

23 QMG (Qingmuguan) model. The structural design of this model is relatively simple, and it is
24 generally divided into surface and underground double-layered structures. The parameters
25 that represent the structural functions of each layer have clear physical meanings, and the
26 parameters are less than those of the current distributed models. This allows modeling in
27 karst areas with only a small amount of necessary hydrogeological data. 18 flood processes
28 across the karst underground river in the Qingmuguan karst trough valley are simulated by
29 the QMG model, and the simulated values agree well with observations, for which the
30 average value of Nash–Sutcliffe coefficient was 0.92. A sensitivity analysis shows that the
31 infiltration coefficient, permeability coefficient, and rock porosity are the parameters that
32 require the most attention in model calibration and optimization. The improved
33 predictability of karst flooding by the proposed QMG model promotes a better mechanistic
34 depicting of runoff generation and confluence in karst trough valleys.

36 (Qingmuguan) model; Parametric optimization; Parameter sensitivity analysis

37 **1 Introduction**

38 Karst trough and valley landforms are very common in China, especially in the southwest. In
39 general, these karst areas are water scarce during most of the year because their surfaces
40 store very little rainfall, but they are also potential birthplaces for floods because trough and
41 valley landforms and topographic features facilitate the formation and propagation of floods
42 (White, 2002; Li et al., 2021). The coexistence of drought and flood is a typical phenomenon
43 in these karst trough and valley areas. Taking the example of the present study area, i.e. the
44 Qingmuguan karst trough valley, floods used to happen here constantly during the rainy
45 season. In recent years, with more extreme rainfall events and the increased area of
46 construction land in the region, rainfall infiltration has decreased and rapid runoff over

47 impervious surfaces has increased, resulting in frequent catastrophic flooding in the basin
48 (Liu et al., 2009). Excess water overflows from karst sinkholes and underground river
49 outlets often occur during floods (Jourde et al., 2007, 2014; Martinotti et al., 2017), flooding
50 large areas of farmland and residential areas and causing serious economic losses (Gutierrez,
51 2010; Parise, 2010; Yu et al., 2020). Therefore, it is both important and urgent to simulate
52 and predict karst flooding events in karst trough and valleys such as the study area.

53 Hydrological models can be effective for forecasting floods and evaluating water
54 resources in karst areas (Bonacci et al., 2006; Ford and Williams, 2007; Williams, 2008,
55 2009). However, modelling floods in karst regions is extremely difficult because of the
56 complex hydrogeological structure. Karst water-bearing systems consist of multiple media
57 under the influence of complex karst development dynamics (Worthington et al., 2000;
58 Kovács and Perrochet, 2008; Gutierrez, 2010), such as karst caves, conduits, fissures and
59 pores, and are usually highly spatially heterogeneous (Chang and Liu, 2015; Teixeiraparente
60 et al., 2019). In addition, the intricate surface hydrogeological conditions and the
61 hydrodynamic conditions inside the karst water-bearing medium result in significant
62 temporal and spatial differences in the hydrological processes in karst areas (Geyer et al.,
63 2008; Bittner et al., 2020).

64 In early studies of flood forecasting in karst regions, simplified lumped hydrological
65 models were commonly used to describe the rainfall–discharge relationship (e.g. Kovács and
66 Sauter, 2007; Fleury et al., 2007b; Jukić and Denić, 2009; Hartmann et al., 2014a). With the
67 development of physical exploration technology and the progress made in mathematics,
68 computing and other interdisciplinary disciplines, the level of modelling has gradually
69 improved (Hartmann and Baker, 2017; Hartmann, 2018; Petrie et al., 2021), and distributed
70 hydrological models have subsequently become widely used in karst areas. The main
71 difference between lumped and distributed hydrological models is that the latter divide the
72 entire basin into many sub-basins to calculate the runoff generation and confluence, thereby
73 better describing the physical properties of the hydrological processes inside the karst
74 water-bearing system (Jourde et al., 2007; Hartmann, 2018; Epting et al., 2018).

75 Because of their simple structure and little demand for modelling data, lumped

76 hydrological models have been used widely in karst areas (Kurtulus and Razack, 2007;
77 Ladouche et al., 2014). In a lumped model, the river basin is considered as a whole to
78 calculate the runoff generation and confluence, and there is no division running into
79 sub-basins (Dewandel et al., 2003; Bittner et al., 2020). Lumped models usually consider the
80 inputs and outputs of the model (Liedl and Sauter, 2003; Hartmann and Bake, 2013, 2017).
81 In addition, most of the model parameters are not optimized in a lumped model, and the
82 physical meaning of each parameter is unclear (Chen, 2009; Bittner et al., 2020).

83 Distributed hydrological models are of active interest in flood simulation and
84 forecasting research (Ambroise et al., 1996; Beven and Binley, 2006; Zhu and Li, 2014).
85 Compared with a lumped model, a distributed model has a more definite physical
86 significance for the model structure in terms of its mechanism (Meng and Wang, 2010;
87 Epting et al., 2018). In a distributed hydrological model, an entire karst basin can be divided
88 into many sub-basins (Birk et al., 2005) using high-resolution digital elevation map (DEM)
89 data. In the rainfall-runoff algorithm of the model, the hydrogeological conditions and karst
90 aquifer characteristics can be considered fully to simulate precisely the runoff generation
91 and confluence (Martinotti et al., 2017; Gang et al., 2019). The commonly used basin
92 distributed hydrological models (i.e. not a special groundwater numerical model such as
93 MODFLOW) have also been applied widely in karst areas and include the SHE/MIKE SHE
94 model (Abbott et al., 1986a,b; Doummar et al., 2012), SWMM model (Peterson and Wicks,
95 2006; Blansett and Hamlett, 2010; Blansett, 2011), TOPMODEL (Ambroise et al., 1996;
96 Suo et al., 2007; Lu et al., 2013; Pan, 2014) and SWAT model (Peterson and Hamlett, 1998;
97 Ren, 2006).

98 The commonly used distributed hydrological models have multiple structures and
99 numerous parameters (Lu et al., 2013; Pan, 2014), which means that a distributed model
100 may need vast amounts of data to build its framework in karst regions. For example, the
101 distributed groundwater model MODFLOW-CFPM1 requires detailed data regarding the
102 distribution of karst conduits in a study area (Reimann et al., 2009). Another example is the
103 Karst–Liuxihe model (Li et al., 2019), there are fifteen parameters and five underground
104 vertical structures in the model. Such a complex structure makes the modeling data demand

105 is large, and the modeling in karst area is extremely difficult. In addition, a special borehole
106 pumping test may be required to obtain the rock permeability coefficient.

107 To overcome the difficulty of the large modelling-data demands for distributed hydrological
108 models in karst areas, a new physically based distributed hydrological model—known as the
109 QMG (Qingmuguan) model-V1.0—was developed in the present study. Other commonly
110 used karst groundwater models with complex structure and parameters—such as the
111 aforementioned MODFLOW-CFPM1 model—require a lot of hydrogeological data for
112 modelling in karst areas (Qin and Jiang, 2014). The new QMG model has a high potential
113 for application in karst hydrological simulation and forecasting. It has certain advantages in
114 its framework and structural design, having a double-layer structure and fewer parameters.
115 The horizontal structure is divided into river channel units and slope units, and the vertical
116 structure below the surface is divided into a shallow karst aquifer and a deep karst aquifer
117 system. This relatively simple model structure reduces the demand for modelling data in
118 karst areas, and only a small amount of hydrogeological data is needed for modelling. To
119 ensure that the QMG model works well in karst flood simulation and prediction despite its
120 relatively simple structure and parameters, we carefully designed the algorithms for runoff
121 generation and confluence in the model. Also, to verify the applicability of the QMG model
122 to flood simulation in karst basins, we selected the Qingmuguan karst trough valley in
123 Chongqing, China as the study area for a flood simulation and uncertainty analysis. In
124 particular, we analysed the sensitivity of the model parameters.

