1 **Abstract.**

2 The global Flow-following finite-volume Icosahedral Model (FIM), which was developed in the Global  
3 Systems Laboratory of NOAA/ESRL, has been coupled inline with aerosol and gas-phase chemistry schemes  
4 of different complexity using the chemistry and aerosol packages from WRF-Chem v3.7, named as FIM-  
5 Chem v1. The three chemistry schemes include 1) the simple aerosol modules from the Goddard Chemistry  
6 Aerosol Radiation and Transport model that includes only simplified sulfur chemistry, bulk aerosols, and  
7 sectional dust and sea salt modules (GOCART); 2) the photochemical gas-phase mechanism RACM coupled  
8 to GOCART to determine the impact of more realistic gas-phase chemistry on the GOCART aerosols  
9 simulations (RACM\_GOCART); and 3) a further sophistication within the aerosol modules by replacing  
10 GOCART with a modal aerosol scheme that includes secondary organic aerosols (SOA) based on the VBS  
11 approach (RACM\_SOA\_VBS). FIM-Chem is able to simulate aerosol, gas-phase chemical species and SOA  
12 at various spatial resolutions with different levels of complexity and quantify the impact of aerosol on  
13 numerical weather predictions (NWP). We compare the results of RACM\_GOCART and GOCART schemes  
14 which uses the default climatological model fields for OH, H<sub>2</sub>O<sub>2</sub>, and NO<sub>3</sub>. We find significant reductions of  
15 sulfate that are on the order of 40% to 80% over the eastern US and are up to 40% near the Beijing region  
16 over China when using the RACM\_GOCART scheme. We also evaluate the model performance by  
17 comparing with the Atmospheric Tomography Mission (ATom-1) aircraft measurements in 2016 summer.  
18 FIM-Chem shows good performance in capturing the aerosol and gas-phase tracers. The model predicted  
19 vertical profiles of biomass burning plumes and dust plumes off the western Africa are also reproduced  
20 reasonably well.

21

## 1 **1 Introduction**

2 The impacts of aerosol on weather and climate are generally attributed to the direct, semidirect, indirect, and  
3 surface albedo effects, with the direct effect predominating radiative forcing over a global scale [e.g. *Bauer*  
4 *and Menon*, 2012]. However, there are significant differences in estimates of direct aerosol radiative forcing  
5 between various global aerosol models, particularly with respect to the attribution of forcing to specific  
6 aerosol species and sources [*Myhre et al.*, 2013]. Discrepancies in direct radiative forcing are also found  
7 between global aerosol model results and determinations based on satellite retrievals, with assumptions  
8 related to aerosol composition and optical properties as the primary source of difference [e.g. *Su et al.*, 2013].  
9 Several processes and steps are necessary to accurately include aerosol effects within a meteorological  
10 forecast. Aerosol abundance, composition, and size distribution are the basic quantities needed within  
11 calculations of the optical properties, which in turn are used within radiative transfer calculations to calculate  
12 heating or cooling rates and are incorporated within the thermodynamic calculations of the numerical forecast.  
13 The importance of aerosol impacts on the meteorological fields for climate modeling have been widely  
14 recognized by many studies [e.g. *Xie et al.*, 2013; *Yang et al.*, 2014; *Wang et al.*, 2014a, 2014b; *Colarco et*  
15 *al.*, 2014]. Since it is increasingly common for modeling systems to start using prognostic online aerosol  
16 schemes and more accurate emissions, many studies exist that show the importance of including aerosols at  
17 least for case studies or over limited time periods. On NWP timescales (5–10 days), *Rodwell and Jung* [2008]  
18 showed an improvement in forecast skill and general circulation patterns in the tropics and extra-tropics by  
19 using a monthly varying aerosol climatology rather than a fixed climatology in the European Centre for  
20 Medium-Range Weather Forecasting (ECMWF) global forecasting system. The inclusion of the direct and  
21 indirect effects of aerosol complexity into a version of the global NWP configuration of the Met Office  
22 Unified Model (Met UM) shows that the prognostic aerosol schemes are better able to predict the temporal  
23 and spatial variations of atmospheric aerosol optical depth, which is particularly important in cases of large  
24 sporadic aerosol events such as large dust storms or forest fires [*Mulcahy et al.*, 2014]. The aerosols from  
25 biomass burning sources have been shown to have an effect on large-scale weather patterns within global  
26 scale models [e.g. *Sakaeda*, 2011] and synoptic scale meteorology within the WRF-Chem regional model  
27 [*Grell et al.*, 2011]. *Toll et al.* [2015] showed considerable improvement in forecasts of near-surface  
28 conditions during Russian wildfires in summer 2010 by including the direct radiative effect of realistic  
29 aerosol distributions. Likewise, many global models [e.g. *Haustein et al.*, 2012] and regional models [e.g.  
30 WRF-Chem, *Zhao et al.*, 2010] have established a clear connection between dust emissions and weather  
31 patterns over synoptic to seasonal time scales. While positive impacts of predicted aerosols on weather  
32 forecasts have been shown on an episodic basis, a systematic verification of current state-of-the-art  
33 operational modeling systems does not yet demonstrate that the impact is statistically significant over longer  
34 periods of time to warrant the required additional computational resources [*Peuch et al.*, 2014]. Operational  
35 forecast systems are usually highly tuned and still use aerosol climatologies. The inclusion of aerosols in the  
36 presence of strong sources or sinks should lead to an improvement of predictive skills. A successful example  
37 of a short-range weather forecasting coupled with the smoke tracer is the High-Resolution Rapid Refresh

1 coupled with Smoke (HRRR-Smoke) model [Ahmadov et al, 2017]. The model forecasts 3D smoke  
2 concentrations and its radiative impacts over the CONUS domain at 3km spatial gridding  
3 [<https://rapidrefresh.noaa.gov/hrrr/HRRRsmoke/>].

4 By applying the chemistry package from WRF-Chem v3.7 into the Flow-following finite-volume Icosahedra  
5 Model (FIM, Bleck et al. 2015), named as FIM-Chem v1, we essentially make it possible to explore the  
6 importance of different levels of complexity in gas and aerosol chemistry, as well as in physics  
7 parameterizations on the interaction processes in global modeling systems. FIM is used in the sub-seasonal  
8 experiment (SUBx) for sub-seasonal to seasonal (S2S) forecasting and is now considered a steppingstone  
9 towards NOAA's Next Generation Global Prediction System, which will be based on the third generation  
10 non-hydrostatic Finite Volume Cubed Sphere (FV3) dynamic core [Sun et al., 2018a, b]. The chemistry  
11 component created here is designed to be moved flawlessly into FV3. WRF-Chem currently has 63 different  
12 gas and aerosol chemistry options, as well as several microphysics and radiation parameterizations, which  
13 are coupled to chemistry to simulate direct and indirect aerosol feedback processes. In this study we  
14 demonstrate three examples of different complexities on the aerosol forecasts by FIM-Chem. The current  
15 real-time forecast uses simple bulk aerosol modules from the GOCART model, with a simplified chemistry  
16 for sulfate production. This chemistry scheme does not include NO<sub>x</sub>/VOC gas chemistry or SOA formation.  
17 Currently the real-time GOCART application uses climatological fields of OH, H<sub>2</sub>O<sub>2</sub> and NO<sub>3</sub> to drive the  
18 oxidation of SO<sub>2</sub> and oceanic dimethyl sulfide to sulfate.

19 Here we also investigate the sensitivity to the addition of complex gas-phase chemistry and a more reasonable  
20 inclusion of Secondary Organic Aerosol formation. Organic matter makes up the significant fraction of the  
21 sub-micron aerosol composition [Zhang et al., 2007], and organic aerosol (OA) along with sulfate and black  
22 carbon are believed to be the main anthropogenic contributors to direct radiative forcing on a global scale  
23 [Myhre et al., 2013]. A computationally efficient SOA parameterization based on the Volatility Basis Set  
24 approach [Donahue, 2011] was implemented in WRF-Chem by Ahmadov et al. (2012).

25 To evaluate the model performance, the observation data from the NASA Atmospheric Tomography aircraft  
26 mission (ATom-1, 2016) is used, in which the DC-8 is instrumented to make high-frequency in situ  
27 measurements of the most the chemical species over the Pacific and Atlantic Oceans, and across the Arctic  
28 and US, to evaluate the model performance. Section 2 describes some aspects of the FIM and FIM-Chem  
29 model, the coupling of aerosol configurations, gas-phase chemical schemes and an overview of the  
30 observation data used to evaluate the model results. The chemical weather forecasts by using three different  
31 gas and aerosol chemistry schemes with different level of complexities are shown in Section 3. Section 4  
32 presents the evaluations of the chemical weather forecasts, and the model evaluations are investigated in  
33 Section 5. We end with discussion and conclusions in Section 6.

## 34 2 Models and Observation

### 35 2.1 FIM

1 FIM is a hydrostatic global weather prediction model based on an icosahedral horizontal grid and a hybrid  
2 terrain following/isentropic vertical coordinate [Bleck et al., 2015]. Icosahedral grids are generated by  
3 projecting an icosahedron onto its enclosing sphere and iteratively subdividing the 20 resulting spherical  
4 triangles until a desired spatial resolution is reached. The main attraction of geodesic grids lies in their fairly  
5 uniform spatial resolution and in the absence of the two pole singularities found in spherical coordinates. The  
6 primary purpose of using a near-isentropic vertical coordinate in a circulation model is to assure that  
7 momentum and mass field constituents (potential temperature, moisture, chemical compounds, etc.) are  
8 dispersed in the model in a manner emulating reality, namely, along neutrally buoyant surfaces. The FIM  
9 model has been tested extensively on real-time medium-range forecasts to ready it for possible inclusion in  
10 operational multi-model ensembles for medium-range to seasonal prediction, and the following simulations  
11 are performed at G6 (~128 km) horizontal resolution.

12 In FIM-Chem, the column physics parameterizations have been taken directly from the 2011 version of the  
13 GFS [Bleck et al., 2015]. The physical parameterizations include the Grell-Freitas convection  
14 parameterization [Grell and Freitas, 2014], the Lin et al. [1983] cloud microphysics scheme, coupled to the  
15 model aerosol parameterization and modified to include second moment effects, and the land surface  
16 processes simulated by the NCEP's Noah land surface model [Koren et al. 1999 and Ek et al. 2003].

## 17 **2.2 FIM-Chem**

18 FIM-Chem, is a version of the FIM model coupled inline with chemical transport model including three  
19 aerosol and gas-phase chemistry schemes of different complexities, where physics and chemistry components  
20 of the model are simulated simultaneously. The chemical modules and coupling schemes are adopted from  
21 the WRF-Chem model v3.6.1 [Grell et al. 2005; Fast et al. 2006; Powers et al., 2017].

### 22 **2.2.1 GOCART scheme**

23 The first chemical option is the simplest aerosol modules that from the GOCART model, which includes  
24 simplified sulfur chemistry for sulfate simulation from chemical reactions of SO<sub>2</sub>, H<sub>2</sub>O<sub>2</sub>, OH, NO<sub>3</sub> and DMS,  
25 bulk aerosols of black carbon (BC), organic carbon (OC), and sectional dust and sea salt. For OC and BC,  
26 hydrophobic and hydrophilic components are considered and the chemical reactions using prescribed OH,  
27 H<sub>2</sub>O<sub>2</sub>, and NO<sub>3</sub> fields for gaseous sulfur oxidations [Chin et al., 2000]. The dust scheme is using the Air  
28 Force Weather Agency (AFWA) scheme with five dust size bins [LeGrand et al., 2019]. The bulk vertical  
29 dust flux is based on the Marticorena and Bergametti scheme [Marticorena et al., 1995], whereas the particle  
30 size distribution is built according to Kok, 2011, which is based on the brittle material fragmentation theory.  
31 Four size bins are considered for the sea salt simulation. The sea salt emissions from the ocean are highly  
32 dependent on the surface wind speed [Chin et al., 2000].

