shown in Fig. 6, which summarizes the statistics of CO₂ mole fraction differences between the warm and cold sectors measured by 15 front-crossing flights: 10 from the summer 2016 season and 5 from the winter 2017 season. The figure confirms that warm sector has higher average CO₂ mole fraction in the boundary layer than the cold sector during summer 2016 as reported by Pal et al. (2020). The figure also shows that the average CO₂ mole fraction in the warm sectors are lower than than the colder sectors in winter 2017, opposite to the summer 2016.

Fig. 6 also shows that MPAS simulated CO₂ well represents the difference between the warm and cold sectors well in all 15 cases. Table 4 lists the mean and standard deviation of the warm and cold sectors as calculated from the ACT measurements, MPAS, WRF-Chem, and CT2019. The table shows that the MPAS simulations are similar to WRF-Chem, and both tend to have larger CO₂ differences between the warm and cold sectors than CT2019. For instance, the 2016-08-24 case where the observed mean CO₂ difference between warm and cold sector is about 14 ppm, MPAS and WRF simulations resulted in 13.8 ppm and 7.8 ppm respectively, while CT2019 results in a 3.3 ppm difference. The above evaluation indicates that MPAS CO₂ model is capable of well representing the observed CO₂ difference between the warm and cold sectors, and its accuracy in this respect is similar to WRF-Chem and CT2019.

3.3.4 Model representation of CO₂ vertical difference

The second feature identified by Pal et al. (2020) is the vertical difference of CO₂ mole fraction between BL and FT. During ACT campaign season, two research aircraft (B200 and C130) took many vertical profile measurements during take off, landing, spiral up and down, and inline ascend and descend maneuvers (Pal, 2019). These profile observations characterize the vertical variation of atmospheric CO₂ mole fraction. From the vertical profile measurements taken during the summer 2016 season, Pal et al. (2020) calculated the mean CO₂ mole fraction in the boundary layer (BL) and free toposphere (FT), denoted as [CO₂]_{BL} and [CO₂]_{FT} respectively. They further defined BL-to-FT CO₂ difference as $\Delta[\text{CO}_2] = [\text{CO}_2]_{\text{BL}} - [\text{CO}_2]_{\text{FT}}$. They found that $\Delta[\text{CO}_2]$ tend to be positive in the warm sector and negative in the cold sector. In this section, we evaluate how well MPAS represent the BL-to-FT CO₂ difference and compare its performance with WRF-Chem and CT2019.

Using the ACT maneuver flag dataset (Pal et al., 2020), we identified all vertical profiles taken during the four campaign seasons, from which we selected profiles that meet two criteria: (1) a vertical profile must include at least 20 5-second measurements in the boundary layer and 20 measurements in the free troposphere; and (2) a vertical profile must extend at least 2 km in the vertical direction. These two criteria are used to ensure that the resulting [CO₂]_{BL} and [CO₂]_{BL} are statistically representative. A total of 199 qualified vertical profiles are identified from the four campaign seasons, including 72 from the summer 2016 season, 27 from winter 2017, 41 from fall 2017, and 59 from spring 2018. For each of the vertical profiles,

$\Delta[\text{CO}_2]$ is calculated for the aircraft CO_2 measurements, and the simulated CO_2 by MPAS, WRF-Chem, and CT2019. We compare $\Delta[\text{CO}_2]$ from the models with that from the observation to assess how each model represents the observed BL-to-FT CO_2 difference. Fig. 7 shows the comparisons grouped by the campaign seasons. The figure indicates a clear distinction in $\Delta[\text{CO}_2]$ between the summer 2016 and the other three seasons: There are substantial number of both positive and negative $\Delta[\text{CO}_2]$ in the summer 2016 season, but the vast majority cases in the rest of three campaign seasons have positive $\Delta[\text{CO}_2]$. The positive BL-to-FT CO_2 differences from the winter 2017 season measurements could be at least partially attributable to the lack of CO_2 draw-down during the non-growing season. In comparison, the fall 2017 and spring 2018 seasons have more mixed results probably because their partial overlap with the growing season. For the summer 2016 season, vertical profiles with negative $\Delta[\text{CO}_2]$ (lower mean CO_2 in BL than FT) suggest photosynthesis during the growing season, but those with positive $\Delta[\text{CO}_2]$ values are probably caused by the interaction between photosynthesis and frontal passage (Pal et al., 2020).

The comparison of $\Delta[\text{CO}_2]$ in Fig. 7 between the aircraft observations and the model simulations show how well the three models represent the BL-to-FT CO_2 difference. For instance, the figure indicates that MPAS represents the BL-to-FT difference more accurately during the fall 2017 seasons than the summer 2016 season. In comparison CT2019 represents BL-to-FT CO_2 difference more accurately during the summer 2015 season than the Fall 2017 season. The figure also show that while the comparisons between CT2019 and the aircraft observations have less scattering than MPAS and WRF-Chem, CT2019 also tend to underestimate the range of the BL-to-FT CO_2 differences, particularly during the spring 2018 season. To provide a quantitative evaluation, we calculated RMSE for each of the model-observation comparison of Fig. 7. In addition, the standard deviation of $\Delta[\text{CO}_2]$ is calculated for the observation and the three models for each season. The resulting statistics are summarized in Table 5 which shows that: MPAS has lower RMSEs than WRF-Chem in all but the summer 2016 season, and it has lower RMSEs than CT2019 for the winter and fall of 2017 but higher in the other two seasons. Regarding the standard deviations, MPAS compares with the observation better than WRF-Chem in all four season, and better than CT2019 in all but the summer 2016 season. In summary, the above model evaluation and comparison demonstrate that MPAS CO_2 transport model is capable of representing the aircraft observed CO_2 difference between boundary layer and free troposphere at least as accurately as WRF-Chem and CT2019.

3.3.5 Model representation of CO_2 enhancement at frontal boundaries

The third feature identified by Pal et al. (2020) in the summer 2016 aircraft measurements is the bands of enhanced CO_2 close to frontal boundaries in the boundary layer. They found these CO_2 enhancement bands are typically about 100 km wide and speculated that it would require a 20-km horizontal resolution model to effectively represent the feature. In this section, we identify the frontal boundary CO_2 enhancements in the four campaign seasons and examine how well they are represented by MPAS. For instance, Fig. 8 shows the MPAS simulated equivalent potential temperature (θ_e) and CO_2 mole fraction at 18:00 UTC 4 August 2016. The sharp boundary in θ_e indicates a surface cold front extending from southern Colorado northeastward to Wisconsin. Abrupt horizontal wind direction changes shown in Fig. S3 (supplement material) also indicate the cold front and

its southeastward movement. Meteorological measurements taken during the flight (not shown) confirm the cold front passage too. The B200 research aircraft crossed the cold front from southeast to northwest at about 400-500 meters above the ground between 17:15 UTC and 19:15 UTC, and its flight track and timing are marked on Fig. 8. The aircraft measurements show an approximately 20 ppm enhancement along the front boundary, which can be clearly identified in the MPAS simulated CO₂ mole fraction (lower panel of Fig. 8).

Using the same approach as Pal et al. (2020), a total of 48 front-crossing level-leg flight are identified from the four seasons (15 from Summer 2016, 5 from Winter 2017, 17 from Fall 2017, and 11 from Fall 2018). To evaluate how well MPAS represents the frontal boundary CO₂ enhancements and compare its performance with WRF-Chem and CT2019, CO₂ mole fraction measured by the aircraft and simulated by the three models are plotted together for each of the identified front-crossing level-leg flight in Fig. 9. For each flight in the figure, the vertical dashed line marks the approximate time when the aircraft crossed the frontal boundary, and the associated warm and cold sectors are labeled on either side of the boundary. Examination of the aircraft observations (black lines) in the figure indicate that frontal boundary CO₂ enhancements can be identified in most of the flights but not all cases. For instance, there is not clearly identifiable CO₂ enhancement in the B200 flights on 2017-10-08 and 2018-04-23.

Fig. 9 shows that MPAS (red lines in the figure) has a varying degree of success in simulating the frontal boundary CO₂ enhancements: it represents both the timing and the magnitude of the enhancements very well in some cases (2017-10-28 and 2017-11-03 by B200), but results in substantial errors in either the timing (2016-08-12 B200) or the magnitude (2017-03-10 C130) in other cases. The figure also shows that the MPAS simulated CO₂ is more similar to WRF-Chem than CT2019: CT2019 tends to substantially underestimate the magnitude of CO₂ enhancement while MPAS and WRF-Chem tend to overestimate.

To provide an quantitative comparison between the three models' accuracy regarding the frontal boundary CO₂ variation, we calculated RMSE and standard deviation for each of the 48 level-leg flights shown in Fig. 9. For each flight, RMSE is calculated for each of the three models as compared with the aircraft observations, and standard deviation is calculated for both the models and aircraft observations. The resulting RMSEs from MPAS are compared with WRF-Chem and CT2019 in Fig. 10. The figure indicates that MPAS RMSEs in general are similar in magnitude to CT2019 and lower than WRF-Chem. Averaged over the 48 cases, the mean RMSE is 4.63 ppm for MPAS, 4.68 ppm for CT2019, and 5.86 ppm for WRF-Chem, indicating MPAS perform as well as the other two models as measured by the RMSEs. We also assess how well the three models estimate the spatial variability of the frontal boundary CO₂ by comparing the standard deviation (σ) of the three models with the observations (Fig. 11). The figure shows that MPAS and WRF-Chem represent the spatial variability in the 48 level-leg flights better than CT2019 which substantially underestimates the variability in the majority of the cases. As horizontal resolution impacts a model's ability to represent small scale spatial variability (Agusti-Panareda et al., 2019), the coarser resolution of CT2019

($1^\circ \times 1^\circ$ over the North America) is likely the primary cause of its underestimation of the frontal boundary CO_2 variability.