125 **2 Study area and data**

126 **2.1 Landform and topography**

127 The Qingmuguan karst trough valley is located in the southeastern part of the Sichuan Basin,
128 China at the junction of the Beibei and Shapingba districts in Chongqing, with the
129 coordinates of 29°40'N–29°47'N, 106°17'E–106°20'E. The basin covers an area of 13.4 km²
130 and is part of the southern extension of the anticline at Wintang Gorge in the Jinyun
131 Mountains, with the anticlinal axis of Qingmuguan located in a parallel valley in eastern

132 Sichuan (Yang et al., 2008). The surface of the anticline is heavily fragmented, and faults
133 are extremely well developed with large areas of Triassic carbonate rocks exposed. Under
134 the long-term erosion of karst water, a typical karst trough landform has formed (Liu et al.,
135 2009). This karst trough landform provides convenient conditions for flood propagation, and
136 the development of karst landforms is extremely common in the karst region of southwest
137 China, especially in the karst region of Chongqing.

138 The basin is oriented in a narrow band of slightly curved arcs and is ~12 km long from
139 north to south. The direction of the mountains in the region is generally consistent with the
140 direction of the tectonic line. The map in Figure 1 gives an overview of the Qingmuguan
141 karst basin.

142 **Figure 1.** The Qingmuguan karst basin.

143 **2.2 Hydrogeological conditions**

144 The Qingmuguan basin is located within the subtropical humid monsoon climate zone, with
145 an average temperature of 16.5 °C and an average precipitation of 1250 mm concentrated
146 mainly in May–September. An underground river system has developed in the karst trough
147 valley, with a length of 7.4 km, and the water supply of the underground river is mainly
148 rainfall recharge (Zhang, 2012). Most of the precipitation is collected along the hill slope
149 into the karst depressions at the bottom of the trough valley, where it is recharged to the
150 underground river through the dispersed infiltration of surface karst fissures and sinkholes
151 (Fig. 1a). An upstream surface river collects in a gentle valley and enters the underground
152 river through the Yankou sinkhole (elevation 524 m). Surface water in the middle and lower
153 reaches of the river system enters the underground river system mainly through cover
154 collapse sinkholes (Gutierrez et al., 2014) or fissures.

155 The stratigraphic and lithologic characteristics of the basin are dominated largely by
156 carbonate rocks of the Lower Triassic Jialingjiang Group (T_{1j}) and Middle Triassic Leikou
157 Slope Group (T_{2l}) on both sides of the slope, with some quartz sandstone and mudstone
158 outcrops of the Upper Triassic Xujiahe Group (T_{3xj}) (Zhang, 2012). The topography of the

159 basin presents a general anticline (Fig. 1b), where carbonate rocks on the surface are
160 corroded and fragmented, high permeability. Compared with the core of the anticline, the
161 shale of the anticline are less eroded and form a good waterproof layer.

162 To investigate the distribution of karst conduits in the underground river system, we
163 conducted a tracer test in the study area. The tracer was placed into the Yankou sinkhole and
164 recovered in the Jiangjia spring (Fig. 1a,c). According to the tracer test results (Gou et al.,
165 2010), the karst water-bearing medium in the aquifer was anisotropic, and the karst conduits
166 in the underground river were extremely well developed, and there was a large
167 single-channel underground river about five meters wide. The response of the underground
168 river to rainfall was very fast, with the peak flow observed at the outlet of Jiangjia spring
169 6–8 h after rainfall based on the tracer test results. The flood peak rose quickly and the
170 duration of the peak flow was short. The underground river system in the study area is
171 dominated by large karst conduits, which is not conducive to water storage in water-bearing
172 media, but is very conducive to the propagation of floods.

173 **2.3 Data**

174 To build the QMG model to simulate the karst flood events, the necessary modelling
175 baseline data had to be collected, including: 1) high-resolution DEM data and
176 hydrogeological data (e.g., the thickness of the epikarst zone, rainfall infiltration coefficient
177 on different karst landforms, and permeability coefficient of rock); 2) land-use and soil type
178 data; and 3) rainfall data in the basin and water flow data of the underground river. The
179 DEM data was downloaded from a free database on the public Internet, with an initial spatial
180 resolution of 30×30 m. The spatial resolution of landuse and soil types were 1000×1000
181 m, and they were also downloaded from the Internet. After considering the applicability of
182 modelling and computational strength, as well as the size of the basin in the study area (13.4
183 km^2), the spatial resolution of the three types of data was resampled uniformly in the QMG
184 model and downscaled to 15×15 m based on a spatial discrete method by Berry et. (2010).

185 The hydrogeological data necessary for modelling was obtained in three simple ways. 1)
186 A basin survey was conducted to obtain the thickness of the epikarst zone, which was

187 achieved by observing the rock formations on hillsides following cutting for road
188 construction. Information was collected regarding the location, general shape, and size of
189 karst depressions and sinkholes, which had a significant impact on compiling the DEM data
190 and determining the convergence process of surface runoff. And the sinkholes in the basin
191 are cover collapse sinkholes (Gutierrez et al., 2014) according to the basin survey. There are
192 3 large sinkholes (more than 3 meters in diameter) and 12 small sinkholes less than 1 meter
193 in diameter. The rest of the sinkholes between 1 and 3 meters in diameter are 5 in total.
194 The confluence calculation of these sinkholes in the model was based on the results of
195 previous study (Meng et al., 2009). 2) Empirical equations developed for similar basins were
196 used to obtain the rainfall infiltration coefficient for different karst landforms and the
197 permeability coefficient of rock. For example, the rock permeability coefficient was
198 calculated based on an empirical equation from a pumping test in a coal mine in the study
199 area (Li et al., 2019). 3) A tracer experiment was conducted in the study area (Gou et al.,
200 2010) to obtain information on the underground river direction and flow velocity, for
201 instance, underground karst conduits are well developed in the area, which form an
202 underground river about five meters wide. There is no hydraulic connection between the
203 underground river system in the area and the adjacent basin, means there is no overflow
204 recharge.

205 Rainfall and flood data are important model inputs, and represent the driving factors
206 that allow hydrological models to operate. In the study area, rainfall data was acquired by
207 two rain gauges located in the basin (Fig. 1a). Point rainfall was then spatially interpolated
208 into basin-level rainfall (for such a small basin area rainfall results obtained from two rain
209 gauges was considered representative). There were 18 karst flood events in the period of 14
210 April 2017 to 10 June 2019. We built a rectangular open channel at the underground river
211 outlet and set up a river gauge on it (Fig. 1a) to record the water level and flow data every 15
212 minutes.

213 **3 Methodology**

214 **3.1 Hydrological model framework and algorithms**

215 The hydrological model developed in this study was named the QMG model after the basin
216 for which it was developed and to which it was first applied, i.e. the Qingmuguan basin. The
217 QMG model has a two-layer structure, including a surface part and an underground part. The
218 surface structure mainly performing the calculation of runoff generation and the confluence
219 of the surface river, while the underground structure performs the confluence calculation
220 of the underground river system.

221 The structure of the QMG model is divided into a two-layer structure, both horizontally
222 and vertically. The horizontal structure of the model is divided into river channel units and
223 slope units. The vertical structure below the surface is divided into a shallow karst aquifer
224 (including soil layers, karst fissures and conduit systems in the epikarst zone) and a deep
225 karst aquifer system (bedrock and underground river system). This relatively simple model
226 structure means that only a small amount of hydrogeological data is needed in karst regions.
227 Figure 2 shows a flowchart of the modelling and calculation procedures required for the
228 QMG model.

229 **Figure 2.** Modelling flow chart of QMG (Qingmuguan) model.

230 To describe accurately the runoff generation and confluence on a grid scale, these karst
231 sub-basins are further divided into many karst hydrological response units (KHRUs) based
232 on the high-resolution (15×15 m) DEM data in the model. The specific steps involved in
233 the division were adopted by referring to studies of hydrological response units (HRUs) in
234 TOPMODEL by Pan (2014). As the smallest basin computing units, the KHRUs can
235 effectively ignore the spatial differences of karst development within the units and reduce
236 the uncertainty in the classification of model units. Figure 3 shows the spatial structure of
237 the KHRUs.

