30 **Abstract**

31 Top-down atmospheric inversion infers surface-atmosphere fluxes from spatially  
32 distributed observations of atmospheric compositions, which is a vital means for  
33 quantifying large-scale anthropogenic and natural emissions. In this study, we  
34 developed a Regional multi-Air Pollutant Assimilation System (RAPAS v1.0) based on  
35 the Weather Research and Forecasting/Community Multiscale Air Quality Modeling  
36 System (WRF/CMAQ) model, the three-dimensional variational (3DVAR) algorithm  
37 and the ensemble square root filter (EnSRF) algorithm. It is capable to simultaneously  
38 assimilate spatially distributed hourly in-situ measurements of CO, SO<sub>2</sub>, NO<sub>2</sub>, PM<sub>2.5</sub>  
39 and PM<sub>10</sub> concentrations to quantitatively optimize gridded emissions of CO, SO<sub>2</sub>, NO<sub>x</sub>,  
40 primary PM<sub>2.5</sub> (PPM<sub>2.5</sub>) and coarse PM<sub>10</sub> (PMC) on regional scale. RAPAS includes two  
41 subsystems, initial field assimilation (IA) subsystem and emission inversion (EI)  
42 subsystem, which are used to generate a “perfect” chemical initial condition (IC), and  
43 conduct inversions of anthropogenic emissions, respectively. A “two-step” inversion  
44 scheme is adopted in the EI subsystem in its each data assimilation (DA) window, in  
45 which the emission is inferred in the first step, and then, it is input into the CMAQ  
46 model to simulate the initial field of the next window, meanwhile, it is also transferred  
47 to the next window as the prior emission. The chemical IC is optimized through the IA  
48 subsystem, and the original emission inventory is only used in the first DA window.  
49 Besides, a “super-observation” approach is implemented based on optimal estimation  
50 theory to decrease the computational costs and observation error correlations and  
51 reduce the influence of representativeness errors.

52 With this system, we estimated the emissions of CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC in  
53 December 2016 over China using the corresponding nationwide surface observations.  
54 The 2016 Multi-resolution Emission Inventory for China (MEIC 2016) was used as the  
55 prior emission. The system was run from 26 November to 31 December, in which the  
56 IA subsystem was run in the first 5 days, and the EI subsystem was run in the following  
57 days. The optimized ICs at the first 5 days and the posterior emissions in December  
58 were evaluated against the assimilated and independent observations. Results showed

59 that the root mean squared error (RMSE) decreased by 50.0-73.2%, and the correlation  
60 coefficient (CORR) increased to 0.78-0.92 for the five species compared to the  
61 simulations without 3DVAR. Additionally, the RMSE decreased by 40.1-56.3%, and  
62 the CORR increased to 0.69-0.87 compared to the simulations without optimized  
63 emissions. For the whole mainland China, the uncertainties were reduced by 44.4%,  
64 45.0%, 34.3%, 51.8% and 56.1% for CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC, respectively.  
65 Overall, compared to the prior emission (MEIC 2016), the posterior emissions  
66 increased by 129%, 20%, 5%, and 95% for CO, SO<sub>2</sub>, NO<sub>x</sub> and PPM<sub>2.5</sub>, respectively,  
67 indicating that there was significant underestimation in the MEIC inventory. The  
68 posterior PMC emissions, including anthropogenic and natural dust contributions,  
69 increased by 1045%. A series of sensitivity tests were conducted with different  
70 inversion processes, prior emissions, prior uncertainties, and observation errors. Results  
71 showed that the “two-step” scheme clearly outperformed the simultaneous assimilation  
72 of ICs and emissions (“one-step” scheme), and the system is rather robust in estimating  
73 the emissions using the nationwide surface observations over China. Our study offers a  
74 useful tool for accurately quantifying multi-species anthropogenic emissions at large  
75 scales and near-real time.