### 33 **2.2.2 RACM\_ GOCART scheme**

1 Based on the GOCART aerosol module, the second chemical option includes the photochemical gas-phase  
2 mechanism of Regional Atmospheric Chemistry Mechanism (RACM), which is able to determine the impact  
3 of the additional gas-phase complexity on the aerosol simulations (RACM\_GOCART). The RACM  
4 chemistry mechanism is based upon the earlier Regional Acid Deposition Model, version 2 (RADM2)  
5 mechanism [Stockwell et al., 1990] and the more detailed Euro-RADM mechanism [Stockwell and Kley,  
6 1994]. It includes a full range of photolysis, biogenic VOCs, full NO<sub>x</sub>/VOC chemistry, inorganic and organic  
7 gaseous species to perform air pollution studies that includes rate constants and product yields from the most  
8 laboratory measurements [Stockwell et al., 1997]. The simplified sulfur chemistry for sulfate formation does  
9 not use climatological fields of OH, H<sub>2</sub>O<sub>2</sub> and NO<sub>3</sub> from GOCART model to drive the oxidation of SO<sub>2</sub> as  
10 that in GOCART, and it is replaced by explicitly simulating the gas-phase RACM chemistry.

### 11 **2.2.3 RACM\_SOA\_VBS scheme**

12 The simple GOCART scheme does not include photolysis, full gas chemistry and secondary organic aerosol  
13 production, and it normally uses climatological fields of OH, H<sub>2</sub>O<sub>2</sub> and NO<sub>3</sub> to drive the oxidation of  
14 SO<sub>2</sub> and oceanic dimethyl sulfide (DMS) to produce sulfate. We implemented a more complex gas-aerosol  
15 chemistry scheme in FIM-Chem. This scheme includes RACM based gas chemistry and updated SOA  
16 scheme, which is based on the VBS approach [Ahmadov et al., 2012]. The RACM\_SOA\_VBS scheme  
17 includes photolysis reactions for multiple species, full nitrogen and VOC (anthropogenic and biogenic)  
18 chemistry, inorganic and organic aerosols. All the secondary gas species that are required for the SO<sub>2</sub>  
19 oxidation are simulated explicitly by the gas chemistry scheme here.

### 20 **2.3.4 Emission, deposition, and aerosol optical properties**

21 The preprocessor PREP-CHEM-SRC v1.5 [Freitas et al., 2011], a comprehensive tool aiming at preparing  
22 emission fields of the chemical species for use in atmospheric-chemistry transport models, is used to generate  
23 the emissions for FIM-Chem. It includes the HTAP v2 global anthropogenic emission inventory [Janssens-  
24 Maenhout et al., 2015] and biogenic VOC emissions simulated by the of Emissions of Gases and Aerosols  
25 from Nature (MEGAN) v2.0 parameterization [Guenther et al., 2006]. The diurnal variability based on a  
26 function of anthropogenic activities is applied to the HTAP emissions and the diurnal cycle of solar radiation  
27 and air temperature is applied to the biogenic emissions. The biomass burning emission estimated by the  
28 Brazilian Biomass Burning Emissions Model [3BEM, Longo et al. 2010; Grell et al., 2011] is also included  
29 in the PREP-CHEM-SRC. The 3BEM is based on near real-time remote sensing fire products to determine  
30 fire emissions and plume rise characteristics [Freitas et al., 2005, 2007; Longo et al., 2010]. The fire emissions  
31 are updated as they become available and are spatially and temporally distributed according to the fire count  
32 locations obtained by remote sensing of Moderate Resolution Imaging Spectroradiometer (MODIS) onboard  
33 Terra and Aqua satellites [Giglio et al., 2003]. The biomass burning emission factors are from Andreae and  
34 Merlot [2001]. Over the CONUS domain the MODIS data are replaced by the Wildfire Automated Biomass  
35 Algorithm (WF\_ABBA) processing system. The WF\_ABBA is able to detect and characterize fires in near

1 real-time, providing users with high temporal and spatial resolution fire detection data  
2 (<http://www.ssd.noaa.gov/PS/FIRE/Layers/ABBA/abba.html>). A one-dimension (1-D) time-dependent  
3 cloud model implemented to calculate injection heights and emission rates online in all of the three chemical  
4 schemes [Freitas et al., 2007].

5 Similar to WRF-Chem model, the flux of gases and aerosols from the atmosphere to the surface is calculated  
6 by multiplying concentrations of the chemical species in the lowest model layer by the spatially and  
7 temporally varying deposition velocities, the inverse of which is proportional to the sum of three  
8 characteristic resistances (aerodynamic resistance, sublayer resistance, surface resistance [Grell et al. 2005].  
9 The GOCART aerosol dry deposition includes sedimentation (gravitational settling) as a function of particle  
10 size and air viscosity and surface deposition as a function of surface type and meteorological conditions  
11 [Wesely, 1989]. The dry deposition of sulfate is described differently. In the case of simulations without  
12 calculating aerosols explicitly, sulfate is assumed to be presented in the form of aerosol particles, and the dry  
13 deposition of aerosol and gas phase species is parameterized as described in Erisman et al. [1994]. For  
14 RACM\_SOA\_VBS chemical option, the dry deposition velocity of the organic condensable vapors (OCVs)  
15 is parameterized as proportional to the model calculated deposition velocity of a very soluble gas, nitric acid  
16 ( $\text{HNO}_3$ ). The parameter which determines the fraction (denoted as “depo\_fact”) of  $\text{HNO}_3$  is assumed in the  
17 model since no observation constraints are available. The dry deposition velocity of  $\text{HNO}_3$  is calculated by  
18 the model during runtime [Ahmadov et al., 2012]. Wet deposition accounts for the scavenging of aerosols in  
19 convective updrafts and rainout/washout in large-scale precipitation [Giorgi and Chameides, 1986; Balkanski  
20 et al., 1993].

21 The aerosol optical properties such as extinction, single-scattering albedo, and the asymmetry factor for  
22 scattering are computed as a function of wavelength. Each chemical constituent of the aerosol is associated  
23 with a complex index of refraction. A detailed description of the computation of aerosol optical properties  
24 can be found in Fast et al. [2006] and Barnard et al. [2010].

### 25 **2.3 Observations**

26 The Atmospheric Tomography Mission (ATom) studies the impact of human-produced air pollution on  
27 greenhouse gases and on chemically reactive gases in the atmosphere [Wofsy et al., 2018]. ATom deploys  
28 instrumentation to sample the atmospheric composition, profiling the atmosphere in 0.2 to 12 km altitude  
29 range. Flights took place in each of 4 seasons over a 22-month period. They originated from the Armstrong  
30 Flight Research Center in Palmdale, California, flew north to the western Arctic, south to the South Pacific,  
31 east to the Atlantic, north to Greenland, and returned to California across central North America over the  
32 Pacific and Atlantic oceans from  $\sim 80^\circ\text{N}$  to  $\sim 65^\circ\text{S}$ . ATom establishes a single, contiguous global-scale data  
33 set. This comprehensive data set is used to improve the representation of chemically reactive gases and short-  
34 lived climate forcers in global models of atmospheric chemistry and climate. Comparisons of model forecasts  
35 with 5 flights from the first ATom mission (August 15–23, 2016) are shown here as examples of model

1 performance for specific events, such as wildfires and dust-storms, or specific conditions such as oceanic  
2 versus continental.

3 The Particle Analysis by Laser Mass Spectrometry (PALMS) instrument samples the composition of single  
4 particles in the atmosphere with diameters within  $\sim 150$  nm -  $5 \mu\text{m}$  range. It measures nearly all components  
5 of aerosols from volatiles to refractory elements, including sulfates, nitrates, carbonaceous material, sea salt,  
6 and mineral dust [Murphy et al., 2006]. The PALMS instrument was originally constructed for high-altitude  
7 sampling [Thomson et al., 2000; Murphy et al., 2014] and has since been improved and converted for other  
8 research aircraft. In August 2016, PALMS was sampling on the NASA DC-8 aircraft as part of the ATom  
9 program (<https://espo.nasa.gov/missions/atom/content/ATom>). Aerosol composition determinations using  
10 the PALMS instrument during ATom have been described and interpreted previously [Murphy et al., 2018,  
11 2019; Schill et al., 2020; Bourgeois et al., 2020]. The PALMS mass concentrations for various species are  
12 derived by normalizing the fractions of particles of each size and type to size distributions measured by  
13 optical particle counters [Froyd et al., 2019].

14 Figure 1 shows the vertical profiles and transect time series of the ATom-1 flight tracks on August 15<sup>th</sup> and  
15 17<sup>th</sup>, 2016 over Atlantic Ocean on August 23<sup>rd</sup>, 2006 over US. The August 15<sup>th</sup> flight originates from the  
16 southwestern Atlantic and ends near the southern equatorial Atlantic; the August 17<sup>th</sup> flight is from the  
17 southern equatorial Atlantic to the northern Atlantic; and the August 23<sup>rd</sup> flight is from Minnesota to Southern  
18 California. For analysis and model validations, here we mark 16 vertical tracks and 3 horizontal tracks for  
19 August 15<sup>th</sup>, 16 vertical tracks and 2 horizontal tracks for August 17<sup>th</sup>, and 8 vertical tracks and 4 horizontal  
20 tracks for August 23<sup>rd</sup>.

### 21 3 Chemical Composition Forecast

22 There is a two-week spin-up period from July 15<sup>th</sup> to July 28<sup>th</sup>, since we don't use chemical initial conditions  
23 at the start of the simulation time period. To provide realistic chemical initial conditions, the near real-time  
24 chemical composition daily forecast has been performed from 00Z July 15<sup>th</sup>, 2016 initialized by the GFS  
25 meteorological fields every 24 hours. Chemical species are cycled every 24 hours from the last output except  
26 the stratospheric  $\text{O}_3$  above tropopause which are from satellite derived fields available within GFS.  $\text{O}_3$  It  
27 should be noted that stratospheric chemistry is incomplete (no halogen chemistry) in the model, and the  
28 model doesn't include any chemical data assimilation.