238 **Figure 3.** Spatial structure of karst hydrological response units (KHRUs) (Li et al., 2021).

239 The right-hand side of Figure 3 shows a three-dimensional spatial model of KHRUs
240 established in the laboratory to reflect visually the storage and movement of water in the

241 karst water-bearing medium with each spatial anisotropy, and to provide technical support
 242 for establishing the hydrological model.

243 The modelling and operation of the QMG model consists of three main stages: 1)
 244 spatial interpolation, and the retention of rainfall and evaporation calculations; 2) runoff
 245 generation and confluence calculation for the surface river; and 3) confluence calculation for
 246 the underground runoff, including the confluence in the shallow karst aquifer and the
 247 underground river system.

248 3.1.1 Rainfall and evaporation calculation

249 In the QMG model, the spatial interpolation of rainfall is accomplished by a kriging method
 250 using the ArcGIS 10.2 software. The Tyson polygon method may be a simpler method for
 251 rainfall interpolation if the number of rainfall gauges in the basin is sufficient. The point
 252 rainfall observed by the two rainfall gauges in the basin (Fig. 1a) was interpolated spatially
 253 into areal rainfall for the entire basin.

254 Basin evapotranspiration in the KHRUs was mainly vegetal, soil evaporation and water
 255 surface evaporation. They were calculated using the following equations (modified from Li
 256 et al., 2020):

$$\begin{cases}
 E_v = V^{t+\Delta t} - V^t - P_v \\
 E_s = \lambda E_p, \text{ if } F = F_c \\
 E_s = \lambda E_p \frac{F}{F_c}, \text{ if } F < F_{\text{sat}} \\
 E_w = \Delta e \cdot \left[1.12 + 0.62(\Delta T)^{0.9} \right] \cdot \left[0.084 + 0.24(1 - \gamma^2)^{1/2} \right] \cdot \left[0.348 + 0.5\omega^{1.8-1.137\omega^{0.05}} \right]
 \end{cases} \quad (1)$$

258 Here, E_v [mm] is the vegetal discharge, $V^{t+\Delta t} - V^t$ [mm] is the rainfall variation by
 259 vegetation interception, P_v [mm] is the vegetation interception of rainfall and E_s [mm]
 260 is the actual soil evaporation. The term λ is the evaporation coefficient. The term E_p
 261 [mm] is the evaporation capability, which can be measured experimentally or estimated
 262 by the water surface evaporation equation E_w . The term F [mm] is the actual soil
 263 moisture, F_{sat} [mm] is the saturation moisture content, F_c [mm] is the field capacity, E_w
 264 [mm/d] is the evaporation of the water surface and $\Delta e = e_0 - e_{150}$ [hPa] is the draught

265 head between the saturation vapour pressure of the water surface and the air vapour
 266 pressure 150 m above the water surface. The term $\Delta T = t_0 - T_{150}$ [°C] is the temperature
 267 difference between the water surface and the temperature 150 m above the water
 268 surface, γ is the relative humidity 150 m above the water surface and ω [m/s] is the
 269 wind speed 150 m above the water surface.

270 3.1.2 Runoff generation

271 In the QMG model, the surface runoff generation in river channel units means the rainfall in
 272 the river system after deducting evaporation losses. This portion of the runoff will
 273 participate in the confluence process directly through the river system, rather than
 274 undergoing infiltration. In contrast, the process of runoff generation in slope units is more
 275 complex, and its classification is related to the developmental characteristics of surface karst
 276 in the basin, rainfall intensity and soil moisture. For example, when the soil moisture content
 277 is already saturated, there is the potential for excess infiltration surface runoff in exposed
 278 karst slope units. The surface runoff generation of the KHRUs in the river channel units and
 279 slope units can be described by the following equations (modified from Chen, 2009, 2018;
 280 Li et al., 2020):

$$281 \begin{cases} P_r(t) = [P_i(t) - E_p] \frac{L \cdot W_{\max}}{A} \\ R_{si} = (P_i - f_{\max}), P_i \geq f_{\max} \\ R_{si} = 0, P_i < f_{\max} \\ f_{\max} = \alpha(F_c - F)^\beta + F_s \end{cases} \quad (2)$$

282 Here, $P_r(t)$ [mm] is the net rainfall (deducting evaporation losses) in the river channel units
 283 at time t [h], $P_i(t)$ [mm] is the rainfall in the river channel units, L [m] is the length of the
 284 river channel, W_{\max} [m] is the maximum width of the river channel selected and A [m²] is
 285 the cross-sectional area of the river channel. R_{si} [mm] is termed the excess infiltration runoff
 286 in the QMG model, when the vadose zone is short of water and has not been filled. The
 287 infiltration capacity f_{\max} is different in different karst landform units, α , β are the parameters
 288 of the Holtan model and F_s [mm] is the stable depth of soil water infiltration.

289 In the KHRUs (Fig. 3), underground runoff is generated primarily from the infiltration

290 of rainwater and direct confluence recharge from sinkholes or skylights. In the QMG model,
 291 the underground runoff is calculated by the following equations (modified from Chen,
 292 2018):

$$293 \quad \begin{cases} R_g = R_0 \exp(-pt^m) \\ R_e = v_e \cdot I_w \cdot z \end{cases} \quad (3)$$

294 where

$$295 \quad \begin{cases} \frac{\partial R_e}{\partial x} + I_w \cdot z \cdot \frac{\partial F}{\partial t} = R_r - R_{\text{epi}} \\ v_e = K \cdot \tan(\alpha), \quad F > F_c \\ v_e = 0, \quad F \leq F_c \end{cases} \quad (4)$$

296 Here, R_g [mm] is the underground runoff depth (this part of the underground runoff is mainly
 297 from the direct confluence supply of the karst sinkholes or karst windows in the study area),
 298 R_0 [mm] is the average depth of the underground runoff, p and m are attenuation coefficients
 299 calculated by conducting a tracer test in the study area, R_e [L/s] is the underground runoff
 300 generated from rainfall infiltration in the epikarst zone, I_w [mm] is the width of the
 301 underground runoff on the KHRUs, z [mm] is the thickness of the epikarst zone, R_r [mm²/s]
 302 is the runoff recharge on the KHRUs during period t , R_{epi} [mm²/s] is the water infiltration
 303 from rainfall, v_e [mm/s] is the flow velocity of the underground runoff, K [mm/s] is the
 304 current permeability coefficient and α is the hydraulic gradient of the underground runoff.
 305 If the current soil moisture is less than the field capacity, i.e. $F \leq F_c$, then the vadose zone
 306 is not yet full, there will be no underground runoff generation, and rainfall infiltration at this
 307 time will continue to compensate for the lack of water in the vadose zone until it is full and
 308 before runoff is generated.