3.4 Model evaluation using near-surface hourly CO_2 observations

The MPAS CO_2 transport model has been evaluated using the extensive high-resolution aircraft measurements from four ACT
5 campaign seasons. Considering that these aircraft measurements were all acquired during the day time hours over the eastern
United States, here we carry out further model evaluation using near-surface hourly CO_2 observations acquired by surface and
tower stations located across the globe. For this evaluation, we conducted another set of MPAS CO_2 simulations which cover
the month of January and July of 2014 using the same model domain and configurations as described in Sect. 3.1. As this is
the same time period that Agusti-Panareda et al. (2019) used for their IFS global CO_2 simulations, we can assess the MPAS
10 model performance through a comparison with the IFS simulations.

As with the simulations for the 2016-2018 ACT campaign seasons, we first evaluate the MPAS simulated horizontal wind
fields using radiosonde observations from 457 stations located around the globe (Fig. S3 of the supplement material). The
resulting statistics, including the RMSE of vector wind, RMSE of wind speed and wind direction, and the mean wind direction
15 difference are shown in Table 3. Compared with the IFS simulations by Agusti-Panareda et al. (2019) (their Fig. 4), the MPAS
simulated horizontal wind fields have larger errors in both January and July of 2014. For instance, the IFS 80 km resolution
simulation has a vector wind RMSE about 4.5 m/s at the 200 hPa level in January while MPAS results in 5.16 m/s at the same
pressure level.

20 We then compare MPAS simulated CO_2 with hourly measurements from 50 stations that were used for the IFS model
evaluation in Agusti-Panareda et al. (2019). The information of the 50 stations, including location, elevation, intake height,
and reference is listed Table 7. Like in Agusti-Panareda et al. (2019), only the highest intake level is used at towers that have
multiple intake heights. When multiple observations within an hour are available (such as those with 30-min or shorter time
interval), they are averaged to yield a single hourly value. For a given station this result in 744 (24×31) hourly measurements
25 per month at the maximum. Following Patra et al. (2008) and Agusti-Panareda et al. (2019), MPAS hourly outputs are horizon-
tally sampled by taking the nearest land cell to a given station. The resulting statistics (RMSE, bias, and STDE) for the MPAS
simulation covering the month of January 2014, along with their counterparts from the IFS 9 km and 80 km resolution simu-
lations (Agusti-Panareda et al., 2019), are listed in Table S1 of the supplement material. The table shows that RMSEs of the
MPAS simulated hourly CO_2 ranges from 0.36 ppm at the spo to 25.96 ppm at ssl station. In comparison, the IFS simulations
30 also resulted in a much lower RMSE at the spo than ssl, the latter of which has a RMSE of 5.83 ppm from 9 km resolution sim-
ulation and 23.99 ppm from the 80 km simulation. Agusti-Panareda et al. (2019) noted that the increasing horizontal resolution
improves model simulation accuracy the most at mountain stations. The Schauinsland station (ssl), located at the southwest
Germany with an elevation of 1205 meters above the means sea level, has considerable CO_2 variability because its vicinity to
biogenic and anthropogenic sources and sinks (Schmidt et al., 2003). This station is located in the 60-km resolution portion

of the MPAS 60-15km global domain, and the MPAS RMSE (25.96 ppm) at the station is closer to the IFS 80 km simulation (23.99ppm) than the 9km simulation (5.83 ppm), suggesting the influence of the model horizontal resolution. At this station, MPAS results in a positive bias of 21.34 ppm and IFS 80 km simulation has a positive bias of 18.72 ppm, meaning that both models substantially overestimate the hourly CO₂. An examination of the MPAS simulated hourly CO₂ (not shown) indicates
5 that the large bias is mostly caused by overestimation at the station during the nighttime hours. Such overestimation could be caused by a combination of errors in fluxes, vertical mixing, and large scale transport.

Finally, we compare RMSE and random error (STDE) of the MPAS simulation at the 46 stations with the IFS simulations in Fig. 12. The figure shows that MPAS has larger RMSE and STDE than the IFS 9 km simulation, but similar to the 80 km IFS
10 simulation. Similar model evaluation and comparison carried out for the month of July 2014 are shown in Table S2 (supplement material) and Fig. 13. Comparing with the January simulation, Fig. 13 shows that both MPAS and IFS have larger RMSEs in July, suggesting the impacts of large uncertainty in biospheric carbon fluxes during boreal summer. Fig. 13 also shows that the MPAS simulation has larger RMSE and STDE than the 9 km IFS simulation but similar to the 80 km IFS simulation, a similar pattern as in January.

15

4 Summary

This paper implemented CO₂ transport in the global variable-resolution model MPAS-A v6.3. The atmospheric CO₂ transport processes, including advection, vertical mixing, and convective transport, are implemented in the model. After the model development details are presented, simulation experiments designed for model evaluation are described. Two sets of simulations
20 over a 60-15 km variable-resolution global domains are conducted for model accuracy evaluation using an extensive aircraft measurements over the eastern United States and near-surface hourly measurements from surface and tower stations distributed across the globe. Meteorology initial conditions for these simulations are from the ERA-interim analysis (Dee et al., 2011), and CO₂ initial conditions and fluxes are from CT2019 posterior mole fraction and fluxes products (Jacobson et al., 2020). To keep model meteorological fields close to the analysis, meteorology re-initialization are applied at 24-hour interval throughout
25 the simulation periods. Global CO₂ mass conservation property is assessed by a continuous simulation without meteorology re-initialization and fluxes, and the results show that MPAS is capable of maintaining CO₂ mass conservation to the limit of machine precision. A 48-days simulation with meteorology re-initialization indicates that changes in dry air density during the re-initialization causes changes in global total CO₂ mass, and a scaling method applied after each re-initialization is able to reduce the global CO₂ mass variation to less than $\pm 0.001\%$ of its initial value.

30

The accuracy of MPAS CO₂ transport is evaluated using the extensive high-resolution aircraft measurements from four ACT campaign seasons during 2016-2018. Compared with a 27 km resolution WRF-Chem simulation and CT2019 posterior CO₂ mole fraction, MPAS simulated CO₂ achieves a comparable level of accuracy (as measured by RMSE). Further evaluation

using three metrics proposed by Pal et al. (2020) shows that MPAS simulation is capable of representing the observed CO₂ features as accurately as the WRF-Chem simulation and CT2019.

5 A second set of MPAS simulations for the month of January and July of 2014 are evaluated using near-surface hourly CO₂ measurements from surface and tower stations across the global. The resulting statistic, including RMSE, random error, and bias, are compared with the ECWMF IFS 9km and 80 km resolution simulations over the same period conducted by Agusti-Panareda et al. (2019). The comparison indicates that RMSE and random error of the MPAS simulation is similar to the 80 km IFS simulation, but larger than the 9 km IFS simulation.

10 The model evaluations using the airborne and near-surface measurements, indicates that the newly developed MPAS CO₂ transport model is capable of achieving a comparable level of accuracy with the more established CO₂ modeling systems, including the regional model system WRF-Chem, the operational assimilation system CarbonTracker, and the lower resolution (80 km) simulation of ECWMF IFS global CO₂ modeling system. Although further improvements are expected, the MPAS CO₂ transport model has the potential to contribute to improving our knowledge of the atmospheric CO₂ transport and fluxes.

15 **Code and data availability**

Source code for MPAS-A CO₂ transport model v6.3 can be retrieved at <https://doi.org/10.5281/zenodo.3976320> (Zheng, 2020). Source code for WRF-Chem v3.6 used in the manuscript can be obtained from NCAR website at http://www2.mmm.ucar.edu/wrf/users/download/get_source.html. Source code for IFS is only available subject to a licence agreement with ECMWF. ECMWF member-state weather services and their approved partners will get access granted. The IFS source code without modules for assimilation and chemistry can be obtained for educational and academic purposes as part of the openIFS release (<https://software.ecmwf.int/wiki/display/OIFS/OpenIFS+Home>). ACT-America in-situ Airborne CO₂ measurement data can be obtained at <https://doi.org/10.3334/ORNLDAAAC/1593>. Surface and tower based CO₂ measurement data from ObsPack GLOBALVIEWplus v6.0 can be obtained from NOAA website <https://esrl.noaa.gov/gmd/ccgg/obspacek/data.php>. CarbonTrack CO₂ flux and posterior mixing ratio data can be obtained from NOAA website <https://www.esrl.noaa.gov/gmd/ccgg/carbontracker/download.php>.

Author contributions

TZ implemented the CO₂ transport processes in MPAS v6.3. SF conducted the WRF 27km simulations. TZ, SF, KD, SP designed model evaluation using ACT-America aircraft measurements. TZ and JM designed the model evaluation using continuous in-situ tower measurements. TZ, SF, KD, SP analyzed the model representation of distinct CO₂ spatial features observed by the aircraft measurements. All authors contributed to writing and commenting on the paper.