29 For the aerosol forecast, the GOCART and RACM\_GOCART scheme are quite similar since they are using  
30 the same GOCART aerosol module. However, the major difference is the impact of including gas-phase  
31 chemistry on aerosol. The simpler GOCART package uses climatological fields for OH,  $\text{H}_2\text{O}_2$ , and  $\text{NO}_3$  from  
32 previous GEOS model simulations, while these species are explicitly simulated in the RACM\_GOCART  
33 chemistry mechanism. The  $\text{PM}_{2.5}$  concentrations are the sum of BC, OC, sulfate, the fine bins (diameter <  
34  $2.5$  micrometers) of dust and sea salt. The forecast aerosol results of  $\text{PM}_{2.5}$  and sulfate using GOGART and  
35 RACM\_GOCART and their differences (RACM\_GOCART minus GOCART) are showed at Fig. 2. The  
36 general patterns of  $\text{PM}_{2.5}$  are quite similar in these two schemes, with the maximum surface concentrations

1 of more than 100  $\mu\text{g}$  over the dust source region of western Africa, wide areas of southern Africa and polluted  
2 areas of south Asia and eastern China. However, the surface concentrations of  $\text{PM}_{2.5}$  in GOCART and  
3 RACM\_GOCART (the latter minus former) show substantial differences, decreasing more than 15  $\mu\text{g}/\text{m}^3$   
4 over eastern US and 20  $\mu\text{g}/\text{m}^3$  over eastern China, when using the RACM\_GOCART scheme. The main  
5 factor that contributes to the significant differences of  $\text{PM}_{2.5}$  concentration is sulfate (figures not shown here).  
6 The maximum sulfate concentrations are over the eastern US, India and eastern China. We find the reductions  
7 of sulfate are about 10  $\mu\text{g}/\text{m}^3$  on the order of 40-80% over the eastern US and are up to 40% over eastern  
8 China in RACM\_GOCART (Fig. 2b). The major differences for sulfate production in the simulations is due  
9 to differences in the  $\text{H}_2\text{O}_2$ , OH, and  $\text{NO}_3$  fields. Fig. 3 shows the comparisons of  $\text{H}_2\text{O}_2$ , OH, and  $\text{NO}_3$  between  
10 GOCART and RACM\_GOCART schemes. Globally the prescribed  $\text{H}_2\text{O}_2$  in GOCART is generally larger  
11 than that explicitly simulated by RACM\_GOCART. The maximum of  $\text{H}_2\text{O}_2$  regions over Africa, India and  
12 eastern Asia show significant diversity. The explicitly real-simulated instantaneous  $\text{H}_2\text{O}_2$  in RACM\_  
13 GOCART is much lower, by 40-60% over India and eastern Asia and 20% over eastern US, while much  
14 higher (> 80%) over middle Africa, northeastern regions of Canada, and northwestern areas of South America.  
15 Even though the patterns of OH are quite comparable in the GOCART and RACM\_GOCART schemes, the  
16 real-simulated instantaneous OH is 80% lower over eastern China when using the RACM\_GOCART scheme.  
17 The other big difference is over the western US with the simulated OH in RACM\_GOCART being much  
18 higher over northwestern US and lower over the southwestern US. The  $\text{NO}_3$  differences are mainly over the  
19 Africa and north Indian Ocean, that the real-simulated instantaneous  $\text{NO}_3$  is much larger using the  
20 RACM\_GOCART scheme. Since  $\text{H}_2\text{O}_2$  and OH are the major species converting  $\text{SO}_2$  to sulfate, their  
21 decreases cause sulfate reductions over broad areas.

22 The RACM\_GOCART model is able to predict gas phase species by using the RACM gas-phase mechanism.  
23 Ozone ( $\text{O}_3$ ) and other gas pollutants are determined by the emissions of nitrogen oxides and reactive organic  
24 species, gas- and aqueous-phase chemical reaction rates, depositions, and meteorological conditions. Fig. 4  
25 represents the 120-hour surface  $\text{O}_3$  forecast globally at 12z August 2nd and 00z August 3rd, 2016. The general  
26 spatial distributions are comparable to the satellite observation. However, similar to other studies, a lot of  
27 chemical transport models (CTMs) tend to significantly overestimate surface  $\text{O}_3$  in the southeast US [Lin et  
28 al., 2008; Fiore et al., 2009; Reidmiller et al., 2009; Brown-Steiner et al., 2015; Canty et al., 2015; Travis et  
29 al., 2016], which is an important issue for the design of pollution control strategies [McDonald-Buller et al.,  
30 2011]. We see similar problem in FIM-Chem that the predicted surface  $\text{O}_3$  concentration on 00z August 3rd  
31 2016 is also overestimated (see Fig. 4b). It well known that the  $\text{O}_3$  production involves complex chemistry  
32 driven by emissions of anthropogenic nitrogen oxide radicals ( $\text{NO}_x=\text{NO}+\text{NO}_2$ ) and isoprene from biogenic  
33 emissions. The primary basis of  $\text{O}_3$  may be due to the inventory of HTAP v2 anthropogenic emission over  
34 North America, which is from U.S. EPA's 2005 National Emission Inventory (NEI2005). A few studies have  
35 pointed out that the  $\text{NO}_x$  emissions in the NEI-2005 and NEI-2011 from the EPA is too high [Brioude, 2011;  
36 Travis et al., 2016] over the US. It must be reduced by 30-60% from mobile and industrial sources in the NEI  
37 2011 inventory [Katherine et al., 2016], while the  $\text{NO}_x$  emissions over United States should be reduced more

1 for 2016 simulation since the NEI2005 NO<sub>x</sub> emission is much larger than that of NEI2011  
2 (<https://cfpub.epa.gov/roe/>). Also, the dry depositions of ozone, isoprene emissions and in the loss of NO<sub>x</sub>  
3 from formation of isoprene nitrates could also result into these overestimations [Lin et al., 2008; Fiore et al.,  
4 2005].

5 A new SOA parameterization based on the volatility basis and VBS approach has been implemented into  
6 FIM-Chem. Thus, it has the ability to simulate and predict SOA using the RACM\_SOA\_VBS scheme  
7 [Ahmadov et al., 2012], which include the anthropogenic secondary organic aerosols (ASOA) and biogenic  
8 secondary organic aerosols (BSAO) for both the nucleation and accumulation modes. Fig. 5 shows the  
9 predicted SOA at 12z August 2nd and 00z August 3<sup>rd</sup>, 2016. The maximum surface SOA concentrations are  
10 over the southern Africa, which may be caused by the wildfire emissions. The Eastern US, western Europe  
11 and eastern Asia are the other high SOA concentrations areas. There is not significant diurnal variability for  
12 the SOA spatial distributions, and the diurnal cycle of fire emission has not been included.

#### 13 **4 Using ATom-1 observations to evaluate the FIM-Chem Model**

14 In this section, we compare 24 hours forecasts of FIM-Chem for the major aerosols and gas tracers for the  
15 three different chemical schemes listed above. The FIM-Chem model results are sampled at the grid with  
16 nearest latitude and longitude, and interpolated logarithmically in altitude according to the ATom-1  
17 measurements. Temporally, 1-second measurements are matched to the nearest hour of the FIM-Chem hourly  
18 model output, which translates into a spatial uncertainty of ~ 128 km, or ~1 model grid cell, for typical DC-  
19 8 airspeeds.

#### 20 **4.1 Comparisons of the gas and aerosols species between FIM-Chem and the ATom-1 measurements** 21 **over Atlantic**

22 The comparison of some of the chemical species, e.g., EC, CO and O<sub>3</sub>, that are mainly affected by the biomass  
23 burning emissions from wild fires during August 15<sup>th</sup> and August 17<sup>th</sup> are shown in Fig. 6. The model shows  
24 very good performance in reproducing the profiles of EC and CO, especially capturing the biomass burning  
25 plumes near the tropics. But it also shows some differences for EC in the results of GOCART (figures not  
26 shown here since it is almost the same as that of RACM\_GOCART) and RACM\_GOCART schemes above  
27 4–5 km, where model results are overestimated. After investigating, we noticed that in the GOCART and  
28 RACM\_GOCART aerosol module, they both assume there is no wet deposition for externally-mixed,  
29 hydrophobic BC, only for hydrophilic BC. This assumption would result into the overestimation of EC at  
30 higher levels due to less wash out of hydrophobic BC. Other models with simple wet removal schemes have  
31 shown similar overestimation of EC in the upper troposphere (Schwarz et al., 2013; Yu et al., 2019). However,  
32 aerosols in the RACM\_SOA\_VBS scheme are internally mixed, so there is a much larger wet deposition,  
33 and less EC in the upper levels. This an important difference about the carbonaceous aerosol for both  
34 hydrophobic BC and OC in the wet removal. The comparison with the observations provides a good resource

1 for further improvements within the wet removal parameterization. The second column in Fig. 6 compares  
2 CO for the observations, RACM\_GOCART and RACM\_SOA\_VBS schemes. Overall, the forecast is able  
3 to capture the observed latitude-height profiles of CO mixing ratio very well. They both show high  
4 concentrations near the low altitude, though there are still some differences at the altitude that the CO mixing  
5 ratio above 6 km is underestimated over the tropics while overestimated near the surface. It looks like that  
6 the model does not reproduce the injection height correctly for the biomass burning emission over this area,  
7 which may be due to relative weak convection or lower injection heights in the model. For O<sub>3</sub>, the model is  
8 able to consistently capture O<sub>3</sub> mixing ratios with both RACM\_GOCART and RACM\_SOA\_VBS schemes,  
9 including the stratospheric intrusion near 40°S at about 9 km height, though it is slightly higher near 40°N at  
10 about 12 km height. We find that over equatorial areas at about 2-4 km height, the modeled O<sub>3</sub> mixing ratio  
11 is underestimated by about 30%. This may also relate to the injection height of biomass burning that resulted  
12 into much lower CO at this altitude, since CO is one of the important precursors for O<sub>3</sub> production. Besides  
13 the aerosol and gas tracers associated with the biomass burning emissions, we also compare the HCHO, OH  
14 and H<sub>2</sub>O<sub>2</sub>, which are the important precursors or oxidants to many other species within the RACM\_GOCART  
15 and RACM\_SOA\_VBS schemes (see Fig. 7). Generally, the pattern of the modeled HCHO mixing ratio is  
16 almost the same as that of the ATom-1 measurements. The variations from south to north are captured by  
17 these two schemes except a little underestimation near about 10 km height. For OH, the model reproduces  
18 the vertical and temporal variations, including the large mixing ratios over the northern hemisphere. Some  
19 slight differences are apparent, e.g., the overestimates over 44°S at 3-9 km height and the underestimates  
20 over 40°N above 10 km height. Similarly, there is more spatial variability in the ATom-1 measurement of  
21 H<sub>2</sub>O<sub>2</sub>. Above 6km the model overestimates H<sub>2</sub>O<sub>2</sub> south of 40°S and overestimates from 20°S to the northern  
22 hemisphere above 6 km. Overall, the model and ATom-1 measurement are more consistent at lower altitudes  
23 for H<sub>2</sub>O<sub>2</sub>.

24 Figures 8 and 9 show more detailed comparisons for vertical tracks of meteorological fields and chemical  
25 species in the biomass burning and dust events. For the biomass burning plume the 16<sup>th</sup> vertical profile on  
26 August 15th, 2016 near 20°S is shown while the 10<sup>th</sup> profile on August 17th, 2016 near 25°N for the Saharan  
27 dust plume is shown. The comparison of the meteorological fields of temperature, virtual potential  
28 temperature, water vapor, relative humidity, wind speed and wind direction are shown in Fig. 8 and do not  
29 change between the different chemical options. The model forecasted temperature and virtual potential  
30 temperature almost overlap the ATom-1 measurements for both the August 15th and 17th vertical tracks. For  
31 water vapor and relative humidity, the variations of the vertical profiles are also reproduced by the model,  
32 except there are some smaller peaks in the observed profiles. There are still some differences between model  
33 and ATom-1 observations for wind speed and wind direction, which may be due to model vertical resolution.  
34 Overall, the model is able to capture the general vertical variations. For the chemical species (see Fig. 9),  
35 the modeled EC using GOCART scheme is almost identical to that by the RACM\_GOCART scheme (the  
36 green line is overlapped by the blue line). Both EC concentration plots show a vertical variation of decreasing  
37 with altitude and the concentrations are overestimated above 2 km in biomass burning plume (see Fig. 9a)

1 and above 4 km in dust storm (see Fig. 9b). The results using the RACM\_SOA\_VBS scheme shows much  
2 better performance to capture the vertical variations of EC. Other than a slight overestimation at 2-4 km  
3 biomass plume (see Fig. 9a first column), the EC vertical profile is very consistent to that of the observation  
4 when using RACM\_SOA\_VBS scheme. In the biomass burning event (see Fig. 9b first column), the modeled  
5 vertical profile with the RACM\_SOA\_VBS scheme captures the general changes of the vertical variations  
6 much better than those of the GOCART and RACM\_GOCART schemes. As mentioned, previously, the  
7 assumption of no wet deposition for hydrophobic BC is the main reason resulting in less EC at high altitude  
8 in the RACM\_SOA\_VBS scheme compared to the GOCART and RACM\_GOCART schemes. Due to less  
9 available observed data for sea salt, it is difficult to perform specific comparisons, but both the observation  
10 and model show strong decreases with altitude. During the dust event (see Fig. 9b third column), even though  
11 the modeled dust concentrations are lower at about 2-6 km than the observed concentrations, they are close  
12 to the observation at the surface and upper levels. For the gas-phase species, the model results are from  
13 GOCART\_RACM (blue line) and RACM\_SOA\_VBS (red line) schemes. The observed O<sub>3</sub> in the biomass  
14 burning event (see Fig. 9a fourth column) shows a peak at about 2 km height, then it decreases with altitude,  
15 but increases again at about 5-9 km height. The model results from these two schemes are quite consistent.  
16 They both indicate a slight enhancement at 1.5 km height, though it is not able to capture the magnitude of  
17 the observed peak, which is underestimated by ~50%. For CO, the model can reproduce the peak at about 2  
18 km height very well, though it overestimates the mixing ratio by 25% below 1 km in the biomass burning  
19 event (see Fig. 9a 5th column). The detailed variations of the O<sub>3</sub> and CO vertical profiles still show some  
20 slight differences between the model and observation, but the model generally forecasts the vertical changes  
21 with altitude, and the CO using RACM\_GOCART is slightly lower than that of the RACM\_SOA\_VBS  
22 scheme above 5 km height.