309 **3.1.3 Channel routing and confluence**

310 In the QMG model, the calculation of runoff confluence on the KHRUs includes the
 311 confluence of surface river channel and underground runoff. There are already many mature
 312 and classical algorithms available for calculating the runoff confluence in river channel units

313 and slope units, such as the Saint-Venant equations and Muskingum convergence model. In
 314 this study, the Saint-Venant equations were adopted to describe the confluence in the surface
 315 river and hill slope units, for which a wave movement equation was adopted to calculate
 316 confluence in slope units (Chen, 2009):

$$317 \quad \begin{cases} \frac{\partial Q}{\partial x} + L \frac{\partial h}{\partial t} = q \\ S_f - S_0 = 0 \end{cases} \quad (5)$$

318 where

$$319 \quad Q = v h L = \frac{L}{n} h^{\frac{5}{3}} S_0^{\frac{1}{2}}. \quad (6)$$

320 Here, we customized two variables a and b :

$$321 \quad \begin{cases} a = \left(\frac{n}{L} S_0^{-\frac{1}{2}}\right)^{\frac{3}{5}} \\ b = \frac{3}{5} \end{cases} \quad (7)$$

322 Equation (7) was substituted into Eq. (5) and discretized by a finite-difference method,
 323 giving

$$324 \quad \begin{cases} \frac{\partial Q}{\partial x} + abQ^{(b-1)} \frac{\partial Q}{\partial t} - q = 0 \\ \frac{\Delta t}{\Delta x} Q_{i+1}^{t+1} + a(Q_{i+1}^{t+1})^b = \frac{\Delta t}{\Delta x} Q_i^{t+1} + a(Q_{i+1}^t)^b + q_{i+1}^{t+1} \Delta t \end{cases} \quad (8)$$

325 The Newton–Raphson method was used for the iterative calculation using Eq. (8):

$$326 \quad [Q_{i+1}^{t+1}]^{k+1} = [Q_{i+1}^{t+1}]^k - \frac{\frac{\Delta t}{\Delta x} [Q_{i+1}^{t+1}]^k + a([Q_{i+1}^{t+1}]^k)^b - \frac{\Delta t}{\Delta x} Q_i^{t+1} - a(Q_{i+1}^t)^b - q_{i+1}^{t+1} \Delta t}{\frac{\Delta t}{\Delta x} + ab([Q_{i+1}^{t+1}]^k)^{b-1}}, \quad (9)$$

327 where Q [L/s] is the confluence of water flow in slope units, L [dm] is its runoff width, h
 328 [dm] is the runoff depth and q [dm²/s] is the lateral inflow on the KHRUs. Here, the friction
 329 slope S_f equals the hill slope S_0 , and the inertia term and the pressure term in the motion
 330 equation of the Saint-Venant equations were ignored. The term v [dm/s] is the flow velocity
 331 of surface runoff in the slope units as calculated by the Manning equation, n is the roughness

332 coefficient of the slope units, Q_i^{t+1} [L/s] is the slope inflow in the KHRU at time $t+1$ and
 333 Q_{i+1}^{t+1} [L/s] is the slope discharge in the upper adjacent KHRU at time $t+1$.

334 Similarly, the surface river channel confluence was described based on the
 335 Saint-Venant equation, where a diffusion wave movement equation was adopted, meaning
 336 that the inertia term in the motion equation was ignored:

$$337 \quad \begin{cases} \frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = q \\ S_f = S_0 - \frac{\partial h}{\partial x} \end{cases} \quad (10)$$

338 A finite-difference method and the Newton–Raphson method were used for the iterative
 339 calculation of the above equation:

$$340 \quad \begin{cases} [Q_{i+1}^{t+1}]^{k+1} = [Q_{i+1}^{t+1}]^k - \frac{\frac{\Delta t}{\Delta x} [Q_{i+1}^{t+1}]^k + c([Q_{i+1}^{t+1}]^k)^b - \frac{\Delta t}{\Delta x} Q_i^{t+1} - c(Q_{i+1}^t)^b - q_{i+1}^{t+1} \Delta t}{\frac{\Delta t}{\Delta x} + cb([Q_{i+1}^{t+1}]^k)^{b-1}} \\ c = \left(\frac{1}{3600} n \chi^{\frac{2}{3}} S_f^{-\frac{1}{2}} \right)^{\frac{3}{5}} \end{cases} \quad (11)$$

341 where Q [L/s] is the water flow in surface river channel units, A [dm²] is the discharge
 342 section area, c is a custom intermediate variable and χ [dm] is the wetted perimeter of the
 343 discharge section area.

344 The underground runoff in the model includes the confluence of the epikarst zone and
 345 underground river. In the epikarst zone, the karst water-bearing media are highly
 346 heterogeneous (Williams, 2008). For example, the anisotropic karst fissure systems and
 347 conduit systems consist of the corrosion fractures. When rainfall infiltrates into the epikarst
 348 zone, water moves slowly through the small (less than 10cm in this study) karst fissure
 349 systems, while it flows rapidly in larger (more than 10cm) conduits. The key to determining
 350 the confluence velocity lies in the width of karst fractures. In the KHRUs (Fig. 3), the 10-cm
 351 width of the fracture was used as a threshold value (Atkinson, 1977) based on the borehole
 352 pumping test in the basin, meaning that if the fracture width exceeded 10 cm, then the water
 353 movement into it was defined as rapid flow; otherwise, it was defined as slow flow. The

354 confluence in the epikarst zone was calculated by the following equation (modified from
 355 Beven and Binley, 2006):

$$356 \quad Q(t)_{ijk} = b_{ijk} \cdot \frac{\Delta h}{\Delta l} R_i C_j \cdot T(t)_{\text{slow/rapid}} \quad (12)$$

357 where

$$358 \quad \begin{cases} T(t)_{\text{slow}} = nr \frac{\rho g R_i C_j L_k}{12\nu} \\ T(t)_{\text{rapid}} = \frac{K_{ij} (e^{-f_{ij} h_{ij}} - e^{-f_{ij} z_{ij}})}{f_{ij}} \end{cases} \quad (13)$$

359 Here, $Q(t)_{ijk}$ [L/s] is the flow confluence in the epikarst zone at time t , b_{ijk} [dm] is the
 360 runoff width, $\frac{\Delta h}{\Delta l}$ is the dimensionless hydraulic gradient, $T(t)_{\text{slow/rapid}}$ is the
 361 dimensionless hydraulic conductivity, ρ [g/L] is the density of the water flow, g [m/s²] is
 362 gravitational acceleration, n is the valid computational units, $R_i C_j L_k$ [L] is the volume of
 363 the ijk -th KHRU, ν is the kinematic viscosity coefficient, f_{ij} is the attenuation coefficient in
 364 the epikarst zone, h_{ij} [dm] is the depth of shallow groundwater and z_{ij} [dm] is the thickness
 365 of the epikarst zone.

366 The distinction between rapid and slow flows in the epikarst zone is not absolute. The
 367 10-cm width of a karst fracture as the dividing threshold is underrepresented due to the only
 368 five limited boreholes have been tested for pumping in the region. In fact, there is usually
 369 water exchange between the rapid and slow flows at the junction of large and small fissures
 370 in karst aquifers. In the QMG model, this water exchange can be described with this
 371 equation (modified form Li et al., 2021):

$$372 \quad \begin{cases} Q = \alpha_{i,j,k} (h_n - h_{i,j,k}) \\ \alpha_{i,j,k} = \sum_{ip=1}^{np} \frac{(K_w)_{i,j,k} \pi d_{ip} \frac{1}{2} (\Delta l_{ip} \tau_{ip})}{r_{ip}} \end{cases} \quad (14)$$

373 Here, $\alpha_{i,j,k}$ [dm²/s] is the water exchange coefficient in the ijk -th KHRU, $(h_n - h_{i,j,k})$
 374 [dm] is the water head difference between the rapid and slow flows at the junction of large

375 and small fissures in KHRUs, np is the number of fissure systems connected to the adjacent
 376 conduit systems, $(K_w)_{i,j,k}$ [dm/s] is the permeability coefficient at the junction of a fissure
 377 and conduit, d_{ip} and r_{ip} [dm] are the conduit diameter and radius, respectively, Δl_{ip}
 378 [dm] is the length of the connection between conduits i and p , and τ_{ip} is the conduit
 379 curvature. Some of the parameters in this equation, such as $(K_w)_{i,j,k}$ and $(h_n - h_{i,j,k})$,
 380 were obtained by conducting an infiltration test in the study area.