84

85 **1. Introduction**

86 Due to rapid economic developments and pollution control legislations, an increasing  
87 demand to provide updated emission estimates has arisen, especially in areas where  
88 anthropogenic emissions are intensive. Accurately estimating source emission  
89 quantities and spatiotemporal changes resulting from various regulations is imperative  
90 and valuable for understanding air quality responses and crucial for providing timely  
91 instructions for the design of future emissions regulations. However, most inventories  
92 have been developed based on a bottom-up approach and are usually updated with a  
93 few years delay due to the complexity of gathering all statistical information on activity  
94 levels and sector-specific emission factors (Ding et al., 2015). The large uncertainty  
95 associated with the low temporal and spatial resolution of these datasets also greatly  
96 limits the assessment of emission changes. Some studies (Bauwens et al., 2020; Shi and  
97 Brasseur, 2020) have evaluated emission changes indirectly through concentration  
98 measurements, but air pollution changes are not only dominated by emission changes,  
99 but also highly affected by meteorological conditions (Shen et al., 2021).

100 Top-down atmospheric inversion infers surface-atmosphere fluxes from spatially  
101 distributed observations of atmospheric compositions. Recent efforts have focused on  
102 developing air pollution data assimilation (DA) system to conduct the top-down  
103 inversion, which is able to integrate model and multi-source and large amount  
104 observational information to constrain emission sources. Two major methods, namely,  
105 4D-variational data assimilation (4DVAR) and ensemble Kalman filter (EnKF), are  
106 widely used in those DA systems. For example, Jiang et al. (2017) used 4DVAR  
107 algorithm to estimate global CO emission trends from 2000–2015 using MOPITT  
108 retrievals. Kurokawa et al. (2009) and Stavrou et al. (2008) also used 4DVAR  
109 technique to estimate NO<sub>x</sub> emission changes. However, the drawback of the 4DVAR  
110 method is the additional development of adjoint models that are technically difficult  
111 and cumbersome for complex chemical transport models. Instead, EnKF uses the flow-  
112 dependent background error covariance generated by ensemble simulations to map the  
113 deviations in concentrations to increments of emissions, which is more flexible and

114 easier to implement. Many previous studies have used EnKF techniques to assimilate  
115 the single or dual species observations to optimize the corresponding emission species  
116 (Chen et al., 2019; Peng et al., 2017; Schwartz et al., 2014; Sekiyama et al., 2010).  
117 Multispecies data assimilation has shown the advantage of efficiently reducing the  
118 uncertainty in emission inventories and has led to improvements in air quality  
119 forecasting (Ma et al., 2019; Miyazaki et al., 2012b), since it would offer additional  
120 constraints on emission estimates through the improvements in related atmospheric  
121 fields, chemical reactions, and gas-particle transformations (Miyazaki and Eskes, 2013).  
122 Barbu et al. (2009) updated sulfur oxide (SO<sub>x</sub>) emissions with SO<sub>2</sub> gas and sulfate  
123 aerosol observations and showed that forecasts were improved overall but degraded  
124 when derived only from SO<sub>2</sub> or sulfate observations.

125 The deviation in chemical initial condition (IC) is one of the important sources of error  
126 that affects the accuracy of emission inversion, because atmospheric inversion fully  
127 attributes the biases in simulated and observed concentrations to the deviations in  
128 emissions (Meirink et al., 2006; Peylin et al., 2005). The biases of concentrations would  
129 be compensated through unreasonable adjustment of pollution emissions without the  
130 optimization of ICs (Tang et al., 2013). Tang et al. (2011) reported that the simultaneous  
131 optimizations of the ICs of O<sub>3</sub>, NO<sub>x</sub> and volatile organic compounds (VOCs) and the  
132 emissions of NO<sub>x</sub> and VOCs produced an overall better performance in ozone forecasts  
133 than the adjustment in emissions only. Similar method of simultaneously optimizing  
134 chemical ICs and emissions were also applied to constraining emissions in many  
135 previous studies (Ma et al., 2019; Miyazaki et al., 2012a; Peng et al., 2018). Although  
136 a large improvement has been achieved, this method still has great limitations because  
137 the contributions from the emissions and the chemical ICs to the model's bias are  
138 difficult to distinguish (Jiang et al., 2017). Besides, the simultaneous optimization  
139 means that assimilation window is independent with each other, generally, the  
140 uncertainties of the emissions cannot be fully corrected in time in a window, resulting  
141 in an accumulation of errors in the estimation (Jiang et al., 2021).