#### 23 **4.2 Comparisons of aerosols and gas tracers between FIM-Chem and ATom-1 over the United States**

24 Figure 10 shows the comparisons of EC and sulfate between ATOM-1 measurements and FIM-Chem model  
25 with three different chemical schemes over the United States. Other than the underestimates of wet removal  
26 for EC in GOCART and RACM\_GOCART schemes that result in the overpredicted EC concentrations above  
27 4 km height, the near surface (below 4 km) EC concentrations over southern California are also higher than  
28 the observation. The overestimate over southern California is also shown in the RACM\_SOA\_VBS scheme.  
29 Similarly, the predicted sulfate concentrations over southern California are much higher than the observation  
30 too. Also, the surface sulfate concentrations throughout the U.S. are much higher than those of observations.  
31 In the FIM-Chem model, the anthropogenic emissions are from the HTAP v2.1 inventory, which based on the  
32 NEI2005 over United States. However, the BC emissions have declined by 50% in California from 1980 to  
33 2008 following a parallel trend the reduction of fossil fuel BC emissions [Bahadur et al., 2011]. The older  
34 emission inventory with relatively higher anthropogenic emissions of BC and SO<sub>2</sub> may possibly induce the  
35 overestimates of near- surface BC and sulfate concentrations for the 2016 simulation in the model results  
36 over southern California and other areas. For the sulfate concentrations at upper levels, the GOCART (see

1 Fig. 10b the second column) scheme using the background fields of  $\text{H}_2\text{O}_2$ , OH and  $\text{NO}_3$  shows much better  
2 performance in capturing the relatively lower sulfate at upper levels than the other two gas-phase schemes.  
3 This finding needs further analysis. For the gas species we compare CO, HCHO and  $\text{O}_3$  (see Fig. 11) using  
4 the RACM\_GOCART and RACM\_SOA\_VBS schemes with the observation. Generally, the model cases  
5 using either RACM\_GOCART or RACM\_SOA\_VBS scheme show good performance in capturing the CO  
6 and HCHO mixing ratios both at the surface and in the free troposphere. But they are both higher than the  
7 observations near the surface over southern California, similar to EC and sulfate concentrations. This may  
8 be also associated with the overestimation of anthropogenic emissions in the NEI-2005 over United States  
9 for the year of 2016. Since CO and HCHO are precursors for  $\text{O}_3$  production, the simulated  $\text{O}_3$  also shows  
10 slight enhancements compared to the observations that may be due to the higher CO and HCHO. Other than  
11 that, the model is able to reproduce the  $\text{O}_3$  profile over the US reasonably well, including the  $\text{O}_3$  stratospheric  
12 intrusions at the upper levels.

13 Figure 12 focuses on the 4<sup>th</sup> vertical profile over Kansas on August 23<sup>rd</sup>, 2016. The model results with  
14 different chemical schemes are very consistent in simulating the meteorological fields. The modeled  
15 temperature and virtual potential temperature show nearly exact agreement with the observations. But there  
16 are still some shortcomings in forecast water vapor and relative humidity, especially above 6 km, where the  
17 model results are overpredicted by nearly a factor of 2 and with less vertical variability. The vertical trend of  
18 modeled wind speed and wind direction are close to the observed changes that increase with altitude. Similar  
19 to Figure 9, the EC vertical profile using the RACM\_SOA\_VBS scheme, without the hydrophobic  
20 assumption in wet removal, is similar to that of the observations while the other 2 schemes significantly  
21 overpredict. Both the observations and models show decreasing vertical trend for sea salt and dust. The  
22 GOCART scheme is able to reproduce the sulfate, except for the underestimate at 1.5-3 km. Otherwise, it  
23 almost overlaps the observed profile at the upper levels. The  $\text{O}_3$  vertical profile is reproduced by the model  
24 using both RACM\_GOCART and RACM\_SOA\_VBS schemes except a slight peak near 9 km where the  
25 model is not able to capture the enhanced variability. The CO measurements have more fluctuations, but the  
26 model roughly shows the major features of the vertical changes with altitude.

## 27 **5 Correlations between FIM-Chem model and ATom-1 observations**

28 For the aerosol size range of the GOCART scheme, the PALMS dataset allows for model evaluation of the  
29 default sea salt emission algorithms by summing those bins less than  $3 \mu\text{m}$  in the model results. The  
30 comparison between the GOCART forecasts and ATom-1 data for all sea salt observations below 6 km are  
31 shown in Figure 13. Different colors show different flight dates from August 15<sup>th</sup> (blue dots), 17<sup>th</sup> (green  
32 dots), 20<sup>th</sup> (orange), 22<sup>nd</sup> (red) and 23<sup>rd</sup> (purple). Generally, modeled sea salt appears too high, especially on  
33 flights of August 15<sup>th</sup> (blue dots), 20<sup>th</sup> (orange dots) and 23<sup>rd</sup> (purple dots) above  $\sim 4\text{km}$ . Some high values  
34 below  $\sim 4\text{km}$  are reproduced by the models on the flight of August 17<sup>th</sup> (green dots). Some of the disagreement  
35 may be due to uncertainties in the size range of sea salt observations, particularly the upper cutoff of 3  $\mu\text{m}$   
36 that is approximate (Murphy et al., 2019).

1 We also investigate the relationships of some key species for the biomass burning plumes observed on  
2 8/15/17 and 8/17/17 between 22°S to 22°N below 6km (Fig. 14) for the RACM\_SOA\_VBS scheme. The  
3 color bar indicates the latitude from south to north. Relative to CO, the model biomass burning emission  
4 ratios are reasonable for EC with the modeled ratio (black color dots) somewhat lower than the observations  
5 (color dots). However, the ratio of NO<sub>y</sub> to CO is apparently too high in the fire emission processor. O<sub>3</sub>  
6 formation in the model plume is highly underpredicted (Fig. 14c and d), which is probably related to VOC  
7 emission uncertainties within the fire emission ratio specifications.

## 8 **6 Conclusions**

9 A two way fully inline coupled global weather -chemistry prediction model FIM-Chem has been developed  
10 at NOAA/ESRL/GSL to forecast the chemical composition and quantify the impacts on NWP. Three different  
11 gas/aerosol chemistry schemes - GOCART, RACM\_GOCART and RACM\_SOA\_VBS from WRF-Chem  
12 have been implemented into FIM-Chem with some modifications as different options of chemical schemes.  
13 In this study, the evaluation and analysis of model performance are focused on the fire events over Atlantic  
14 from south to north on August 15<sup>th</sup> and 17<sup>th</sup> 2016 and the flight over United States from Minnesota to southern  
15 California according to the NASA ATom-1 observations. The major conclusions are summarized as follows:  
16 Compared with the explicitly simulated instantaneous H<sub>2</sub>O<sub>2</sub>, OH and NO<sub>3</sub> in RACM\_GOCART mechanism,  
17 there are about 10 µg/m<sup>3</sup> enhancements of sulfate and 15 µg/m<sup>3</sup> enhancements of PM<sub>2.5</sub> over the eastern US  
18 and more than 20 µg enhancements of PM<sub>2.5</sub> over eastern China in the GOCART scheme, which has a simple  
19 parameterization of sulfur/sulfate chemistry using prescribed background fields of OH, H<sub>2</sub>O<sub>2</sub> and NO<sub>3</sub> to  
20 calculate the sulfate production. Simulated instantaneous H<sub>2</sub>O<sub>2</sub> is lower by 20% over eastern US and 40-60%  
21 over India and eastern Asia, while the OH is 80% lower over eastern China in the RACM\_GOCART scheme.  
22 The GOCART and RACM\_GOCART results are very consistent in forecasting sulfate, sea salt and EC due  
23 to the same aerosol mechanism. For the fire events sampled over the Atlantic, the model shows very good  
24 performance in reproducing the profiles of EC, CO, and O<sub>3</sub>, especially in capturing the biomass burning  
25 plumes near the equatorial areas (Fig. 6). However, for EC the RACM\_SOA\_VBS scheme shows much  
26 better performance than that of the GOCART and RACM\_GOCART schemes at the upper levels. That is  
27 because it assumed that there is no wet deposition for hydrophobic BC in the GOCART and  
28 RACM\_GOCART schemes, which results into an underestimate of EC wet removal and overestimate of EC  
29 concentrations at higher levels. The CO mixing ratio above ~2 km is underestimated over the tropics, which  
30 may be related to lower simulated fire injection heights in the model. Otherwise, the general CO profiles are  
31 well reproduced. The model using both RACM\_GOCART and RACM\_SOA\_VBS schemes are able to  
32 consistently reproduce O<sub>3</sub> mixing ratios, including the stratospheric intrusions above ~9 km at 40°S. There  
33 is some slight underestimation of O<sub>3</sub> near the tropics, which might be associated with the underprediction of  
34 CO. Meanwhile, we also evaluated other gas-phase species of CH<sub>2</sub>O, OH and H<sub>2</sub>O<sub>2</sub>, which are important  
35 precursors to many other chemical species within the RACM\_GOCART and RACM\_SOA\_VBS schemes

1 (see Fig. 7). Generally, the pattern of the modeled HCHO, OH and H<sub>2</sub>O<sub>2</sub> mixing ratio are almost the same  
2 as that of the ATom-1 observations except for some underestimates above 9 km for HCHO and OH at some  
3 latitudes, and some overestimates of H<sub>2</sub>O<sub>2</sub> above 6 km in the southern hemisphere.

4 All of the chemical schemes are able to reproduce the general vertical gradients seen in the observations. The  
5 RACM\_SOA\_VBS scheme is able to reproduce the vertical profile of EC much better than that of the  
6 GOCART and RACM\_GOCART schemes, which overestimate the EC concentrations above 2-4 km due to  
7 the assumption of no wet deposition for hydrophobic BC. This comparison highlights the value of the ATom  
8 data in examining basic assumptions within the wet removal parametrization of carbonaceous aerosol in the  
9 GOCART mechanism. Results from the RACM\_GOCART and RACM\_SOA\_VBS schemes show  
10 consistency with observed O<sub>3</sub> and CO vertical profiles during the fire events. Both schemes show a slight  
11 enhancement of O<sub>3</sub> at 1.5 km even though it underestimates the magnitude of the observed peak. For CO, the  
12 model results capture the peak at about 2 km very well but overestimates the mixing ratio by about 30% near  
13 the surface.