381 The confluence of the underground river system plays an important role for the
 382 confluence at the basin outlet. To facilitate the calculation of confluence in the QMG model,
 383 the underground river systems can be generalized into large multiple conduit systems.
 384 During floods, these conduit systems are mostly under pressure. Whether the water flow is
 385 laminar or turbulent depends on the flow regime at that time. The water flow into these
 386 conduits is calculated by the Hagen–Poiseuille equation and the Darcy–Weisbach equation
 387 (Shoemaker et al., 2008):

$$\left\{ \begin{array}{l} Q_{\text{laminar}} = -A \frac{gd^2 \partial h}{32\nu \partial x} = -A \frac{\rho g d^2 \Delta h}{32\mu\tau\Delta l} \\ Q_{\text{turbulent}} = -2A \sqrt{\frac{2gd|\Delta h|}{\Delta l\tau}} \log \left(\frac{H_c}{3.71d} + \frac{2.51\nu}{d \sqrt{\frac{2gd^3|\Delta h|}{\Delta l\tau}}} \right) \frac{\Delta h}{|\Delta h|} \end{array} \right. \quad (15)$$

389 Here, Q_{laminar} [L/s] is the water flow of the laminar flow in the conduit systems, A [dm²] is
 390 the conduit cross-sectional area, d [dm] is the conduit diameter, ρ [kg/dm³] is the density
 391 of the underground river, $\nu = \mu / \rho$ is the coefficient of kinematic viscosity, $\Delta h / \tau \Delta l$ is
 392 the hydraulic slope of the conduits, τ is the dimensionless conduit curvature, $Q_{\text{turbulent}}$ [L/s]
 393 is the turbulent flow in the conduit systems and H_c [dm] is the average conduit wall height.

394 3.2 Parameter optimization

395 In total, the QMG model has 12 parameters, of which flow direction and slope are

396 topographic parameters that can be determined from the DEM without parametric
397 optimization, while the remaining 10 parameters require calibration. Other distributed
398 hydrological models with multiple structures usually have many parameters. For example,
399 the Karst–Liuxihe model (Li et al., 2021) has 15 parameters that must be calibrated. In the
400 QMG model, each parameter is normalized as

$$401 \quad x_i = x_i^* / x_{i0}, \quad (16)$$

402 where x_i is the dimensionless parameter value i after it is normalized, x_i^* is the parameter
403 value i in actual physical units, and x_{i0} is the initial or final value of x_i . Through the
404 processing of Eq. (16), the value range of the model parameters is limited to a hypercube
405 $K_n = (X \mid 0 \leq x_i \leq 1, i = 1, 2, \dots, n)$, K is a dimensionless value. This normalized treatment
406 ignores the influence of the spatiotemporal variation of the underlying surface attributes on
407 the parameters, while also simplifying the classification and number of the model parameters
408 to a certain extent. Accordingly, the model parameters can be divided further into
409 rainfall-evaporation ones, epikarst-zone ones and underground-river ones. Table 1 lists the
410 parameters of the QMG model.

411 **Table 1.** Parameters of QMG model.

412 Because the QMG model has relatively few parameters, it is possible to calibrate them
413 manually, which has the advantage that the operation is easy to implement and does not
414 require a special program for parameter optimization. However, the disadvantage is that it is
415 subjective, which can lead to great uncertainty in the manual parameter calibration process.
416 To compare the effects of parameter optimization on model performance, this study used
417 both manual parameter calibration and the improved chaotic particle swarm optimization
418 algorithm (IPSO) for the automatic calibration of model parameters, and compared the
419 effects of both on flood simulation.

420 In general, the structure and parameters of a standard particle swarm optimization
421 algorithm (PSO) are simple, with the initial parameter values obtained at random. For
422 parameter optimization in high-dimensional multi-peak hydrological models, the standard
423 PSO is easily limited to a local convergence and cannot achieve the optimal effect, while the

424 late evolution of the algorithm may also cause problems, such as precocity and stagnant
 425 evolution, due to the ‘inert’ aggregation of particles, which seriously affects the efficiency of
 426 parameter selection. It is necessary to overcome the above problems and make the algorithm
 427 converge to the global optimal solution with a high probability. In parameter optimization
 428 for the QMG model, we improved the standard PSO algorithm by adding chaos theory, and
 429 developed the IPSO, where 10 cycles of chaotic disturbances were added to improve the
 430 activity of the particles. The inverse mapping equation of the chaotic variable is

$$431 \quad \begin{cases} X_{ij} = X_{\min} + (X_{\max} - X_{\min}) * Z_{ij} \\ Z'_{ij} = (1 - \alpha)Z^* + \alpha Z_{ij} \end{cases} \quad (17)$$

432 where X_{ij} is the optimization variable for the model parameters, $(X_{\max} - X_{\min})$ is the
 433 difference between its maximum and its minimum, Z_{ij} is the variable before the disturbance is
 434 added and Z'_{ij} represents the chaotic variables after a disturbance is added, α is a variable
 435 determined by the adaptive algorithm, $0 \leq \alpha \leq 1$, and Z^* is the chaotic variable formed when
 436 the optimal particle maps to the interval [0,1]. In parameter optimization, the flowchart of the
 437 IPSO is shown in Figure 4.

438 **Figure 4.** Algorithm flow chart of IPSO.

439 3.3 Uncertainty analysis

440 Uncertainties in hydrological model simulation results usually originate from three aspects:
 441 input data, model structure and model parameters (Krzysztofowicz, 2014). In the present
 442 study, the input data (e.g. rainfall, flood events and some hydrogeological data) were first
 443 validated and pre-processed through observations to reduce their uncertainties.

444 Second, we simplified the structure of the QMG model to reduce the structural
 445 uncertainty. As a mathematical and physical model, a hydrological model has some
 446 uncertainty in flood simulation and forecasting because of the errors in system structure and
 447 the algorithm (Krzysztofowicz and Kelly, 2000). The model was designed with full
 448 consideration of the relationship between the amount of data required to build the model and

449 its performance for flood simulation and forecasting in karst regions, and the model's entire
 450 framework was integrated through simple structures and easy-to-implement algorithms,
 451 using the concept of distributed hydrological modelling. Conventionally, the extent of
 452 uncertainty is increased with the growing complexity of the model structure. We therefore
 453 ensured that the structure of the QMG model was simple when it was designed, and the
 454 model was divided into surface and underground double-layer structures to reduce its
 455 structural uncertainty.

456 Third, we focus on analysing the uncertainty and sensitivity of the model parameters
 457 and their optimization method, for which a multi-parametric sensitivity analysis method
 458 (Choi et al., 1999; Li et al., 2020) was used to analyse the sensitivity of the parameters in the
 459 QMG model. The steps in the parameter sensitivity analysis are as follows.

460 1) Selection of appropriate objective function

461 The Nash–Sutcliffe coefficient is widely used as the objective function to evaluate the
 462 performance of hydrological models (Li et al., 2020, 2021). It was therefore used to assess
 463 the QMG model. Because the most important factor in flood forecasting is the peak
 464 discharge, it is used in the Nash coefficient equation:

$$465 \quad NSC = 1 - \frac{\sum_{i=1}^n (Q_i - Q_i')^2}{\sum_{i=1}^n (Q_i - \bar{Q})^2}, \quad (18)$$

466 where NSC is the Nash–Sutcliffe coefficient, Q_i [L/s] are the observed flow discharges, Q_i'
 467 [L/s] are the simulated discharges, \bar{Q} [L/s] is the average observed discharge and n [h] is
 468 the observation period.

469 2) Parameter sequence sampling

470 The Monte Carlo sampling method was used to sample 8000 groups of parameter
 471 sequences. The parametric sensitivity of the QMG model was analysed and evaluated by
 472 comparing the differences between the a priori and a posteriori distributions of the
 473 parameters.