142 Since 2013, China has deployed an air pollution monitoring network that publishes

143 nationwide and real-time hourly surface atmospheric observations. This dataset  
144 provides an opportunity to improve emission estimates using DA. In this study, a  
145 regional multi- air pollutant assimilation system introducing 3DVAR and EnKF DA  
146 techniques is constructed to simultaneously assimilate various surface observations  
147 (e.g., CO, SO<sub>2</sub>, NO<sub>2</sub>, O<sub>3</sub>, PM<sub>2.5</sub> and PM<sub>10</sub>). Against the limitations of the simultaneous  
148 optimization of emissions and chemical ICs in each DA window (here, named as “one-  
149 step” method), a “two-step” approach (Sect. 3) is performed, in which the IC of each  
150 DA window is simulated using the posterior emission of the pervious DA window. The  
151 capability of RAPAS in reanalysis field generation and emission inversion estimation  
152 is evaluated. The robustness of the system is also investigated with different prior  
153 inventories, uncertainty settings of the prior emission, and observation errors. This  
154 paper is organized as follows: in Sect. 2, we introduce the DA system and the  
155 observation data, and in Sect. 3, we describe the experimental design. The results of the  
156 system performance and sensitivity runs are presented and discussed in Sect. 4,  
157 followed by the conclusions in Sect. 5.