Acknowledgment

We thank the MPAS development team for making their code available for the public; we thank NOAA CarbonTracker team for providing the CT2019 flux and mole fraction data; we thank ECWMF for the ERA-interim analysis data; we thank ObsPack data providers for the in-situ continuous CO₂ measurement data. The model simulations were carried out on Michigan State University High Performance Computing Center (HPCC). FS and KD were supported by the Atmospheric Carbon and Transport-America (ACT) Earth Venture Suborbital 2 project funded by NASA's Earth Science Division (Grant NNX15AG76G to Penn State), SP was supported by NASA Grant Number 80NSSC19K0730 and Texas Tech University start up research grant.

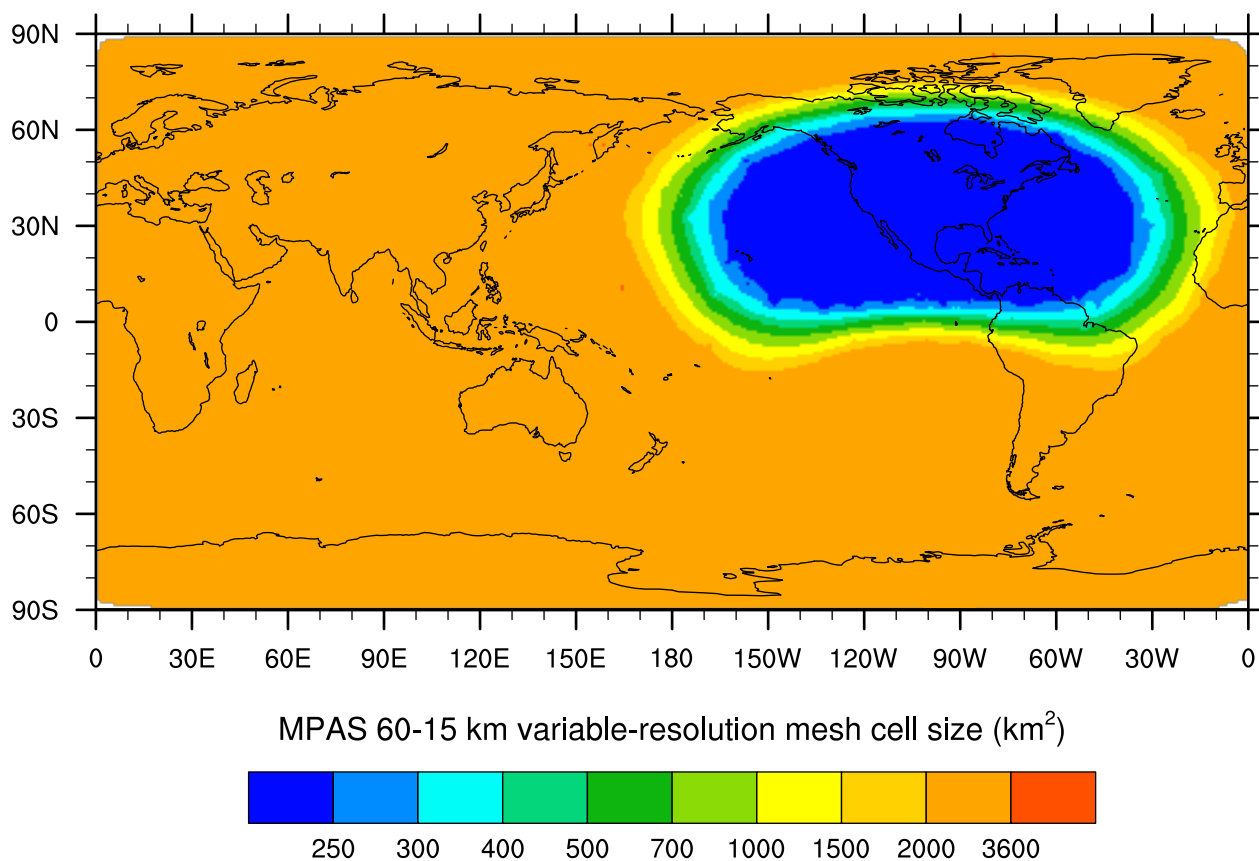

Figure 1. Variable-resolution 60-15 km global domain for MPAS CO₂ simulations conducted for model evaluation using aircraft and near-surface CO₂ observations. The highest resolution (15 km) grid covering the most of the North America has cell size less than 250 km². The cell sizes (represented by color) gradually increase to about 3,600 km² for the rest of the global domain.

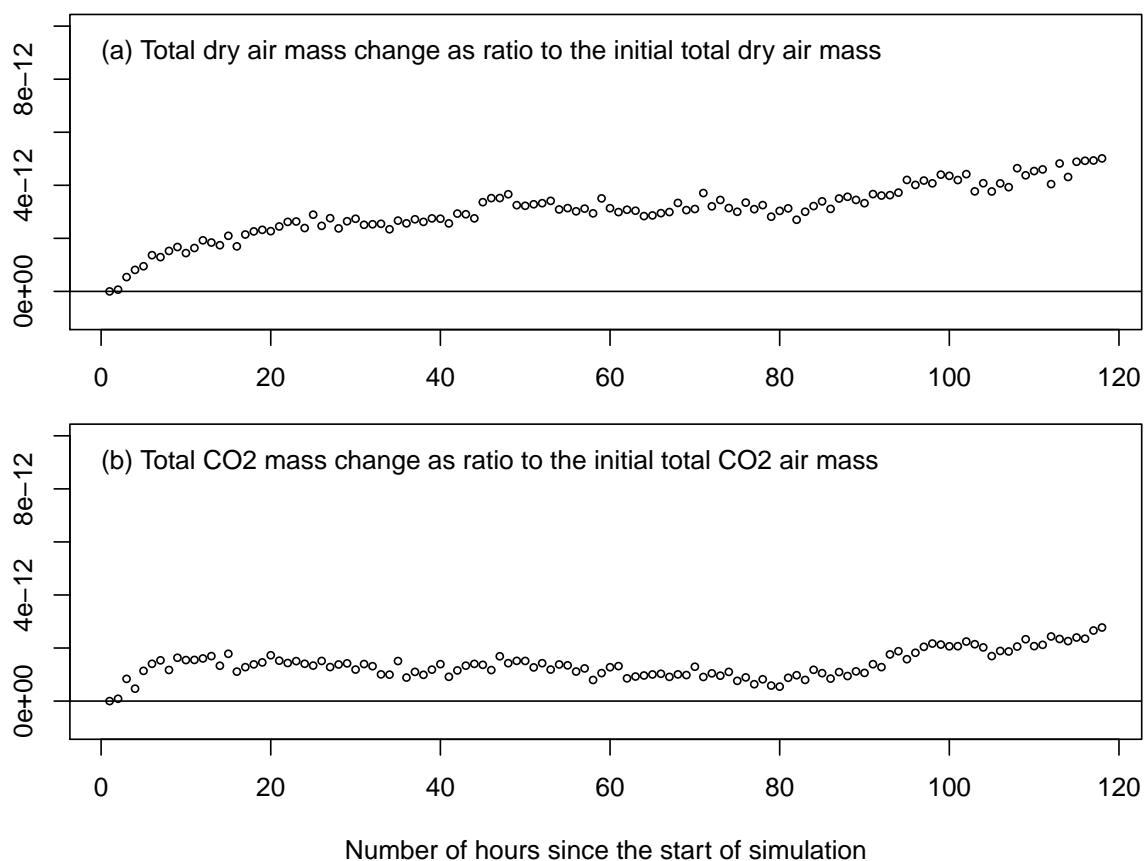

Figure 2. Variation of total dry air mass (a) and total CO₂ mass (b) as the ratio to their respective starting values during a 120-hour continuous MPAS simulation without meteorology re-initialization. The X-axis represents the number of hours after the start of the simulation, and the Y-axis the ratio of the total mass change to the starting values.

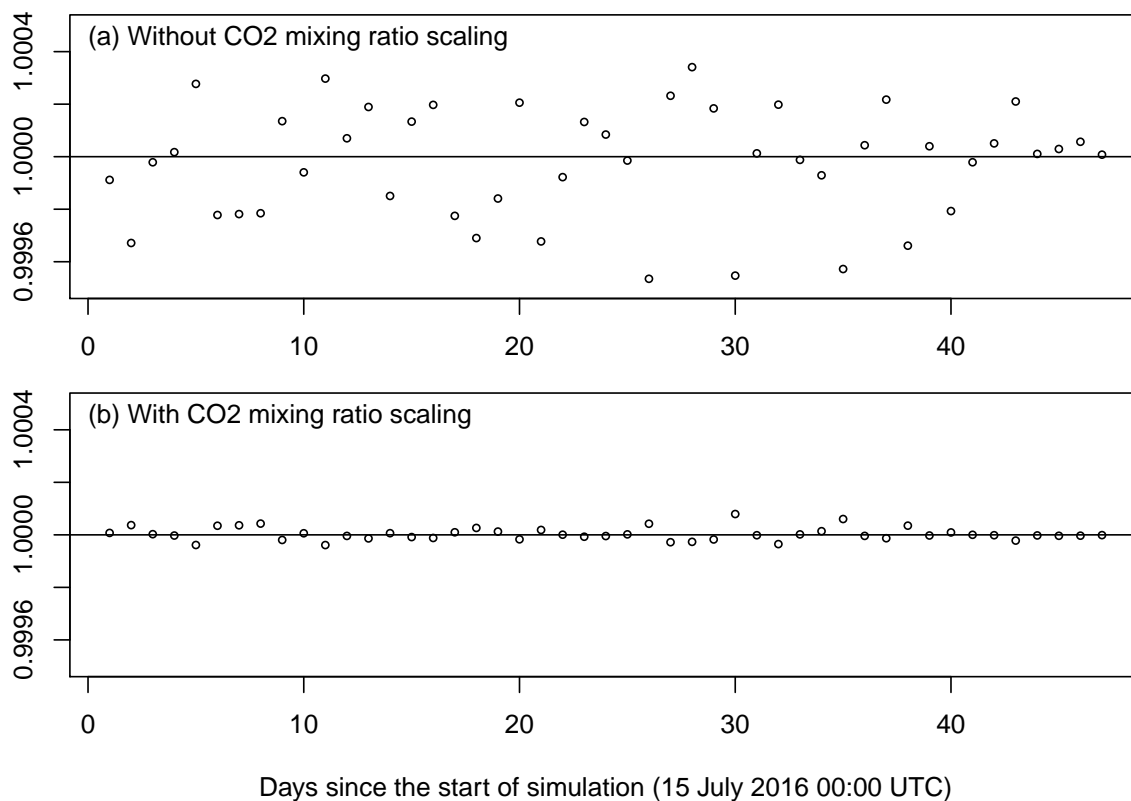

Figure 3. Variation of total CO₂ mass as the ratio to its starting value during a 48-day MPAS simulation with meteorology re-initializations at 24-hour intervals. The top figure is from the simulation without applying CO₂ mixing ratio scaling as described in Sect. 3.2.2, and the bottom figure is from the simulation with the scaling. In each figure, X-axis represents the number of days after the start of the simulation, and Y-axis the ratio of total CO₂ mass variation to its starting value.