14 For the gas-phase species, the model either using the RACM\_GOCART or RACM\_SOA\_VBS scheme  
15 shows very good ability in forecasting the CO, O<sub>3</sub> and HCHO mixing ratio both at the surface and free  
16 troposphere, including the O<sub>3</sub> stratospheric intrusions at the upper levels (Fig. 11). For EC and CO, a  
17 precursor for O<sub>3</sub> production, there appears to be overestimated emissions over California causing much higher  
18 surface mixing ratios in the forecasts than observed. For the comparisons of vertical profiles over California  
19 on August 23<sup>rd</sup> 2016, the modeled meteorological fields of temperature and potential temperature show  
20 agreement with the observations. The modeled water vapor and relative humidity are consistent with  
21 observations below 6 km though they are overestimated above 6km. The RACM\_SOA\_VBS scheme shows  
22 the best agreement with EC. For sulfate, the GOCART scheme is almost the same as the observation above  
23 3km while it overestimates near the surface due to the high anthropogenic emissions used within the  
24 inventory. The simulated O<sub>3</sub> and CO vertical profiles almost overlap the ATom-1 measurements but with  
25 less vertical variability. Though data is somewhat sparse in our analysis, the sea salt emission algorithm  
26 appears to be a model component that could be improved due to apparent consistent overestimation.

27 The comparison in this study successfully demonstrates that the FIM-Chem model with three difference  
28 chemical schemes show good performance in forecasting the chemical composition for both aerosol and gas-  
29 phase tracers when compared with the high temporal resolution (1-second) observations of ATom-1. The wet  
30 removal assumption for hydrophobic BC is not reasonable, which need to be improved in the GOCART and  
31 RACM\_GOCART schemes. Thus, it is not necessary to use the complexity of a gas-phase scheme if the  
32 focus is only on aerosol forecasts, in order to save time and computer resources. Using anthropogenic  
33 emissions for the specific year of the simulation may help to improve the forecasts. Also, a new dynamic  
34 core of Finite-volume cubed-sphere dynamical core (FV3) developed by GFDL will be used to replace of  
35 FIM and coupled with the chemical schemes in the next generation global prediction system (NGGPS), as  
36 FV3GFS-Chem, by using that to demonstrates the chemical impacts on NWP.

37

## 1 **Code and data availability**

2 Basically, the chemical modules of GOCART, RACM\_GOCART and RACM\_SOA\_VBS are based on the  
3 WRF-Chem 3.7, which can be obtained from  
4 [http://www2.mmm.ucar.edu/wrf/users/download/get\\_source.html](http://www2.mmm.ucar.edu/wrf/users/download/get_source.html). The FIM-Chem\_v1 code and model  
5 configuration for chemical composition forecast here are available at [https://github.com/NOAA-GSL/FIM-](https://github.com/NOAA-GSL/FIM-Chem_v1)  
6 [Chem\\_v1](https://github.com/NOAA-GSL/FIM-Chem_v1). ATom-1 data is publicly available at the Oak Ridge National Laboratory Distributed Active  
7 Archive Center: [https://daac.ornl.gov/ATOM/guides/ATom\\_merge.html](https://daac.ornl.gov/ATOM/guides/ATom_merge.html) (Wofsy et al., 2018).

## 8 **Author contribution**

9 Li Zhang and Georg A. Grell developed the model coupling code and implemented the chemical modules  
10 from WRF-Chem into FIM model. Li Zhang designed the experiments and performed the simulations. Stuart  
11 A. McKeen evaluated the model performance and provided the suggestions to improve model performance.  
12 Ravan Ahmadov developed the RACM-SOA-VBS scheme in WRF-Chem. Karl D. Froyd and Daniel  
13 Murphy performed the measurements and provided the measured data of ATom-1 experiments. Li Zhang  
14 prepared the manuscript with contributions from all co-authors.

## 15 **Competing interests**

16 The authors declare that they have no conflict of interest.

## 17 **Acknowledgements**

18 NOAA's next generation global prediction system (NGGPS) grant. Li Zhang, Stuart A. McKeen, Ravan  
19 Ahmadov, and Karl Froyd are supported by funding from NOAA Award Number NA17OAR4320101.

2 **Figure 1.** Vertical profiles and transect time series of the ATom-1 flight tracks on August 15<sup>th</sup> and 17<sup>th</sup>, 2016  
3 over Atlantic Ocean and August 23<sup>rd</sup> 2006 over US.

4 **Figure 2.** 120 hours forecast of PM<sub>2.5</sub> and sulfate using (a) GOCART and (b) RACM\_GOCART schemes,  
5 and their (c) differences (RACM\_GOCART minus GOCART) at 00Z July 29<sup>th</sup> 2016. Unit:  $\mu\text{g}/\text{m}^3$ .

6 **Figure 3.** Comparisons of H<sub>2</sub>O<sub>2</sub>, OH, and NO<sub>3</sub> between (a) GOCART and (b) RACM\_GOCART schemes,  
7 and their (c) differences (RACM\_GOCART minus GOCART) at 00Z July 29<sup>th</sup> 2016. Unit: ppb

8 **Figure 4.** 120 hours forecast of surface O<sub>3</sub> using RACM\_GOCART scheme at 12z August 2<sup>nd</sup> and 00z  
9 August 3<sup>rd</sup> 2016. Unit: ppb

10 **Figure 5.** 120 hours forecast of surface SOA using RACM\_SOA\_VBS scheme at 12z August 2<sup>nd</sup> and 00z  
11 August 3<sup>rd</sup> 2016. Unit:  $\mu\text{g}/\text{m}^3$ .

12 **Figure 6.** Height-latitude profiles of EC, CO and O<sub>3</sub> over Atlantic on August 15<sup>th</sup> and August 17<sup>th</sup>, 2016 for  
13 (a) ATom-1; (b) RACM\_GOCART; and (c) RACM\_SOA\_VBS.

14 **Figure 7.** Height-latitude profiles of HCHO, OH and H<sub>2</sub>O<sub>2</sub> over Atlantic on August 15<sup>th</sup> and August 17<sup>th</sup>,  
15 2016 for (a) ATom-1 observations; (b) RACM\_GOCART; and (c) RACM\_SOA\_VBS.

16 **Figure 8.** ATom-1 observations and model results for temperature, virtual potential temperature, water vapor,  
17 relative humidity, wind speed and wind direction in the (a) biomass burning and (b) dust events. The biomass  
18 burning plume is from August 15, 2016, profile #16 near 20°S while the Saharan dust plume is from August  
19 17, 2016, profile #10 near 25°N.

20 **Figure 9.** Comparisons between ATom-1 observations and model vertical profiles of EC, sea salt, dust, O<sub>3</sub>  
21 and CO in the biomass burning (a) and dust (b) events. The biomass burning plume is from August 15, 2016,  
22 profile #16 near 20°S while the Saharan dust plume is from August 17, 2016, profile #10 near 25°N. Green  
23 and blue lines are nearly identical for aerosol.

24 **Figure 10.** Height-latitude profiles of EC and sulfate over United States on August 23<sup>rd</sup>, 2016 for (a) ATom-  
25 1; (b) GOCART; (c) RACM\_GOCART; and (d) RACM\_SOA\_VBS.

26 **Figure 11.** Height-latitude profiles of CO, O<sub>3</sub> and HCHO over United States on August 23<sup>rd</sup>, 2016 for (a)  
27 ATom-1; (b) RACM\_GOCART; and (c) RACM\_SOA\_VBS.

28 **Figure 12.** Observations and model results for profile #4, 8/23/16 over southeastern Kansas.

29 **Figure 13.** GOCART model forecast versus ATom-1 observed sea salt below 6 km.

30 **Figure 14.** Model (black color dot) and observation (color dot) ratios of (a) EC relative to CO; (b) NO<sub>y</sub>  
31 relative to CO; (c) O<sub>3</sub> relative to CO and (d) O<sub>3</sub> relative to NO<sub>y</sub>. Color scale is degree latitude.

32

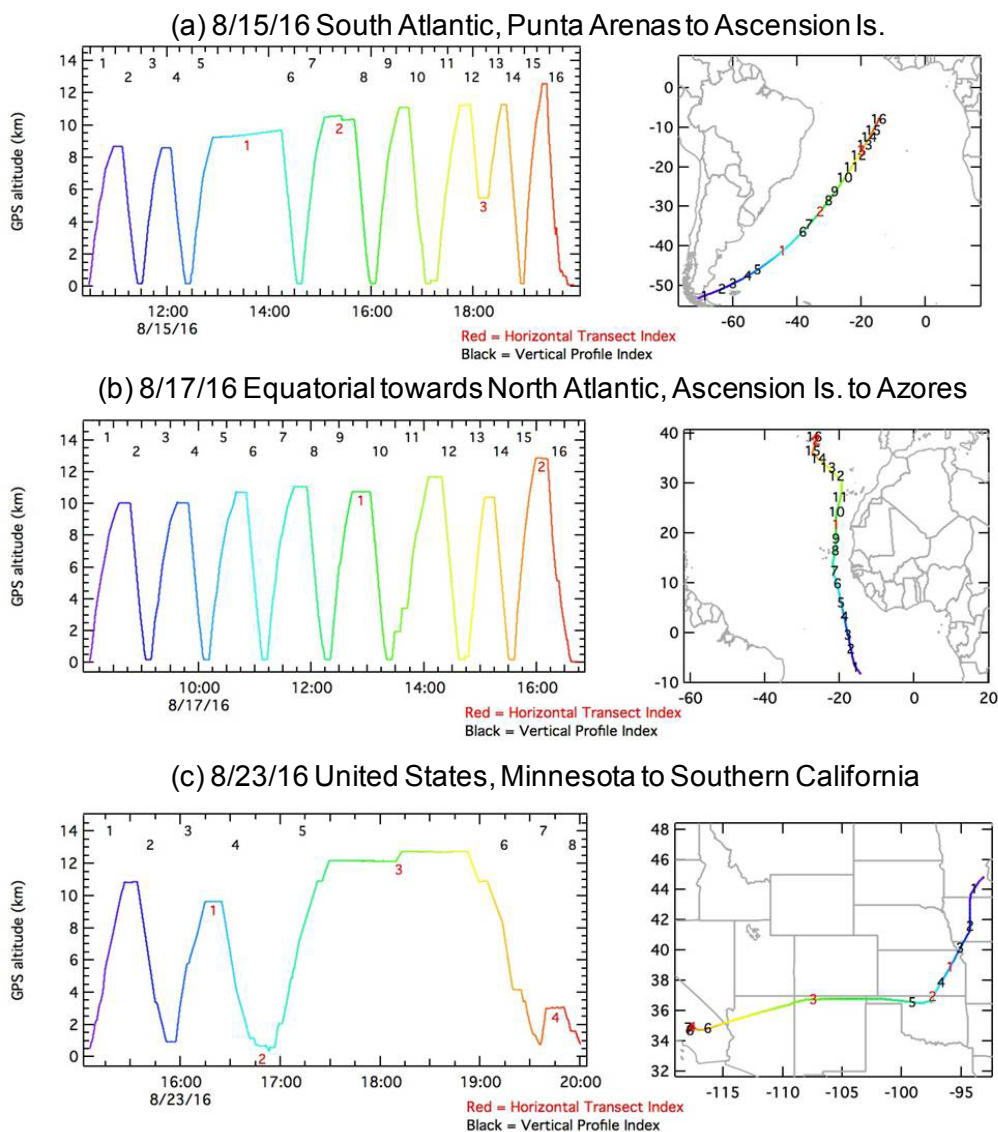

Figure 1: Vertical profiles and transect time series of the ATom-1 flight tracks on August 15th and 17th, 2016 over Atlantic Ocean and August 23rd 2006 over US.