## 158 **2. Method and data**

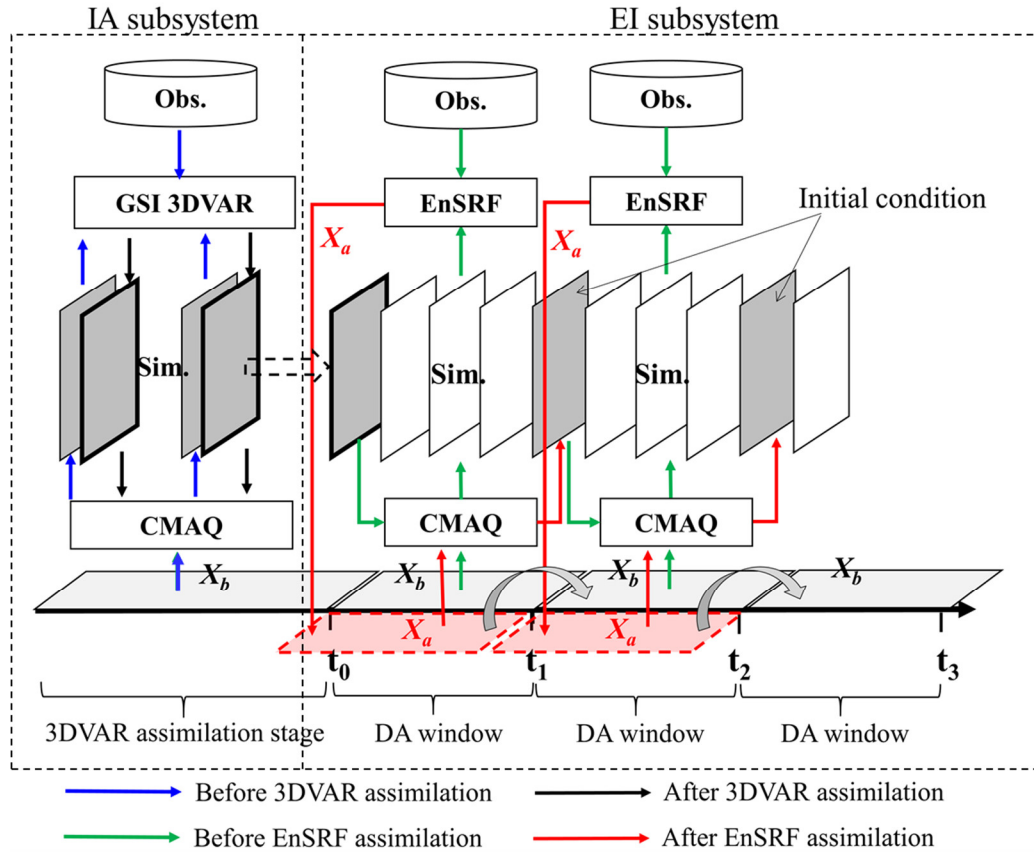

### 159 **2.1 System description**

#### 160 **2.1.1 Procedure of the assimilation system**

161 A regional air pollutant assimilation system has been preliminarily constructed and  
162 successfully applied in our previous studies to optimize gridded CO and NO<sub>x</sub> emissions  
163 (Feng et al., 2020a; Feng et al., 2020b). Herein, the system is further extended to  
164 simultaneously assimilate multiple species (e.g., CO, SO<sub>2</sub>, NO<sub>2</sub>, O<sub>3</sub>, PM<sub>2.5</sub> and PM<sub>10</sub>)  
165 and officially named as the Regional multi- Air Pollutant Assimilation System  
166 (RAPASv1.0). The RAPAS mainly includes three components: a regional chemical  
167 transport model (CTM), which is coupled offline and used to simulate the  
168 meteorological fields and atmospheric compositions, and the 3DVAR and ensemble  
169 square root filter (EnSRF) modules, which are used to optimize chemical ICs (Feng et  
170 al., 2018; Jiang et al., 2013) and anthropogenic emissions (Feng et al., 2020a; Feng et

171 al., 2020b), respectively.

172 Based on above three components, the RAPAS is divided into two subsystems, namely  
173 the IC assimilation (IA) subsystem (CTM plus 3DVAR) and the emission inversion (EI)  
174 subsystem (CTM plus EnSRF). As shown in Fig. 1, the IA subsystem is run separately  
175 to optimize chemical ICs using the CTM model and cycling assimilation within the  
176 3DVAR framework (Kleist et al., 2009; Wu et al., 2002). It runs only once and provides  
177 a “perfect” chemical ICs for the subsequent EI subsystem. The EI subsystem runs  
178 cyclically, and in each cycle (DA window), we use a “two-step” calculation scheme. In  
179 the first step, the prior emissions ( $X^b$ ) are perturbed and put into the CTM model to  
180 simulate chemical concentration ensembles, which are then sampled according to the  
181 locations and times of the observations. The sampled data together with observations  
182 and prior emission ensembles are entered into the EnSRF algorithm to generate the  
183 optimized emissions ( $X^a$ ). In the second step, the optimized emissions are entered again  
184 into the CTM model to generate the initial fields of the next DA window. Meanwhile,  
185 the optimized emissions are transferred to the next window as the prior emissions,  
186 which means that the original emission inventory is only used in the first DA window  
187 in the EI subsystem. Different from the synchronously scheme (“one-step” scheme),  
188 which only runs the model once and optimizes the ICs of the next window and emission  
189 at the same time, this “two-step” scheme needs to run the simulations twice, which is  
190 time consuming, but it could transfer the errors in the inverted emissions of current DA  
191 window to the next one for further correction. The benefit of this scheme will be further  
192 presented in Sect. 4.3.