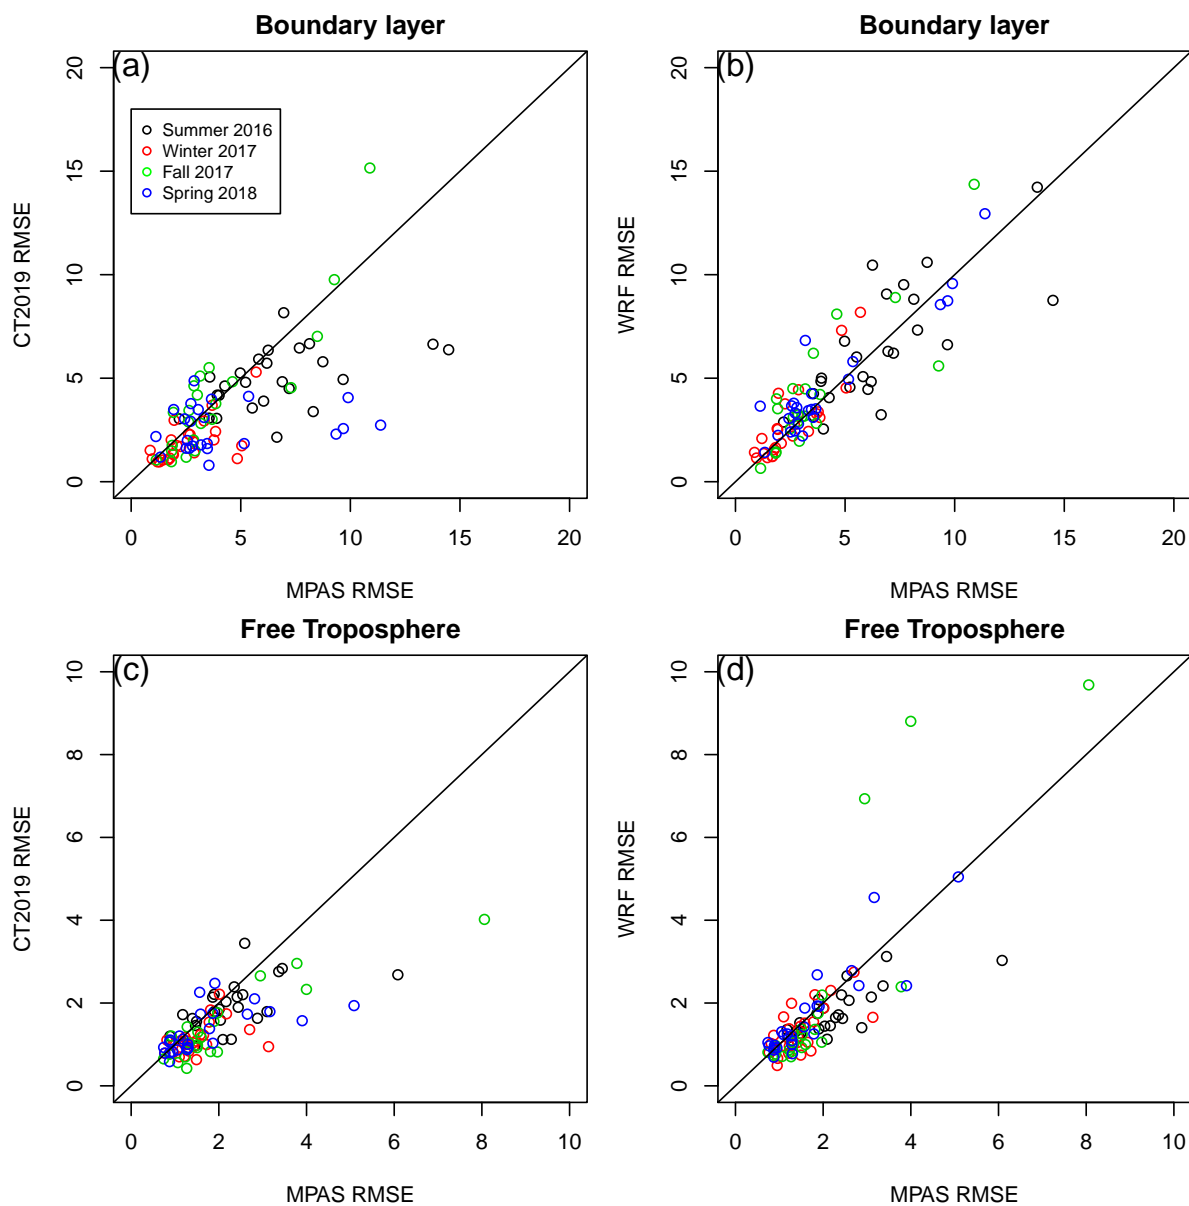

Figure 4. Comparison of model simulated CO₂ RMSE from MPAS with that from WRF-Chem and CT2019. The two figures on the top panel are the results from the boundary layer comparison and figures from the bottom panel are from the free troposphere. The RMSE comparison between MPAS and CT2019 are on the left side (a, c), and comparison between MPAS and WRF-Chem are on the right side (b, d). In each figure, a open circle represents model validation from one day's aircraft measurement and the color of the circle indicates the ACT campaign season it belongs to. All four subplots use the same legend as in the Fig. 4a