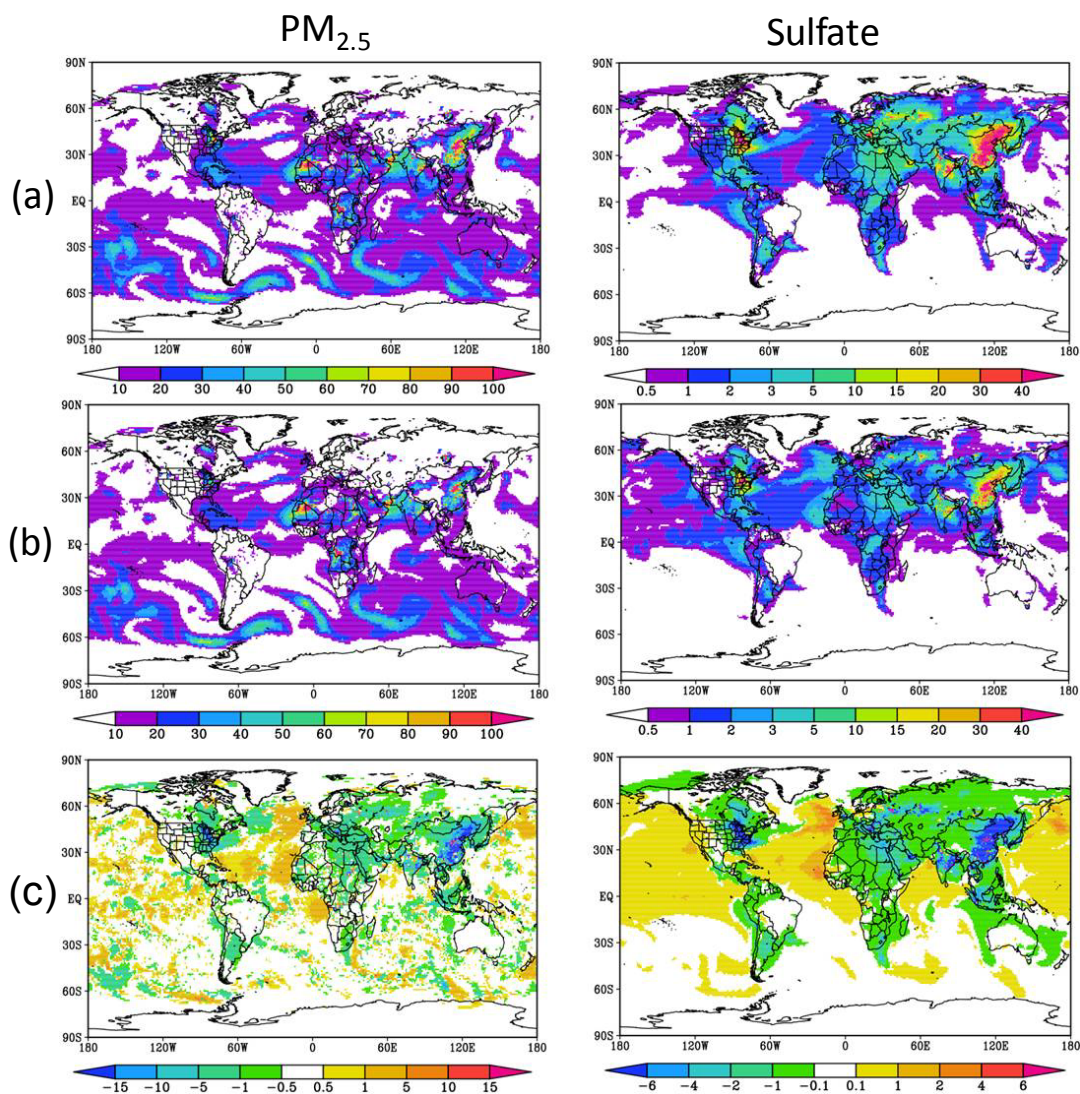

Figure 2: 120 hours forecast of PM<sub>2.5</sub> and sulfate using (a) GOCART and (b) RACM\_GOCART schemes, and their (c) differences (RACM\_GOCART minus GOCART) at 00Z July 29th 2016. Unit:  $\mu\text{g}/\text{m}^3$

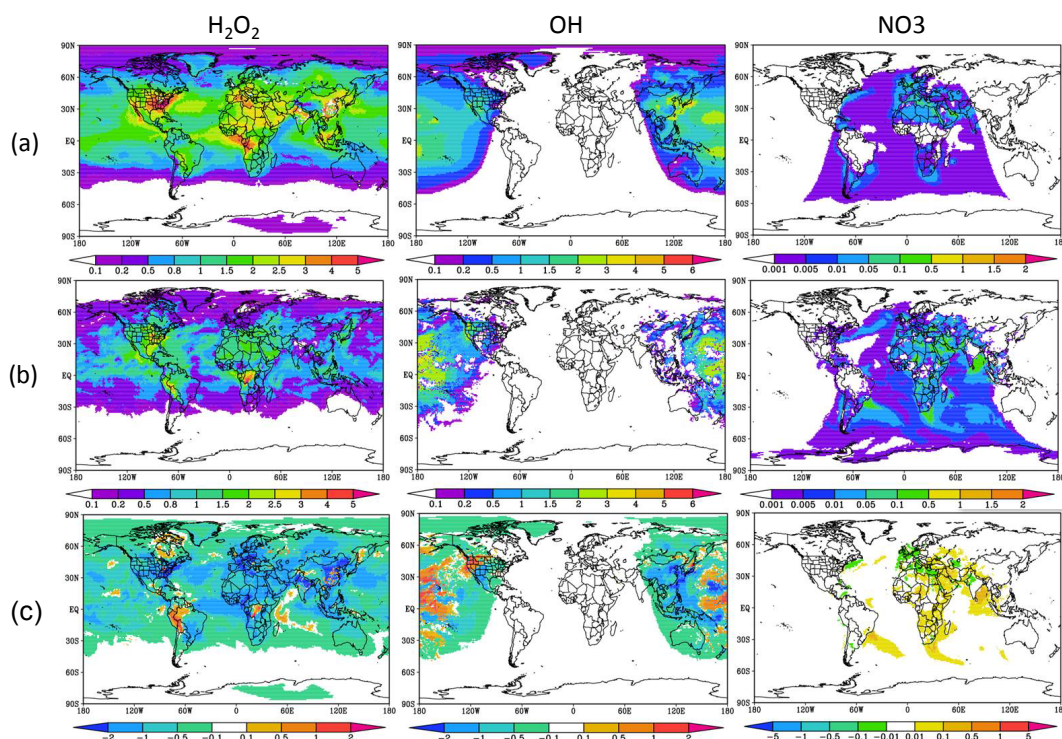

Figure 3: Comparisons of H<sub>2</sub>O<sub>2</sub>, OH, and NO<sub>3</sub> between (a) GOCART and (b) RACM\_GOCART schemes, and their (c) differences (RACM\_GOCART minus GOCART) at 00Z July 29th 2016.

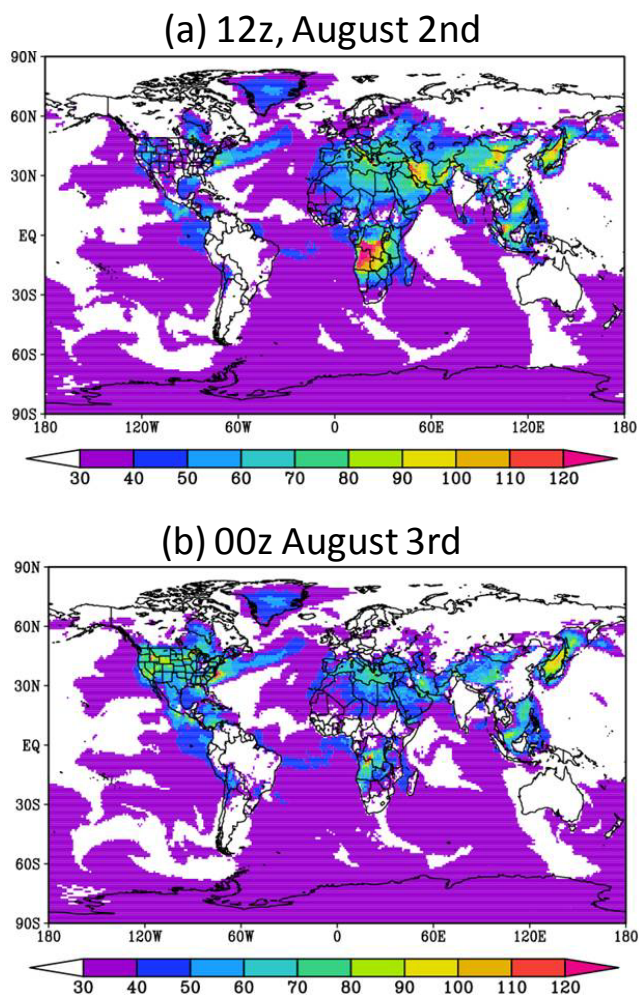

Figure 4: 120 hours forecast of surface O<sub>3</sub> using RACM\_GOCART scheme at 12z August 2nd and 00z August 3rd 2016.

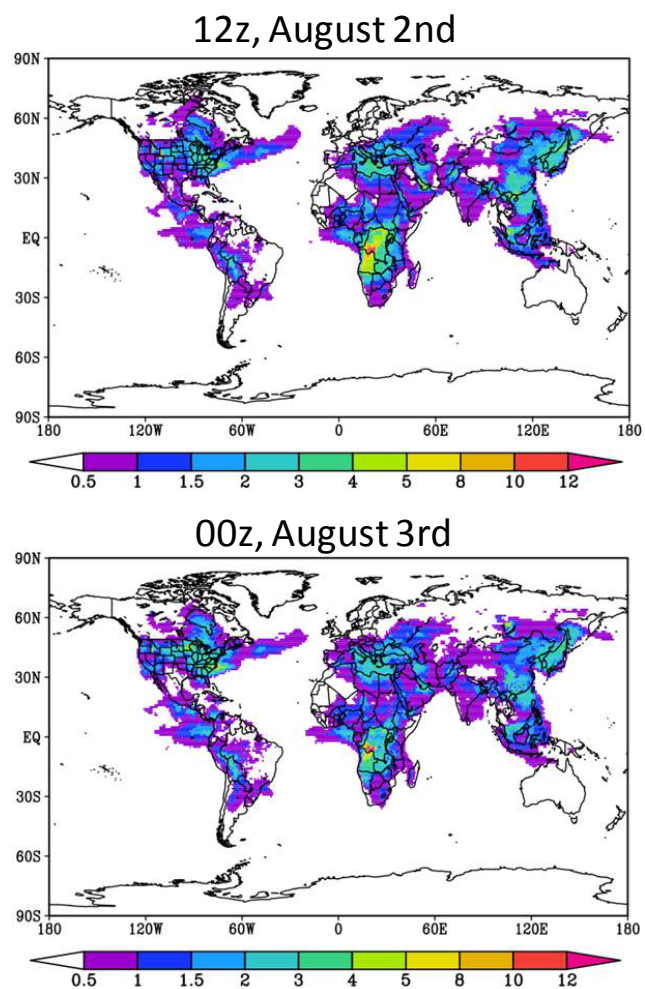

Figure 5: 120 hours forecast of surface SOA using RACM\_SOA\_VBS scheme at 12z August 2nd and 00z August 3rd 2016.