193

194

195

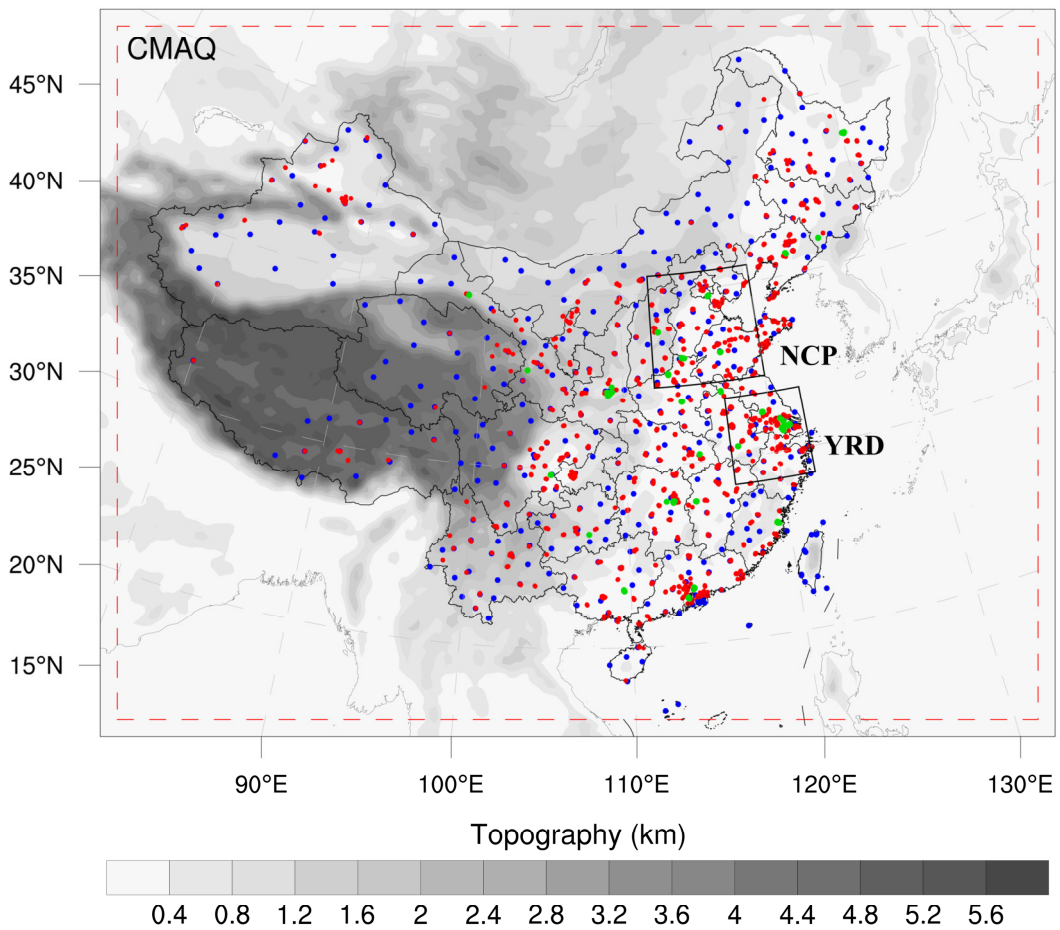

### 2.1.2 Atmospheric transport model

196 The regional chemical transport model of WRF/CMAQ is adopted in this study. CMAQ  
 197 is a regional 3-D Eulerian atmospheric chemistry and transport model with a “one-  
 198 atmosphere” design developed in the US Environmental Protection Agency (EPA). It  
 199 could address the complex interactions among multiple pollutants/air quality issues  
 200 simultaneously. CMAQ is driven by the WRF model, which is a state of the art  
 201 mesoscale numerical weather prediction system designed for both atmospheric research  
 202 and meteorological field forecasting. In this study, WRF version 4.0 and CMAQ version  
 203 5.0.2 are adopted. The WRF simulations are performed with a 36-km horizontal  
 204 resolution on  $169 \times 129$  grids, and it covers the whole mainland of China (Fig. 2). In  
 205 the vertical direction, there are 51 sigma levels on sigma-pressure coordinates  
 206 extending from the surface to 100 hPa. The underlying surface of urban and built-up  
 207 land is replaced by the MODIS land cover retrieval of 2016 to adapt to the rapid

208 expansion of urbanization. The CMAQ model is run with the same domain but with  
209 three grid cells removed from each side of the WRF domain. There are 15 layers in the  
210 CMAQ vertical coordinate, which are compressed from the 51 WRF layers.

211 The meteorological initial and lateral boundary conditions are both provided by the  
212 Final (FNL) Operational Global Analysis data of the National Center for Environmental  
213 Prediction (NCEP) with a  $1^\circ \times 1^\circ$  resolution at 6-h intervals. The chemical lateral  
214 boundary conditions and chemical ICs in the IA subsystem come from the background  
215 profiles. As mentioned above, in the EI subsystem, the chemical IC in the first window  
216 is provided by the IA subsystem, and in the following windows, it is forward simulated  
217 using optimized emission of previous window. The Carbon Bond 05 with updated  
218 toluene chemistry (CB05tucl) and the 6th generation aerosol module (AERO6) are  
219 chosen as the gas-phase and aerosol chemical mechanisms, respectively (Appel et al.,  
220 2013; Sarwar et al., 2012). Detailed physical and chemical configurations are listed in  
221 Table 1.

222

223 **Figure 2.** Model domain and observation network. The red dashed frame depicts the  
 224 CMAQ computational domain; the blue dots represent the meteorological measurement  
 225 sites; and the red and green dots represent the measurement sites. Observations of all  
 226 sites are assimilated in the 3DVAR subsystem, while observations of city sites where  
 227 red dots are averaged are used for assimilation and where green dots are averaged are  
 228 used for independent evaluation in EI subsystem; the boxed subregions are the North  
 229 China Plain (NCP) and Yangtze River Delta (YRD); and the shaded area depicts the  
 230 topography.