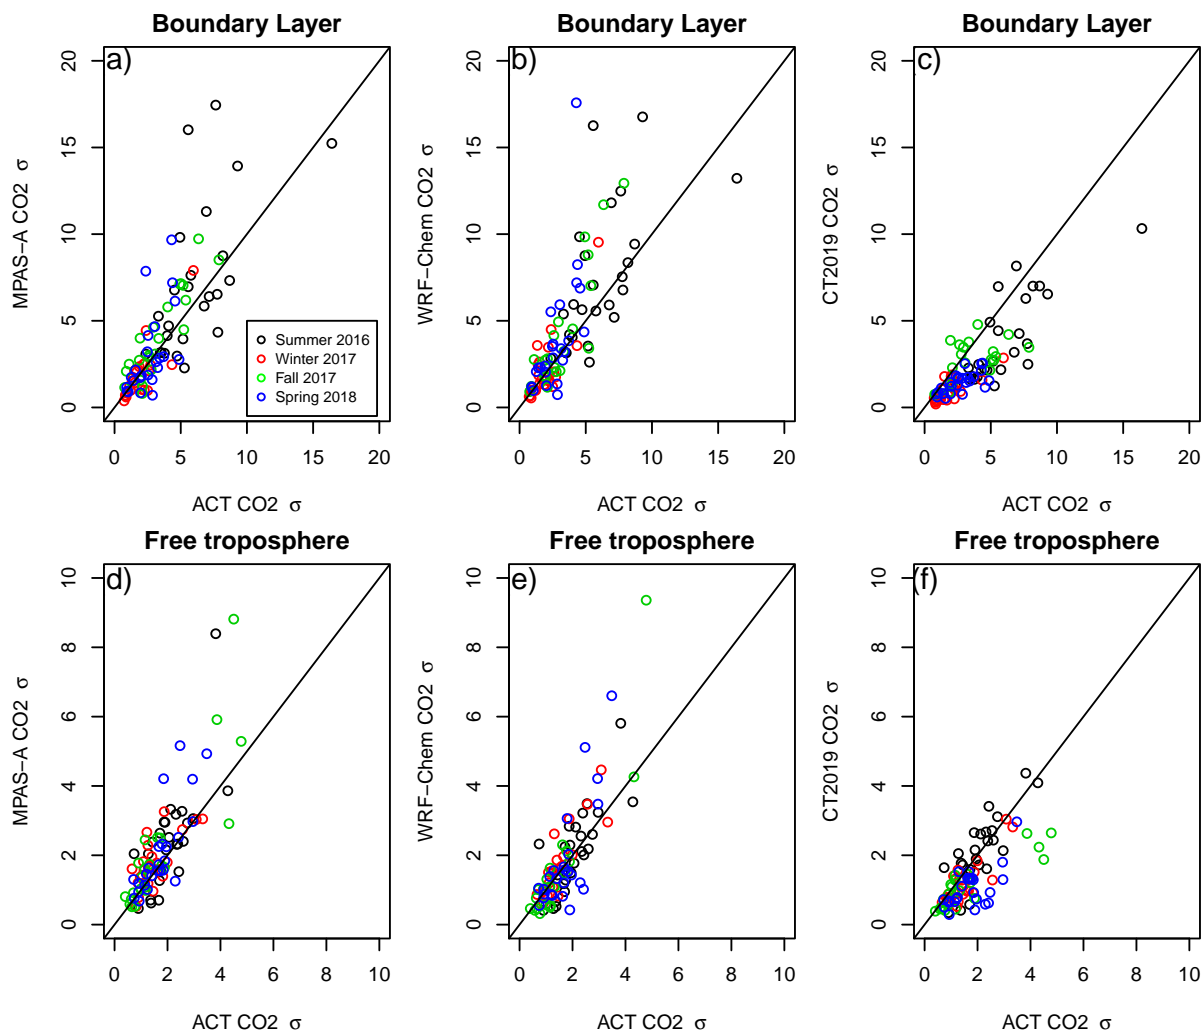

Figure 5. Comparison of standard deviation (σ , unit ppm) of aircraft observed CO₂ against that simulated by MPAS (a,d), WRF (b,e), and CT2019 (c,f). The comparison of standard deviation in boundary layer are in the top panels (a,b,c) and comparison in the free troposphere are in the bottom panel (d,e,f). In each subplot, a open circle represents one day's result and the color of the circle indicates its campaign season. All six subplots share the the legend in Fig. 11a.

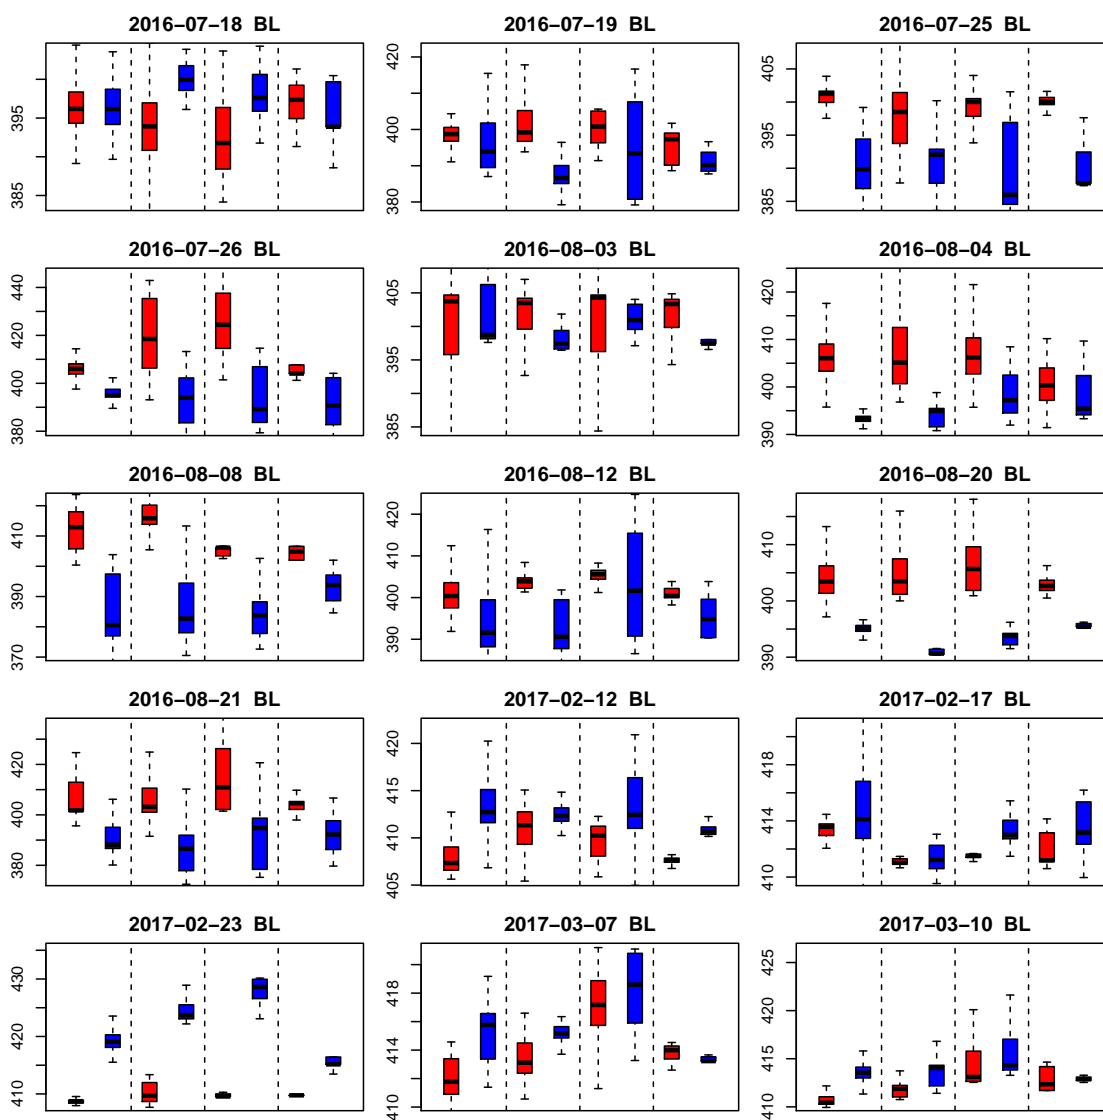

Figure 6. Box plots comparing mean boundary layer (BL) CO₂ mole fraction of the warm sector (red color) and cold sector (blue color) for 15 frontal crossing flights from summer 2016 and winter 2017 ACT campaign seasons. The flight date of each plot is labeled in its title. Data are combined when both aircraft (C130 and B200) took measurement for a given day. Each sub-figure is separated into four groups by the dotted lines: the first group is from ACT observations, the second is MPAS simulation, the third is WRF-Chem simulation, and the last is CT2019. In each boxplot, the bottom and top edge of the box represent the 1st (Q1) and 3rd (Q3) percentiles, the horizontal line represent the median, the ends of the whisker represents Q1-1.5×IQR and Q3+1.5×IQR respectively, where IQR=Q3-Q1.

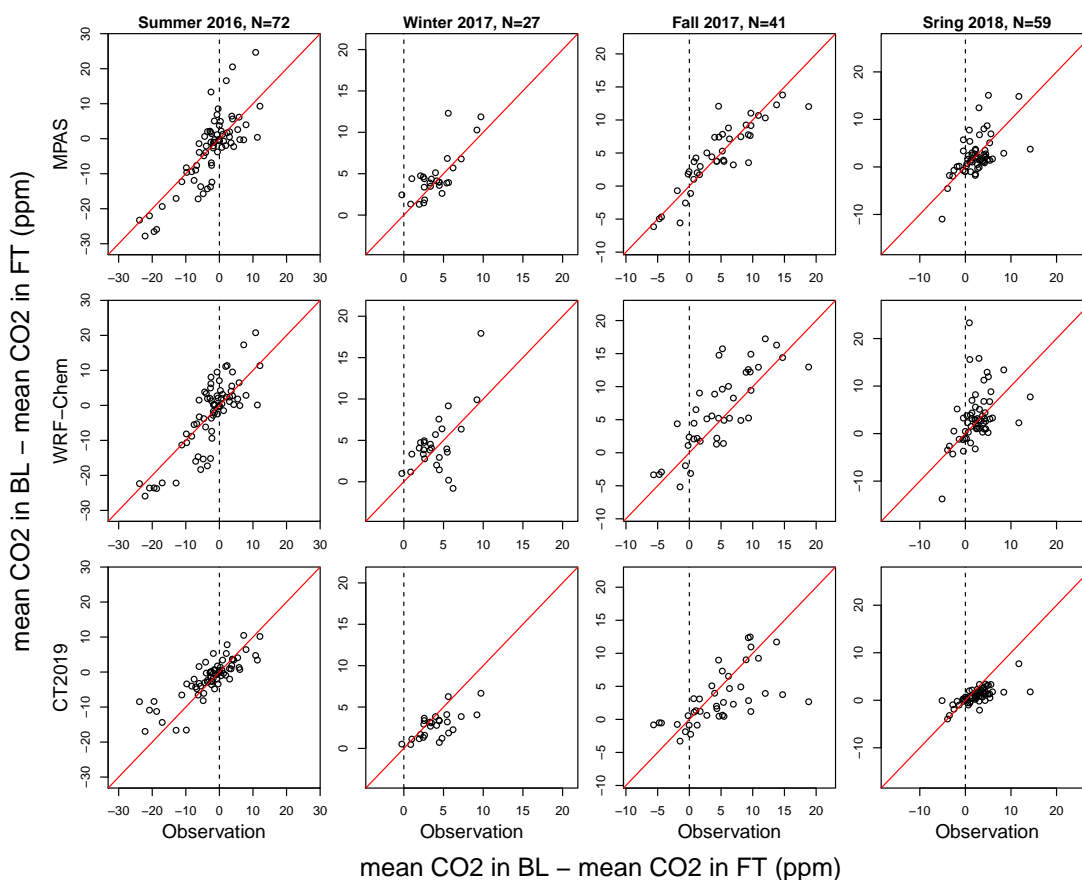

Figure 7. The difference of mean CO_2 mole fraction between boundary layer (BL) and free troposphere (FT) ($\Delta[\text{CO}_2] = [\text{CO}_2]_{\text{BL}} - [\text{CO}_2]_{\text{FT}}$) at vertical profiling flight legs. In each subplot, each open circle represents an individual vertical profiling flight leg, and its values on the X-axis and Y-axis represent its $\Delta[\text{CO}_2]$ value from the aircraft observations and the model simulation respectively. $\Delta[\text{CO}_2]$ from MPAS simulations are the first row, WRF-Chem the second row, and CT2019 the third. The four columns in the figure are for the four ACT campaign seasons. The number of vertical profiles in each season is labeled in the column title. The vertical dashed line marks where $\Delta[\text{CO}_2] = 0$ based on the aircraft measurements.