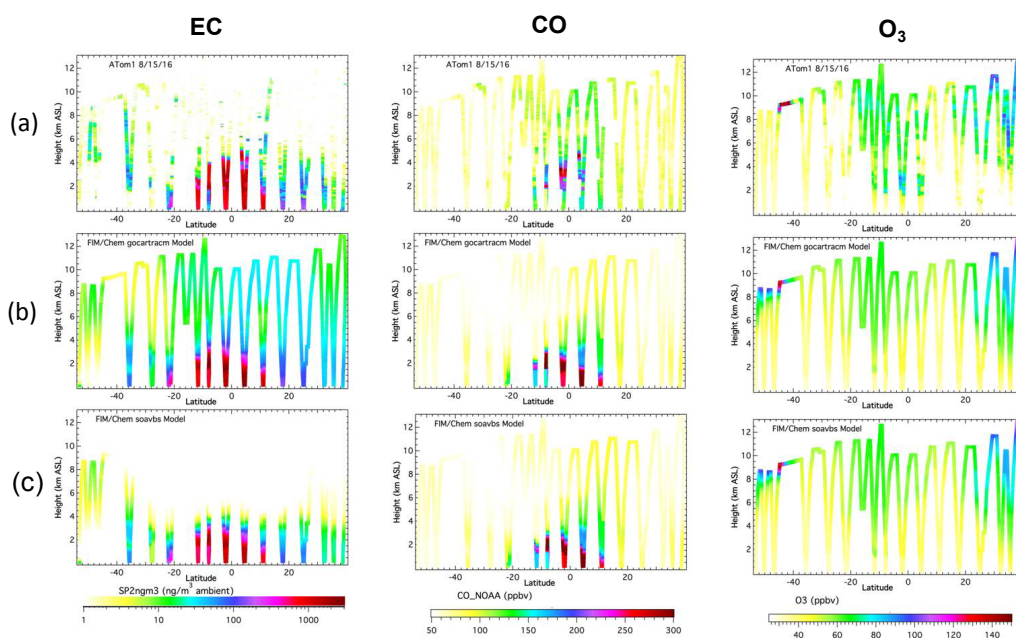

Figure 6: Height-latitude profiles of EC, CO and O<sub>3</sub> over Atlantic on August 15th and August 17th, 2016 for (a) ATom-1; (b) RACM\_GOCART; and (c) RACM\_SOA\_VBS.

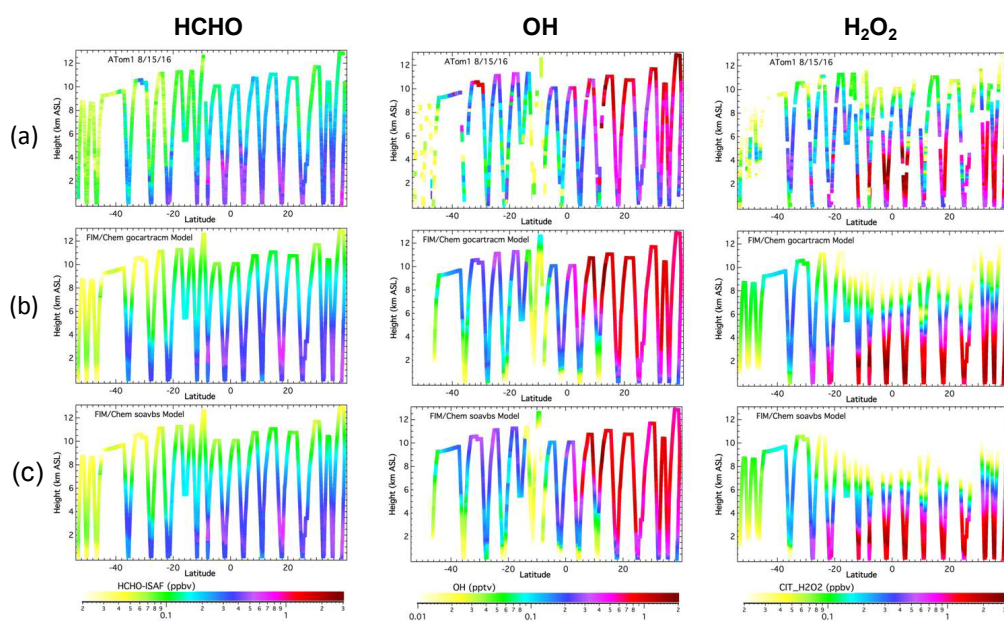

Figure 7: Height-latitude profiles of HCHO, OH and H<sub>2</sub>O<sub>2</sub> over Atlantic on August 15th and August 17th, 2016 for (a) ATom-1 observations; (b) RACM\_GOCART; and (c) RACM\_SOA\_VBS.

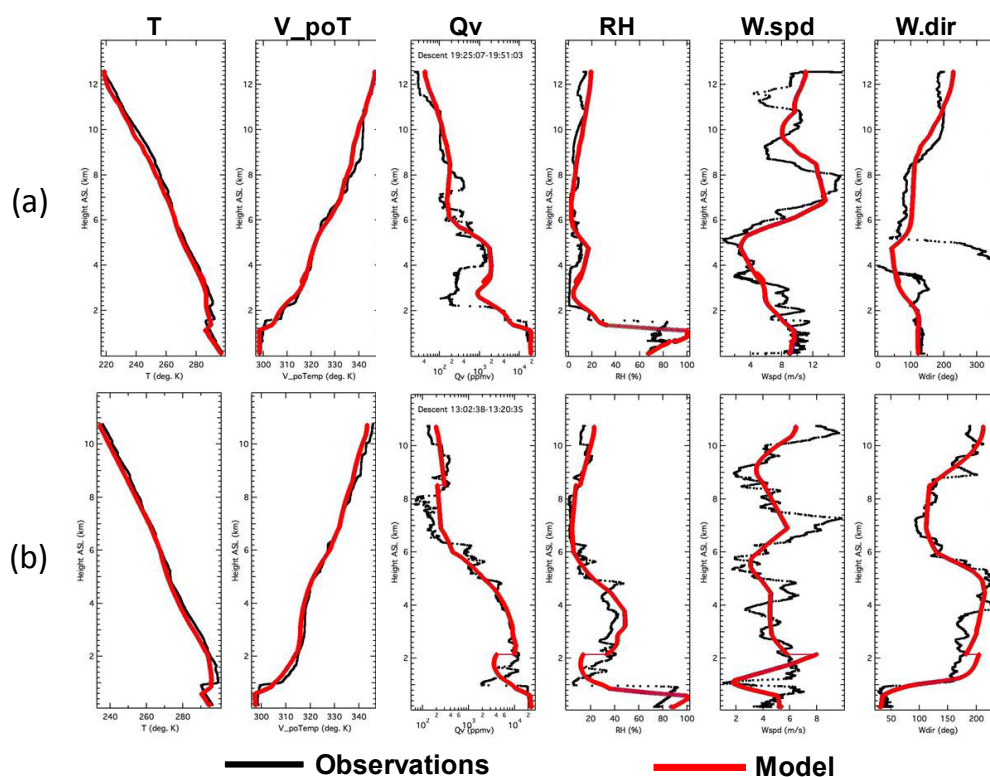

Figure 8: ATom-1 observations and model results for temperature, virtual potential temperature, water vapor, relative humidity, wind speed and wind direction in the (a) biomass burning and (b) dust events. The biomass burning plume is from August 15, 2016, profile #16 near 20°S while the Saharan dust plume is from August 17, 2016, profile #10 near 25°N.

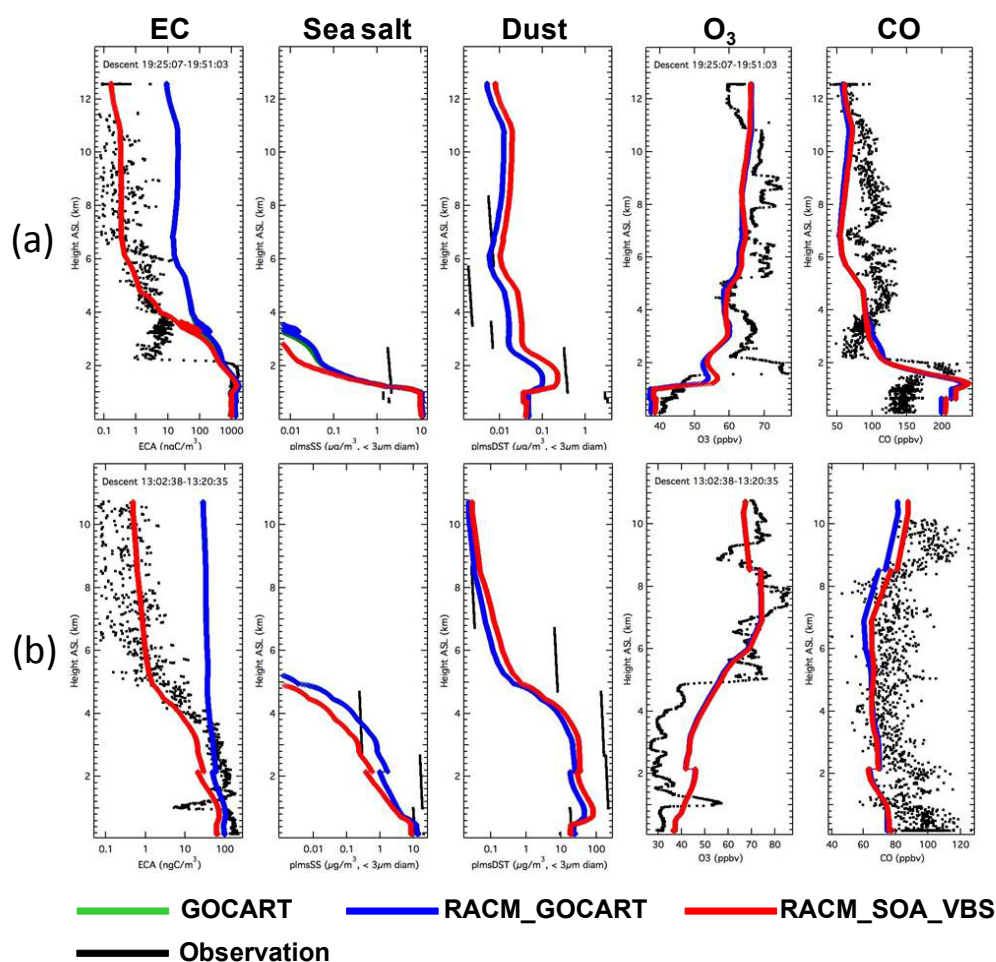

Figure 9: Comparisons between ATom-1 observations and model vertical profiles of EC, sea salt, dust, O<sub>3</sub> and CO in the biomass burning (a) and dust (b) events. The biomass burning plume is from August 15, 2016, profile #16 near 20°S while the Saharan dust plume is from August 17, 2016, profile #10 near 25°N. Green and blue lines are nearly identical for aerosol.