474 3) Parameter sensitivity assessment

475 The a priori distribution of a model parameter means its probability distribution, while
476 the a posteriori distribution refers to the conditional distribution calculated after sample
477 sampling, and it can be calculated based on the simulation result of the parametric
478 optimization. If there is a significant difference between the priori distribution and its
479 posteriori distribution of the parameter, then the parameter being tested has a high sensitivity,
480 whereas if there is no obvious difference, then the parameter is insensitive. The parametric
481 priori distribution is calculated as

$$482 \begin{cases} P_{i,j}(NSC_{i,j} \geq 0.85) = \frac{n}{N+1} \times 100 \\ \sigma_i = \sum_{j=1}^n (P_{i,j} - \overline{P_{i,j}})^2 \end{cases} \quad (19)$$

483 where $P_{i,j}$ is the a priori distribution's probability when $NSC_{i,j} \geq 0.85$. We used a
484 simulated Nash coefficient of 0.85 as the threshold value, and n was the number of
485 occurrences of a Nash coefficient greater than 0.85 in flood simulations. In each simulation,
486 only a certain parameter was changed, while the remaining parameters remained unchanged.
487 If the Nash coefficient of this simulation exceeded 0.85, then the flood simulation results
488 were considered acceptable. The term σ_i is the difference between the acceptable value
489 and its mean, which represents the parametric sensitivity ($0 < \sigma_i < 1$). The higher the σ_i
490 value, the more sensitive the parameter. N is the 8000 parameter sequences, and $\overline{P_{i,j}}$ is the
491 average value of the a priori distribution.

492 3.4 Model Setting

493 Once the model was built, some of the initial conditions had to be set before running it
494 to simulate and forecast floods, such as basin division, the setting of initial soil moisture, and
495 the assumption of the initial parameter range. 1) In the study area, the entire Qingmuguan
496 karst basin was divided into 893 KHRUs, including 65 surface river units, 466 hill slope
497 units, and 362 underground river units. The division of these units formed the basis for
498 calculating the process of runoff generation and convergence. 2) The initial soil moisture

499 was set to 0–100% of the saturation moisture content in the basin, and the specific soil
500 moisture before each flood had to be determined by a trial calculation. 3) The waterhead
501 boundary conditions of the groundwater were determined by a tracer test in the basin, where
502 a perennial stable water level adjacent the groundwater-divide was used as the fixed
503 waterhead boundary. The base flow of the underground river was determined to be 35 L/s
504 from the perennial average dry season runoff. 4) The range of initial parameters and
505 convergence conditions were assumed before parameter optimization (Figure 4). 5)
506 Parameter optimization and flood simulation validated the performance of the QMG model
507 in karst basins.

508 **4 Results and discussion**

509 **4.1 Parameter Sensitivity Results**

510 The number of parameters in a distributed hydrological model is generally large, and it
511 is important to perform a sensitivity analysis of each parameter to quantitatively assess the
512 impact of the different parameters on model performance. In the QMG model, each
513 parameter was divided into four categories according to its sensitivity: (i) highly sensitive,
514 (ii) sensitive, (iii) moderately sensitive, and (v) insensitive. In the calibration of model
515 parameters, insensitive ones do not need to be calibrated, which can greatly reduce the
516 amount of calculation and improve the efficiency of model operation.

517 The flow process in the calibration period (14 April to 10 May 2017) was adopted to
518 calculate the sensitivity of the model parameters, for which the calculation principle was
519 equation (19), and the parameter sensitivity results are calculated in Table 2.

520 Table 2 Parametric sensitivity results in QMG model.

521 In Table 2, the value of σ_i [equation (19)] represents a parameter's sensitivity, and the
522 higher the value, the more sensitive the parameter is. From the results in Table 2, it was
523 found that the rainfall infiltration coefficient, rock permeability coefficient, rock porosity,
524 and the related parameters of soil water content, such as the saturated water content, and
525 field capacity, were sensitive parameters. The order of parameter sensitivity was as follows:
526 infiltration coefficient > permeability coefficient > rock porosity > specific yield > saturated

527 water content > field capacity > flow direction > thickness > slope > Soil coefficient >
528 channel roughness > evaporation coefficient.

529 In the QMG model, parameters are classified as highly sensitive, sensitive, moderately
530 sensitive, and insensitive according to their influence on the flood simulation results. In
531 Table 4, we divided the sensitivity of model parameters into four levels based on the σ_i
532 value: 1) highly sensitive parameters, $0.8 < \sigma_i < 1$; 2) sensitive parameters, $0.65 < \sigma_i < 0.8$;
533 3) moderately sensitive parameters, $0.45 < \sigma_i < 0.65$; and 4) insensitive parameters,
534 $0 < \sigma_i < 0.45$. The highly sensitive parameters were the infiltration coefficient, permeability
535 coefficient, rock porosity, and specific yield. The sensitive parameters were the saturated
536 water content, field capacity, and thickness of the epikarst zone. The moderately sensitive
537 parameters were flow direction, slope, and soil coefficient. The insensitive parameters were
538 channel roughness and the evaporation coefficient.

539 **4.2 Parametric Optimization**

540 In total, the QMG model has 12 parameters, of which only eight need to be optimized,
541 which is relatively few for distributed models. The parameters of flow direction and slope as
542 well as the insensitive parameters of channel roughness and the evaporation coefficient need
543 not be calibrated, which can improve the convergence efficiency of the model parameter
544 optimization.

545 In the study area, 18 karst floods during the period 14 April 2017 to 10 June 2019 were
546 recorded at the underground river outlet to validate the effects of the QMG model in karst
547 hydrological simulations. The calibration period was 14 April to 10 May 2017 at the
548 beginning of the flow process, with the remainder of the time being the validation period. In
549 the QMG model, the IPSO algorithm was used to optimize the model parameters. To show
550 the necessity of parameter optimization for the distributed hydrological model, the study
551 specifically compared the flood simulations obtained using the initial parameters of the
552 model (without parameter calibration) and the optimized parameters. Figure 5 shows the
553 iteration process of parameter optimization for the QMG model.

554

558

559

560

561

562

563

564

565

Figure 5 shows that almost all parameters fluctuated widely at the beginning of the optimization, and then after about 15 iterations of the optimization calculation, most of the linear fluctuations become significantly less volatile, which indicated that the algorithm tended to converge (possibly only locally). When the number of iterations exceeded 25, all parameters remained essentially unchanged, meaning that the algorithm had converged (at this point there was global convergence). It took only 25 iterations to reach a definite convergence of the parameter rates with this IPSO algorithm, which is extremely efficient in terms of the parameter optimization of distributed hydrological models. In previous studies of the parametric optimization for the Karst-Liuxihe model in similar basin areas, 50 automatic parameter optimization iterations were required to reach convergence (Li et al., 2021), demonstrating the effectiveness of the IPSO algorithm.

566

567

568

To evaluate the effect of parameter optimization, the convergence efficiency of the algorithm, and more importantly, the parameters after calibration were used to simulate floods. Figure 6 shows the flood simulation effects.

569

570

571

572

573

574

575

576

577

578

Figure 6 shows that the flows simulated by parameter optimization were better than those simulated by the initial model parameters. The simulated flow processes based on the initial parameters were relatively small, with the simulated peak flows in particular being smaller than the observed values, and there were large errors between the two values. In contrast, the simulated flows produced by the QMG model after parameter optimization were very similar to the observed values, which indicates that calibration of the model parameters is necessary and that there was an improvement in parameter optimization through the use of the IPSO algorithm in this study. In addition, it was found that the flow simulation effect was better in the calibration periods than in the validation periods (Fig. 6).

579

580

581

To compare the results of the flow processes simulation with the initial model parameters and the optimized parameters, six evaluation indices (Nash–Sutcliffe coefficient, correlation coefficient, relative flow process error, flood peak error, water balance

582 coefficient, and peak time error) were applied in this study, and the results are presented in
583 Table 3.

584 Table 3 Flood simulation evaluation index through parametric optimization.

585 Table 3 shows that the evaluation indices of the flood simulations after parametric
586 optimization were better than those of the initial model parameters. The average values of
587 the initial parameters for these six indices 0.81, 0.74, 27%, 31%, 0.80, and 5 h, respectively.
588 For the optimized parameters, the average values were 0.90, 0.91, 16%, 14%, 0.94, and 3 h,
589 respectively. The flood simulation effects after parameter optimization clearly improved,
590 implying that parameter optimization for the QMG model is necessary, and the IPSO
591 algorithm for parameter optimization is an effective approach that can greatly improve the
592 convergence efficiency of parameter optimization, and also ensure that the model performs
593 well in flood simulations.