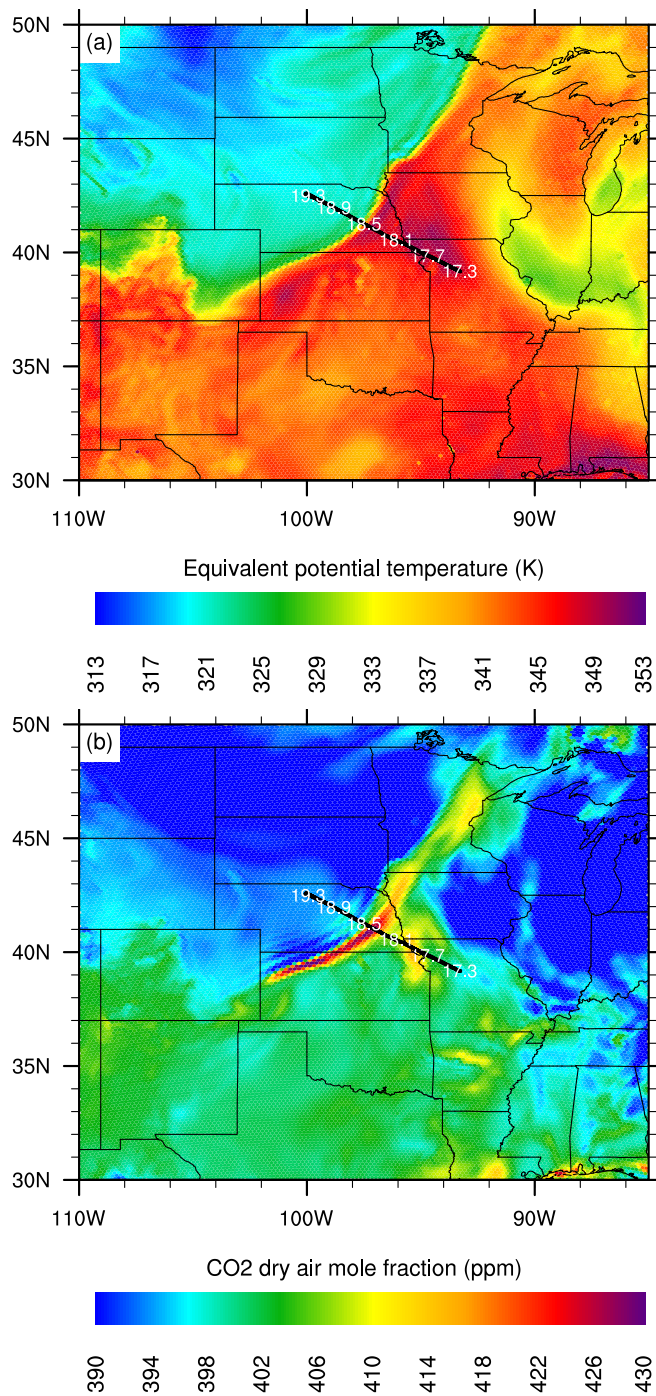

Figure 8. MPAS simulated equivalent potential temperature (θ_e , top panel) and CO₂ mole fraction (bottom panel) at 18:00 UTC 4 August 2016. Both figures are plotted at MPAS 6th vertical level, which is about 400 meters above the ground.

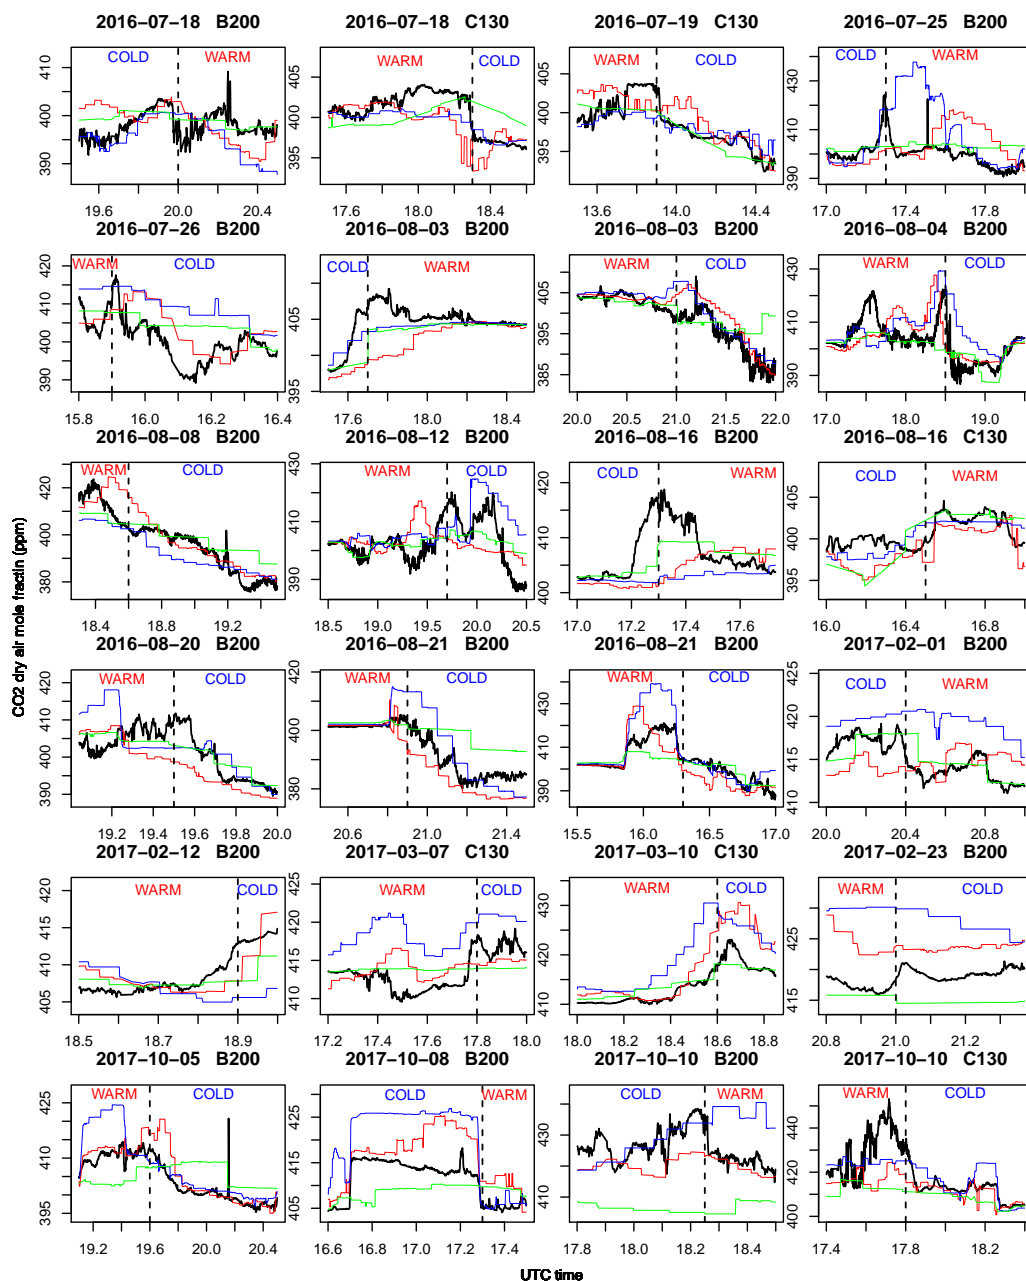

Figure 9. Comparison of CO₂ mole fraction in frontal-crossing level-leg flights in boundary layer between ACT aircraft measurements and model simulations. Flight date and aircraft type are labeled in title for each flight leg. In each figure, X-axis is UTC time, and Y-axis is CO₂ mole fraction (ppm). Aircraft measurements are in black, MPAS in red, WRF-Chem in blue, and CT2019 in green. The vertical dotted line in each figure marks the approximate location of boundary between warm and cold sectors, which are labeled as 'WARM', and 'COLD' respectively.