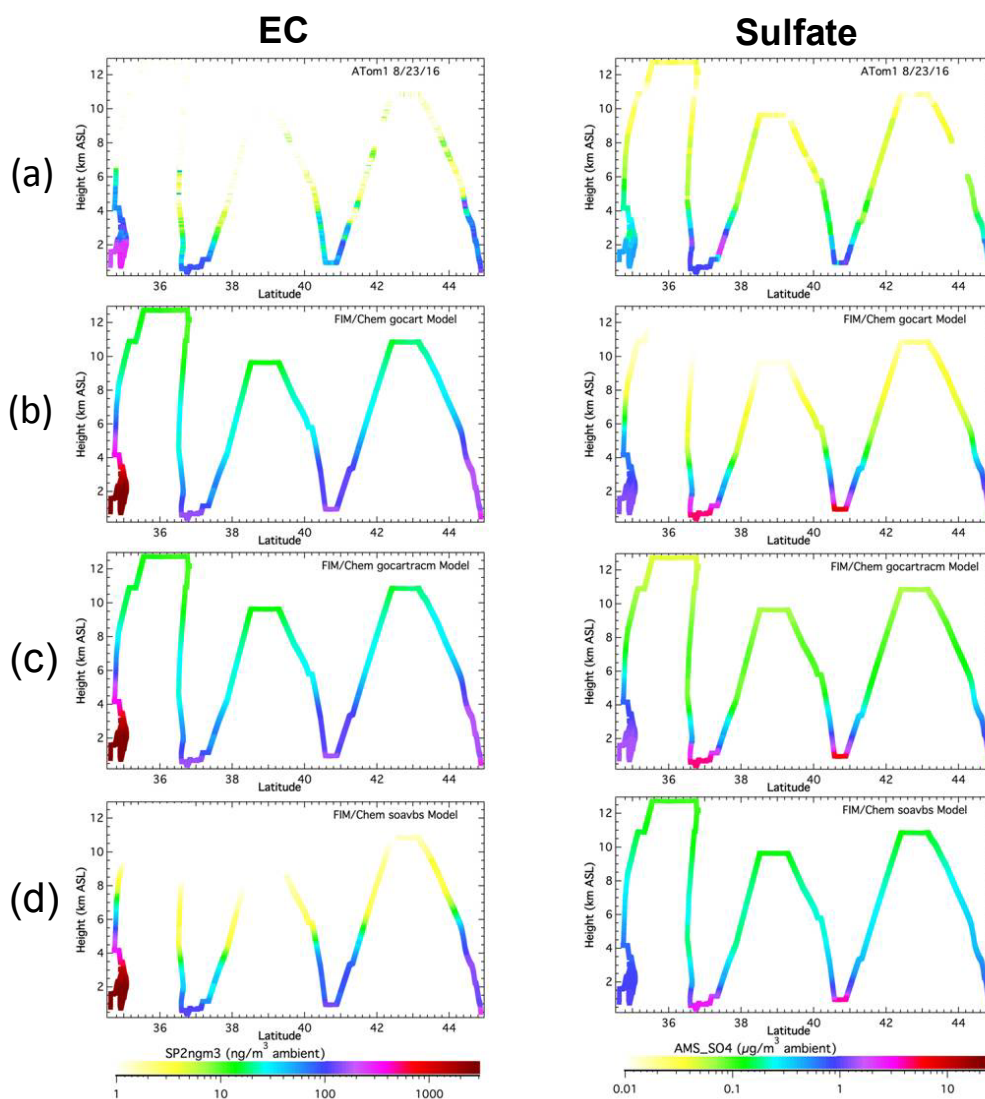

Figure 10: Height-latitude profiles of EC and sulfate over United States on August 23rd, 2016 for (a) ATom-1; (b) GOCART; (c) RACM\_GOCART; and (d) RACM\_SOA\_VBS.

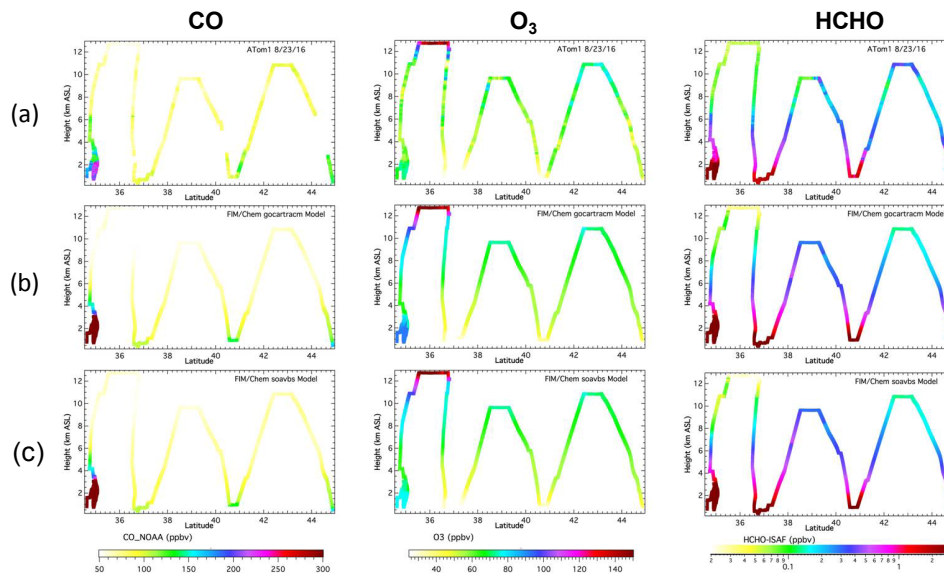

Figure 11: Height-latitude profiles of CO, O<sub>3</sub> and HCHO over United States on August 23rd, 2016 for (a) ATom-1; (b) RACM\_GOCART; and (c) RACM\_SOA\_VBS.

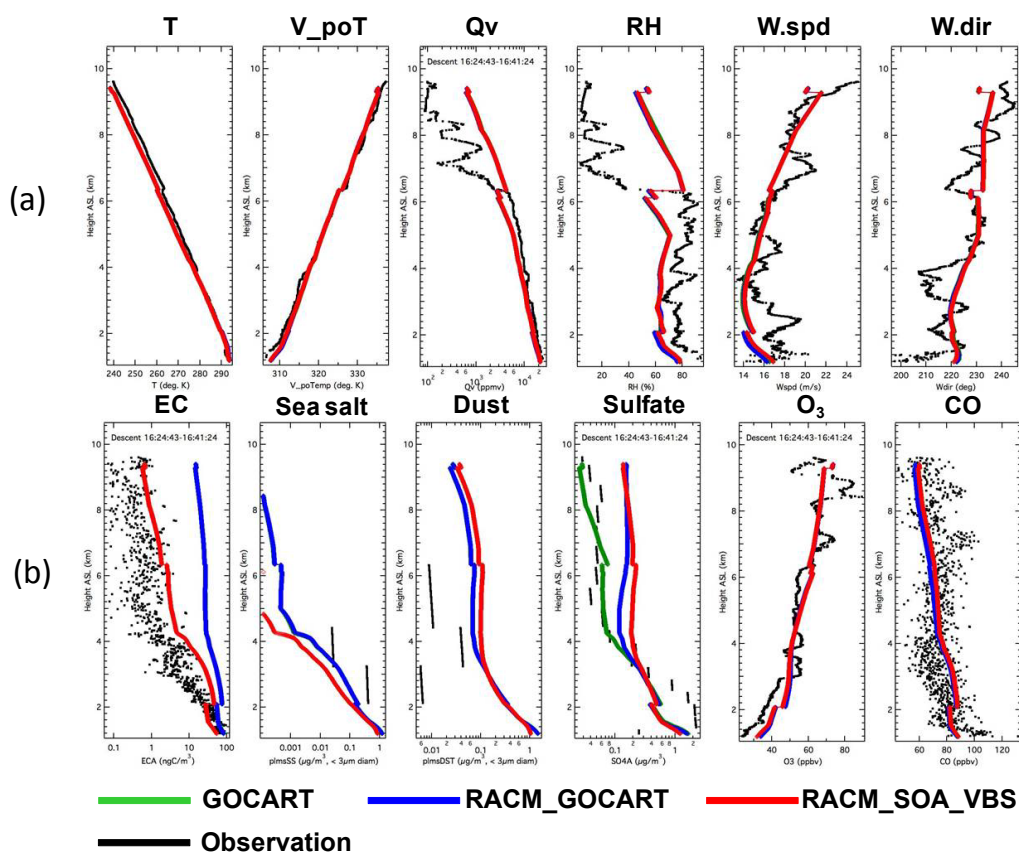

Figure 12: Observations and model results for profile #4, 8/23/16 over southeastern Kansas.

## Sea salt

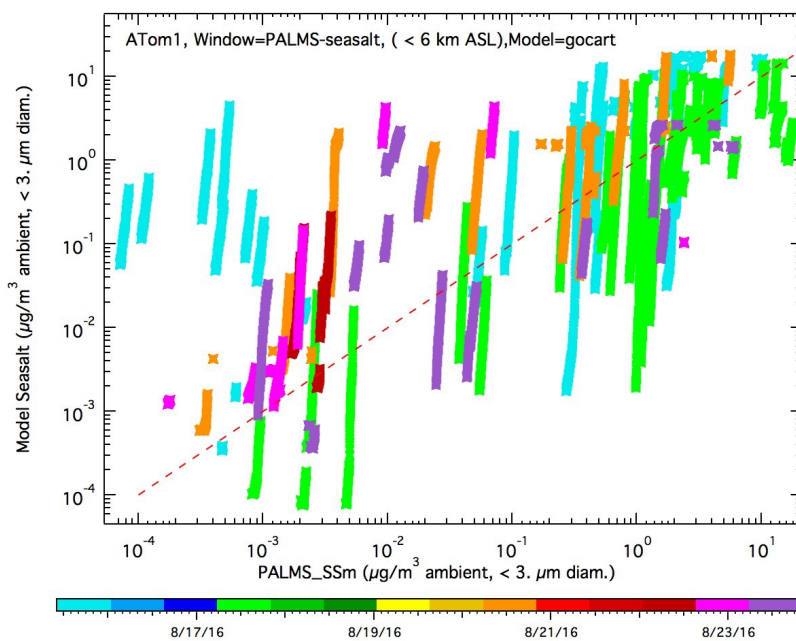

Figure 13: GOCART model forecast versus ATom-1 observed sea salt below 6 km.

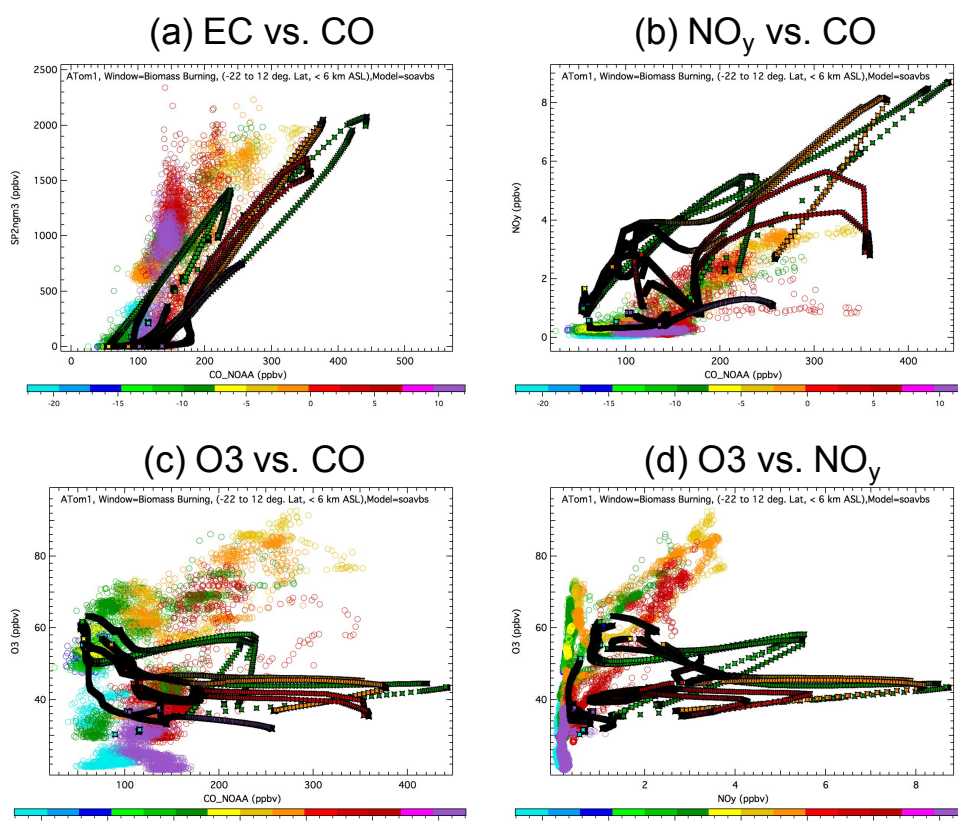

Figure 14: Model (black color dot) and observation (color dot) ratios of (a) EC relative to CO; (b) NO<sub>y</sub> relative to CO; (c) O<sub>3</sub> relative to CO and (d) O<sub>3</sub> relative to NO<sub>y</sub>. Color scale is degree latitude.