594 **4.3 Model Validation in Flood Simulations**

595 Following parameter optimization, we simulated the whole flow process (14 April 2017
596 to 10 June 2019) based on the optimized and initial parameters of the QMG model (Fig. 6),
597 which enabled a visual reflection of the model used in the simulation of a long series of flow
598 processes. To reflect the simulation effect of the model for different flood events, we divided
599 the whole flow process into 18 flood events, then used the initial parameters of the model
600 and the optimized parameters, respectively, to verify the model performance in flood
601 simulations. Figure 7 and Table 4 show the flood simulation effects and their evaluation
602 indices using both the initial and the optimized parameters.

603 Figure 7 Flood simulation effects based on initial and optimized parameters.

604 Table 4 Flood simulation indices for model validation.

605 Figure 7 shows that the flood simulation results using the initial parameters were
606 smaller than the observed values, and the model performance improved in flood simulations
607 after parameter optimization. The simulated flood processes were in good agreement with
608 observations, and were especially effective for simulating flood peak flows. From flood
609 simulation indices in Table 4, the average water balance coefficient based on the initial

610 parameters was 0.69, i.e., much less than 1, indicating that the simulated water in the model
611 was unbalanced. After parameter optimization, the average value was 0.92, indicating that
612 parameter optimization had a significant impact on the model water balance calculation.

613 Table 4 shows that the average values of the six indices (Nash–Sutcliffe coefficient,
614 correlation coefficient, relative flow process error, flood peak error, water balance
615 coefficient, and peak time error) for the initial parameters were 0.79, 0.74, 26%, 25%, 0.69,
616 and 5 h, respectively, while for the optimized parameters the average values were 0.92, 0.90,
617 10%, 11%, 0.92, and 2 h, respectively. All evaluation indices improved after parameter
618 optimization, with the average values of the Nash coefficient, correlation coefficient, and
619 water balance coefficient increasing by 0.13, 0.16, and 0.23, respectively. The average
620 values of the relative flow process error, flood peak error, and peak time error decreased by
621 15%, 14%, and 3 h, respectively. These reasonable flood simulation results confirmed that
622 parameter optimization by the IPSO algorithm was necessary and effective for the QMG
623 model.

624 Compared with the overall flow process simulation shown in Figure 6, each flood
625 process was better simulated by the QMG model (Fig. 7). This was because in the function
626 of the QMG model and its algorithm design, the main consideration was the calculation of
627 the flood process, but the correlation algorithm of the dry season runoff was not described
628 well enough. For example, equations (12)–(15) are the flood convergence algorithm. As a
629 result, the model is not good at simulating other flow processes, such as dry season runoff,
630 leading to a low accuracy in the overall flow process. The next phase of our research will
631 focus on refining the algorithm related to dry season runoff and improving the
632 comprehensive performance of the model.

633 **4.4 Uncertainty analysis**

634 **4.4.1 Assessment and reduction of uncertainty**

635 In general, the uncertainty in model simulation is due mainly to three aspects of the model:
636 (i) the uncertainty of its input data, (ii) the uncertainty of its structure and algorithm and (iii)
637 the uncertainty of its parameters. In the practical application of a hydrological model, these

638 three uncertainties are usually interwoven, which leads to the overall uncertainty of the final
639 simulation results (Krzysztofowicz, 2014). Therefore, the present study focused on the
640 uncertainties in the input data, the model structure and the parameters to reduce the overall
641 uncertainty of the simulation results.

642 First, the input data—mainly rainfall-runoff data and hydrogeological data—were
643 pre-processed, which substantially reduced their uncertainty. Second, we simplified the
644 structure of the QMG model, which is reflected in the fact that it has only two layers of
645 spatial structure in the horizontal and vertical directions. This relatively simple structure
646 reduced greatly the uncertainty due to the model structure. In contrast, the underground
647 structure of our previous Karst–Liuxihe model (Li et al., 2021) has five layers, which leads
648 to great uncertainty. Third, appropriate algorithms for runoff generation and confluence were
649 selected. Different models were designed for different purposes, which leads to great
650 differences in the algorithms used. In the QMG model, most of the rainfall-runoff algorithms
651 used have been validated by the research results of others, and some of them were improved
652 to suit karst flood simulation and forecasting by the QMG model. For example, the
653 algorithm for the generation of excess infiltration runoff [Eq. (2)] was an improvement of
654 the version used in the Liuxihe model (Chen, 2009, 2018; Li et al., 2020). Finally, the
655 algorithm for parameter optimization was improved. Considering the shortcomings of the
656 standard PSO algorithm that tends to converge locally, this study developed the IPSO for
657 parameter optimization by adding chaotic perturbation factors. The flood simulation results
658 after parameter optimization were much better than those of the initial model parameters
659 (Figs. 6 and 7 and Tables 2 and 3), which indicates that parameter optimization is necessary
660 for a distributed hydrological model and can reduce the uncertainty of the model parameters.

661 **4.4.2 Parameter sensitivity analysis**

662 The parameter-sensitivity results in Table 2 show that the rainfall-infiltration coefficient in
663 the QMG model was the most sensitive parameter. It was the key to determining the
664 generation of excess infiltration surface runoff and separating surface runoff from subsurface
665 runoff. If the rainfall infiltration coefficient was greater than the infiltration capacity, excess
666 infiltration surface runoff was generated on the exposed karst landforms; otherwise, all

667 rainfall would infiltrate to meet the water deficit in the vadose zone, and then continue to
668 seep down into the underground river system, eventually flowing out of the basin through
669 the underground river outlet. The confluence modes of surface runoff and underground
670 runoff were completely different, resulting in a large difference in the simulated flow results.
671 Therefore, the rainfall infiltration coefficient had the greatest impact on the final flood
672 simulation results.

673 Other highly sensitive parameters such as the rock permeability coefficient, rock
674 porosity and specific yield were used as the basis for dividing between slow flow in karst
675 fissures and rapid flow in conduits. The division of slow and rapid flows also had a great
676 impact on the discharge at the outlet of the basin. Slow flow plays an important role in water
677 storage in a karst aquifer and is very important for the replenishment of river base flow in
678 the dry season. Rapid flow in large conduit systems dominates the flood runoff and is the
679 main component of the flood water volume in the flood season.

680 Parameters related to the soil water content, including the saturated water content, field
681 capacity and thickness, were sensitive parameters and had a large influence on the flood
682 simulation results. This is because the soil moisture content prior to flooding affects how
683 flood flows rise and when peaks occur. If the soil is already very wet or even saturated
684 before the flooding, the flood will rise quickly to reach a peak, and the process line of the
685 flood peak flow will be sharp and thin. This type of flood process forms easily and can lead
686 to disaster-causing flood events. In contrast, if the soil in the basin is very dry before the
687 flooding, the rainfall will first meet the water shortage of the vadose zone, and after it is
688 replenished the rainfall will infiltrate into the underground river. The flood peak of the river
689 basin outlet is therefore delayed.

690 The moderately sensitive parameters were flow direction, slope and the soil coefficient.
691 They had a specific influence on the flood simulation results, but the influence was not as
692 great as that of the highly sensitive and sensitive parameters. The insensitive parameters
693 were channel roughness and the evaporation coefficient. The amount of water lost by
694 evapotranspiration is very small in the total flood water, and it was therefore the least
695 sensitive parameter in the QMG model.

696 **5 Conclusions**

697 This study proposed a new distributed physically based hydrological model, i.e. the QMG
698 model, to simulate floods accurately in karst trough and valley landforms. The main
699 conclusions of this paper are as follows.