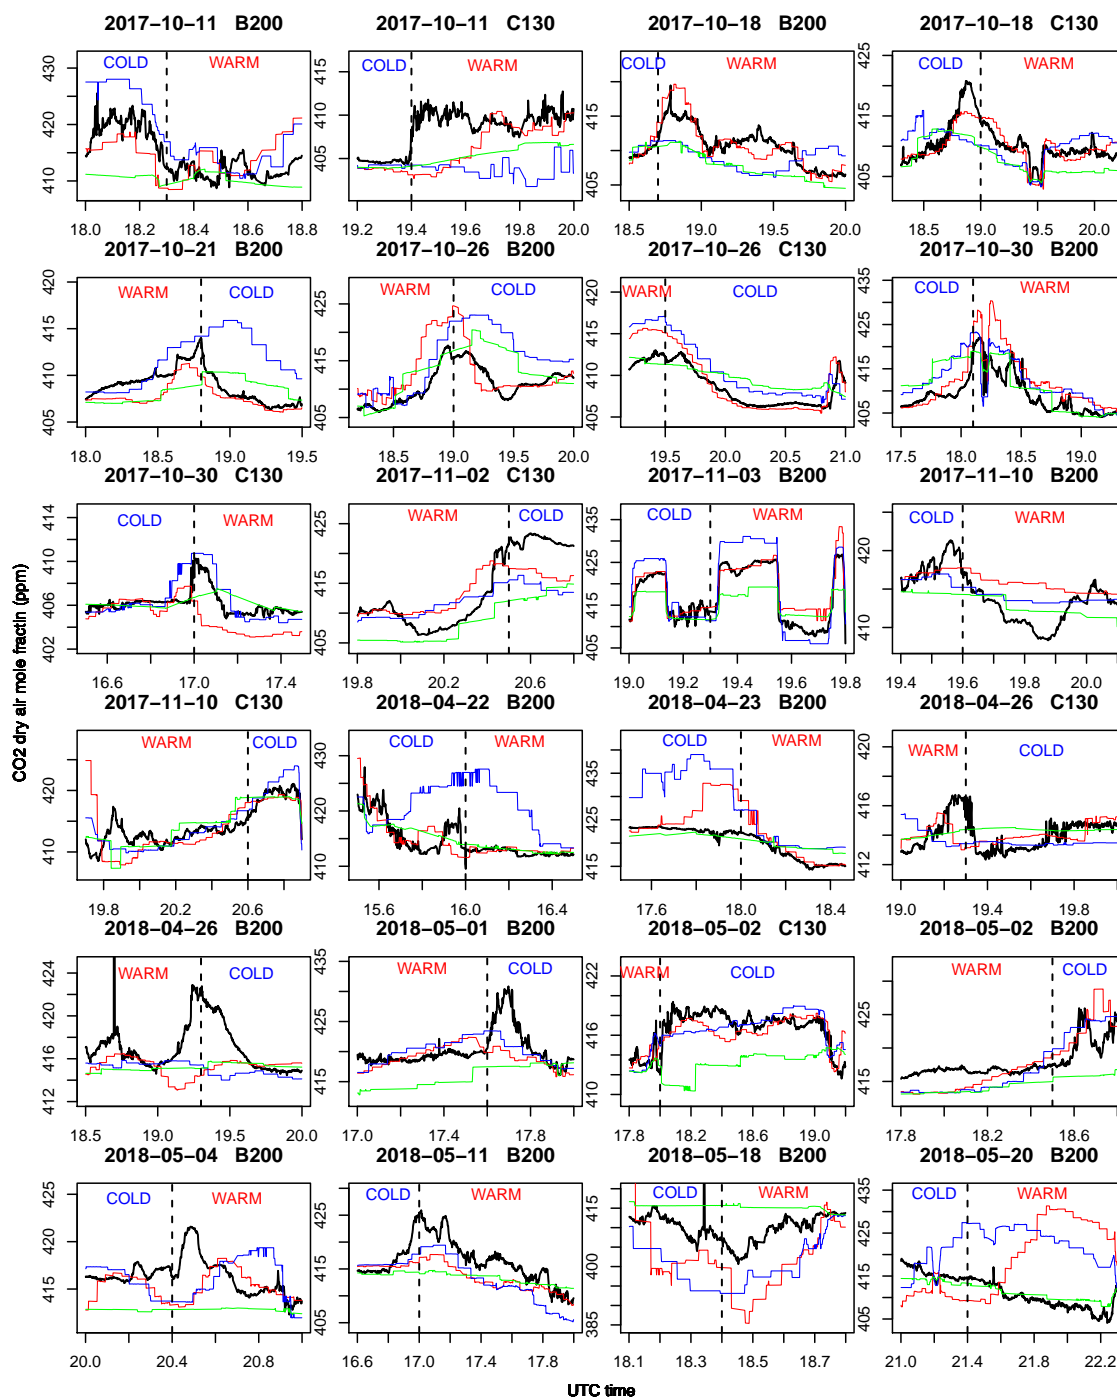

Figure 9. Continued from Fig. 9

Figure 10. Comparison of RMSEs of model simulated CO₂ at front-crossing horizontal flight legs (Figs. 9 and 9). Each open circle represent a horizontal flight leg, and its color represent the ACT campaign seasons. Comparison of RMSE between MPAS and CT2019 is in the left figure, and comparison between MPAS and WRF-Chem the right figure.

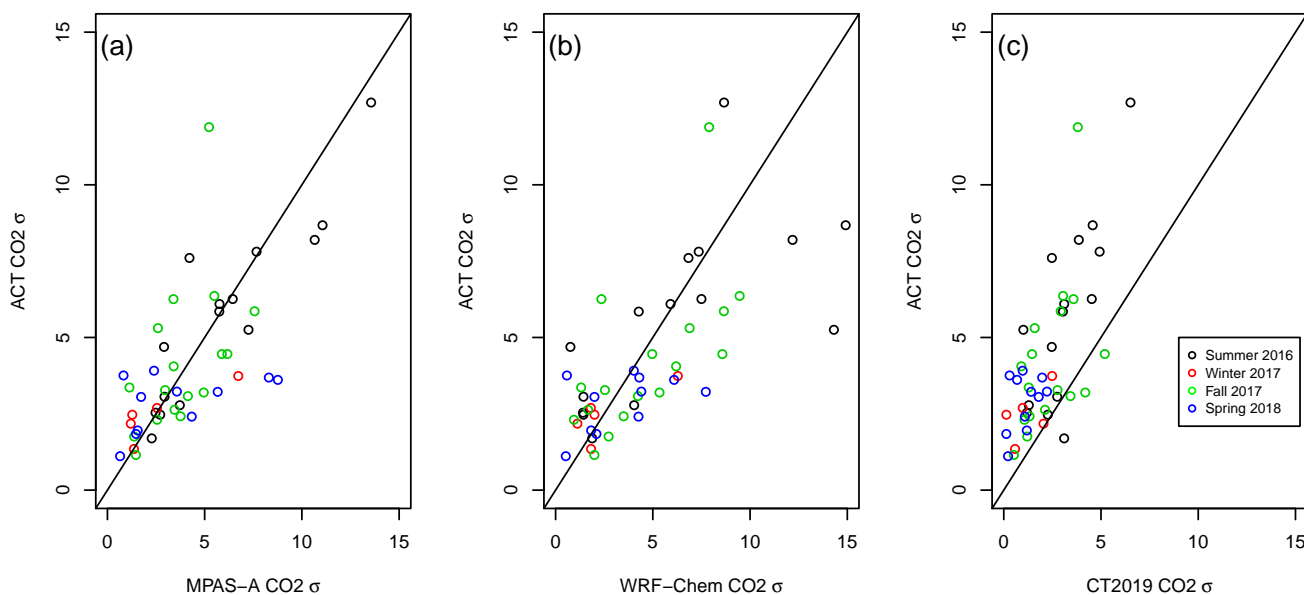

Figure 11. Comparisons of CO₂ mole fraction standard deviation (σ , unit in ppm) between aircraft measurement and model simulations: MPAS (a), WRF-Chem (b), and CT2019 (c). In each figure, the X-axis is σ of CO₂ mixing ratio from aircraft measurements, the Y-axis from a model. Each circle represent front-crossing horizontal flight leg in Figs. 9 and 9 and its color represent the ACT campaign season.