700 This QMG model has a high application potential in karst hydrology simulations. Other
701 distributed hydrological models usually have multiple structures, resulting in the need for a
702 large amount of data to build models in karst areas (Kraller et al., 2014). The QMG model
703 has only a double-layer structure, with a clear physical meaning, and a small amount of
704 basic data is needed to build the model in karst areas, such as some necessary
705 hydrogeological data. For example, the distribution and flow direction of underground rivers
706 is required, which can be inferred from a tracer test, leading to a low modelling cost. There
707 were fewer parameters in the QMG model than in other distributed hydrological models,
708 with only 10 parameters that needed to be calibrated.

709 The flood simulation after parameter optimization was much better than the simulation
710 using the initial model parameters. After parameter optimization, the average values of the
711 Nash coefficient, correlation coefficient and water balance coefficient increased by 0.13,
712 0.16 and 0.23, respectively, while the average relative flow process error, flood peak error
713 and peak time error decreased by 15%, 14% and 3 h, respectively. Parameter optimization is
714 necessary for a distributed hydrological model, and the improvement of the IPSO algorithm
715 in this study was an effective way to achieve this.

716 In the QMG model, the rainfall infiltration coefficient I_c , rock permeability coefficient
717 K , rock porosity R_p and the parameters related to the soil water content were sensitive
718 parameters. The order of parameter sensitivity was infiltration coefficient > permeability
719 coefficient > rock porosity > specific yield > saturated water content > field capacity > flow
720 direction > thickness > slope > soil coefficient > channel roughness > evaporation
721 coefficient.

722 This QMG model is suitable for karst trough and valley landform like this study area,
723 where the topography is conducive to the spread of flood water. Whether this model is

724 applicable to the karst areas of other landforms still needs to be verified in the future studies.
725 In addition, the basin area is very small, where the hydrological similarity between different
726 small basin areas varies greatly (Kong and Rui, 2003). The size of the area to be modelled
727 has a great influence on the choice of model spatial resolution (Chen et al., 2017). Therefore,
728 whether the QMG model is suitable for flood forecasting in large karst basins needs to be
729 determined.

730 **Model development.**

731 This QMG model presented in this study uses the Visual Basic language programming. The
732 general framework of the model and the algorithm consist of three parts: the modeling
733 approach, the algorithm of rainfall-runoff generation and confluence, and the parameter
734 optimization algorithm. As a free and open source hydrological modeling program (QMG
735 model-V1.0), we provide all modeling packages, including model code, installation package,
736 simulation data package and user manual, free of charge. It is important to note that the
737 model we provide are for scientific research purposes only and should not be used for any
738 commercial purposes. Creative Commons Attribution 4.0 International.

739 Model installation program can be downloaded from ZENODO, cite as JI LI. (2021, June
740 16). QMG model-V1.0. Zenodo. <http://doi.org/10.5281/zenodo.4964701>, and

742 downloaded from <http://doi.org/10.5281/zenodo.4964754>.

743 **Code availability.**

744 All code for the QMG model-V1.0 in this paper are available and free, the code can be
745 downloaded from ZENODO, Cite as JI LI. (2021, June 16). QMG model-V1.0 code
746 (Version v1.0). Zenodo. <http://doi.org/10.5281/zenodo.4964709> (registration required).

747 **Data availability.**

748 All data used in this paper are available, findable, accessible, interoperable, and reusable.
749 The simulation data and modelling data package can be downloaded from
750 <http://doi.org/10.5281/zenodo.4964727>. The DEM was downloaded from the Shuttle Radar
751 Topography Mission database at <http://srtm.csi.cgiar.org>. The land use-type data were
752 downloaded from <http://landcover.usgs.gov>, and the soil-type data were downloaded from
753 <http://www.isric.org>. These data were last accessed on 15 October 2020.

754 **Author contributions.** JIL was responsible for the calculations and writing of the whole
755 paper. DY helped conceive the structure of the model. ZF and JL provided significant
756 assistance in the English translation of the paper. MM provided flow data of the study area.

757 **Competing interests.**

758 The authors declare that they have no conflicts of interest.

980 **Tables**

981 Table 1 Parameters of the QMG model.

Parameters	Variable name	Physical property
Infiltration coefficient	I_c	Meteorology
Evaporation coefficient	λ	Vegetation cover
Soil thickness	h	Karst aquifer
Soil coefficient	S_b	Soil type
Saturated water content	S_c	Soil type
Rock porosity	R_p	Karst aquifer
Field capacity	F_c	Soil type
Permeability coefficient	K	Karst aquifer
Flow direction	F_d	Landform
Slope	S_o	Landform
Specific yield	S_y	Karst aquifer
Channel roughness	n	Landform

982 Table 2 Parametric sensitivity results in QMG model.

I_c	λ	h	S_b	S_c	S_y	F_d	S_o	R_p	F_c	K	n
0.92	0.24	0.71	0.58	0.8	0.83	0.74	0.68	0.86	0.78	0.89	0.36

983 Table 3 Flood simulation evaluation index through parametric optimization.

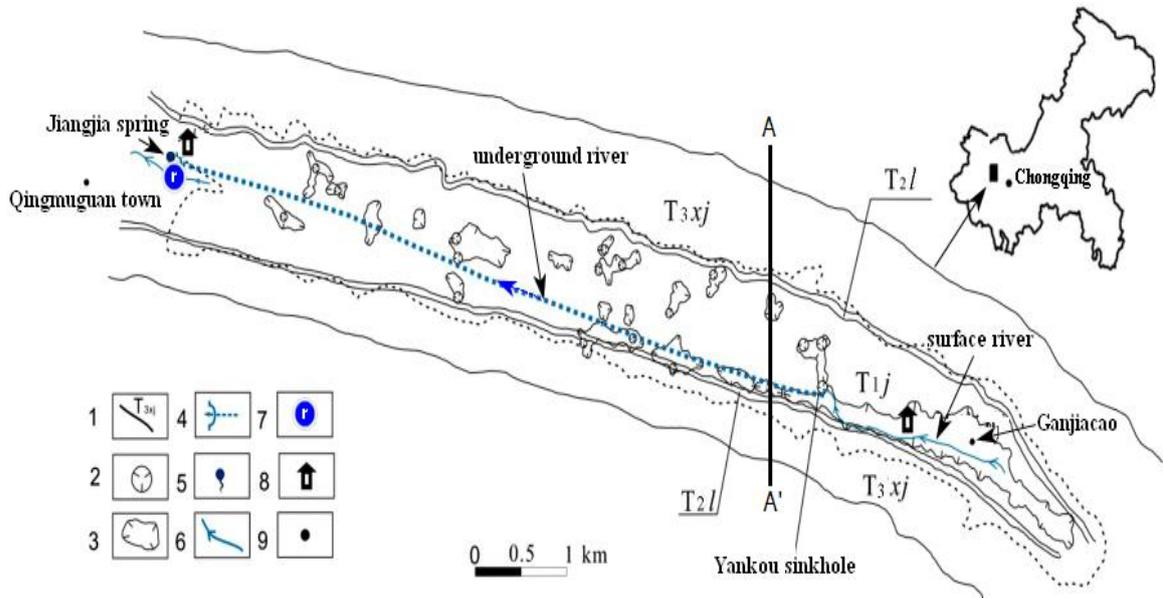

Parameter optimization	Parameter types	Nash coefficient	Correlation coefficient	Relative flow process error/%	Flood peak error/%	Water balance coefficient	Peak time error (hours)
calibration	initial	0.82	0.77	24	29	0.82	4
periods	optimized	0.91	0.94	14	12	0.95	2
validation	initial	0.79	0.71	29	32	0.77	6
periods	optimized	0.88	0.87	18	16	0.92	3
average	initial	0.81	0.74	27	31	0.8	5
value	optimized	0.9	0.91	16	14	0.94	3

984 Table 4 Flood simulation indices for model validation.

Floods	Parameter types	Nash coefficient	Correlation coefficient	Relative flow process error/%	Flood peak error/%	Water balance coefficient	Peak time error/(hours)