January 2014

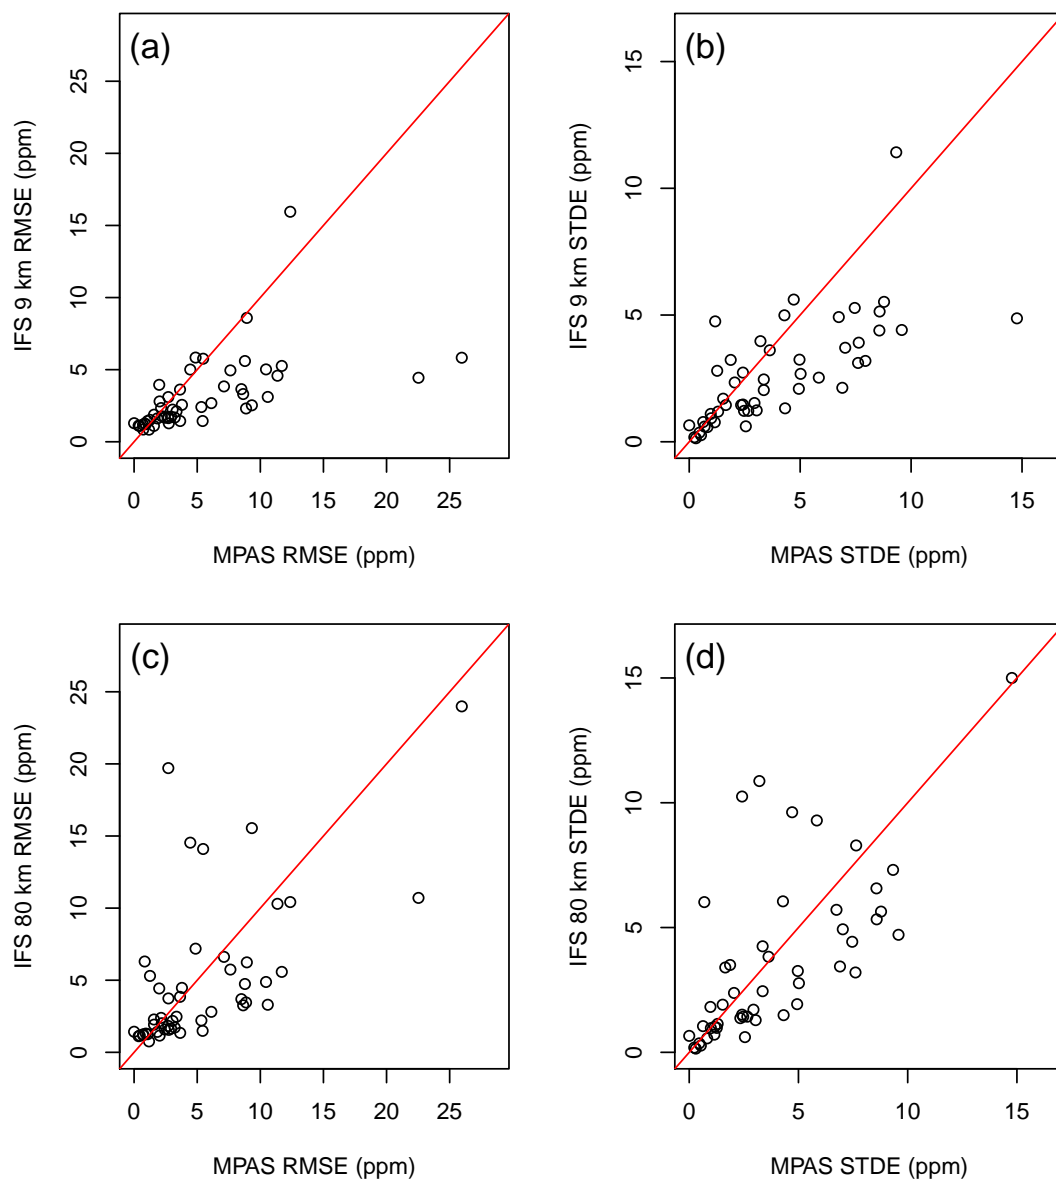

Figure 12. Comparison of model simulated hourly CO₂ accuracy (RMSE and STDE) between MPAS and IFS at 50 surface and tower stations. Each open circle in the figures represent a station. Comparison of MPAS with the IFS 9 km resolution simulations are in the top panel (a and b), and comparison with IFS 80 km resolutions simulations are in the top panel (c and d).

July 2014

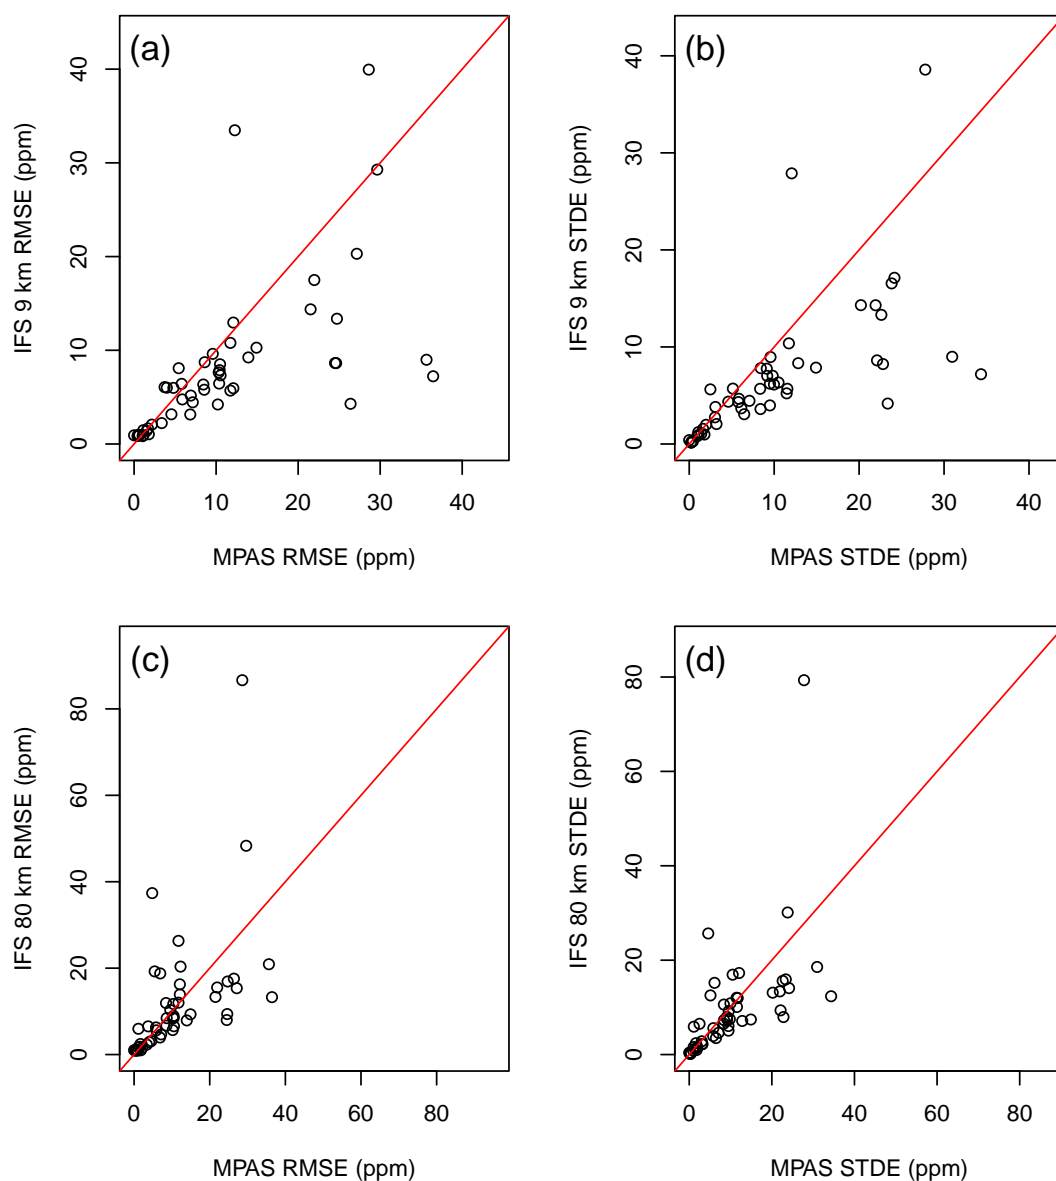

Figure 13. Same as Fig. 12, but for the month of July 2014

Table 1. MPAS CO₂ transport model simulation physical parameterizations summary.

| Parameterization | Option Used | References |
|--------------------|---------------------------|------------------------|
| Longwave | RRTMG LW | Iacono et al. (2008) |
| Shortwave | RRTMG SW | Iacono et al. (2008) |
| PBL | YSU | Hong et al. (2006) |
| Surface layer | Monin-Obukhov | |
| Land Surface Model | Noah | Chen and Dudhia (2001) |
| Cumulus | Kain-Fritsch | Kain (2004) |
| Microphysics | WRF Single Moment 6-class | Hong and Lim (2006) |

Table 2. The duration of four ACT aircraft campaign seasons and their corresponding MPAS simulations

| | MPAS CO ₂ simulation | | ACT campaign season | |
|-------------|---------------------------------|--------|---------------------|--------|
| | Start | End | Start | End |
| Summer 2016 | Jul 15 | Aug 31 | Jul 18 | Aug 28 |
| Winter 2017 | Jan 29 | Mar 12 | Feb 01 | Mar 10 |
| Fall 2017 | Oct 01 | Nov 15 | Oct 03 | Nov 13 |
| Spring 2018 | Apr 10 | May 23 | Apr 12 | May 20 |

Table 3. Evaluation of MPAS simulated horizontal wind using NOAA IGRA radiosonde data. Radiosonde data from 457 stations over the globe are used for the evaluation. Wind speed and direction are compared at 00:00 UTC and 12:00 UTC at four pressure levels (1000, 850, 500, and 200 hPa) for each day of the MPAS simulation. The number of data samples (N) are smaller at 1000 hPa because some stations are located above that pressure level.

| | Pressure level | Mean RMSE vector wind (m/s) | RMSE Wind speed(m/s) | Bias Wind speed(m/s) | Mean difference Wind direction ° | N |
|-----------------|----------------|--------------------------------|-------------------------|-------------------------|-------------------------------------|----------|
| January 2014 | 1000 hPa | 3.83 | 2.92 | 0.89 | 31.00 | 8,856 |
| | 850 hPa | 4.04 | 2.96 | -0.45 | 23.08 | 22,369 |
| | 500 hPa | 3.72 | 2.66 | -0.50 | 12.98 | 23,222 |
| | 200 hPa | 4.38 | 3.07 | -0.58 | 8.36 | 22,795 |
| July 2014 | 1000 hPa | 3.47 | 2.50 | 0.27 | 32.94 | 7504.00 |
| | 850 hPa | 3.56 | 2.55 | -0.51 | 27.12 | 22832.00 |
| | 500 hPa | 3.39 | 2.39 | -0.59 | 17.89 | 23745.00 |
| | 200 hPa | 4.19 | 2.99 | -0.55 | 12.19 | 23455.00 |

Table 4. Comparison of mean and standard deviation (in parenthesis) of CO₂ mole fraction (ppm) in the boundary layer between the warm and the cold sectors. The statistics for ACT aircraft measurements are in the first column, MPAS the second column, WRF-Chem the third column, and CT2019 the last column.

| | ACT | | MPAS | | WRF-Chem | | CT2019 | |