236 **2.1.3 3DVAR assimilation algorithm**

237 The Grid-point Statistical Interpolation (GSI) developed in the US National Centers for  
 238 Environmental Prediction (NCEP) is employed in this study. Building upon the work  
 239 of Liu et al. (2011), Jiang et al. (2013) and Feng et al. (2018), we extended it to  
 240 simultaneously assimilate multiple species (including CO, SO<sub>2</sub>, NO<sub>2</sub>, O<sub>3</sub>, PM<sub>2.5</sub>, and  
 241 PM<sub>10</sub>) and first used individual aerosol species of PM<sub>2.5</sub> as analysis variables within the  
 242 GSI/WRF/CMAQ framework. Additional works include the construction of surface air  
 243 pollutant observation operators, the updating of observation errors, and the statistics of  
 244 background error covariance for the analysis variables. Moreover, the data interface is  
 245 also modified to read/write the CMAQ output/input file directly, which is easy to  
 246 implement.

247 In the sense of a minimum analysis error variance, the 3DVAR algorithm optimizes  
 248 analysis fields with observations by iterative processes to minimize the cost function  
 249 (J(x)) defined below:

250 
$$J(\mathbf{x}) = \frac{1}{2}(\mathbf{x}_a - \mathbf{x}_b)^T \mathbf{B}^{-1}(\mathbf{x}_a - \mathbf{x}_b) + \frac{1}{2}[H(\mathbf{x}_a) - \mathbf{y}]^T \mathbf{R}^{-1}[H(\mathbf{x}_a) - \mathbf{y}], \quad (1)$$

251 where  $\mathbf{x}_a$  is a vector of the analysis field;  $\mathbf{x}_b$  denotes the background field;  $\mathbf{y}$  is the  
 252 vector of observations;  $\mathbf{B}$  and  $\mathbf{R}$  are the background and observation error covariance  
 253 matrices, respectively, representing the relative contributions to analysis; and  $H$  is the  
 254 observation operator that maps the model variables to the observation space.

255 The analysis variables are the 3D mass concentrations of the pollution compositions  
 256 (e.g., CO and sulfate) at each grid point. Hourly surface pollution observations within  
 257 1 hour window of the analysis are assimilated. To assimilate the surface pollution  
 258 observations, model-simulated compositions are first diagnosed at the observation  
 259 locations. For gas pollutions that are directly used as analysis variables, data units need  
 260 to be converted from ppm or ppb to  $\text{mg m}^{-3}$  or  $\mu\text{g m}^{-3}$  to match with observations. The  
 261 model-simulated  $\text{PM}_{2.5}$  and  $\text{PM}_{10}$  concentrations at the ground level are diagnosed as  
 262 follows:

$$263 \quad PM_{2.5} = f_i \times PM_i + f_j \times PM_j + f_k \times PM_k = \text{OC} + \text{EC} + \text{SO}_4^{2-} + \text{NO}_3^- + \text{NH}_4^+ + \\
 264 \quad \text{SEAS} + \text{AP}_{2.5} \quad (2)$$

$$265 \quad PM_{10} = PM_i + PM_j + PM_k = PM_{2.5} + \text{PMC} \quad (3)$$

266 where  $f_i$ ,  $f_j$ , and  $f_k$  are the  $\text{PM}_{2.5}$  fractions of the Aitken, accumulation, and coarse  
 267 modes, respectively. These ratios are recommended as the concentrations of  $\text{PM}_{2.5}$  and  
 268 fine mode aerosols (i.e., Aitken plus accumulation) could differ because the  $\text{PM}_{2.5}$   
 269 particles include small tails from the coarse mode in the CMAQ model (Binkowski and  
 270 Roselle, 2003; Jiang et al., 2006).  $PM_i$ ,  $PM_j$ , and  $PM_k$  represent the mass  
 271 concentrations of the 3 modes in the CMAQ model. Seven aerosol species of  $\text{PM}_{2.5}$ ,  
 272 including organic carbon (OC), elemental carbon (EC), sulfate ( $\text{SO}_4^{2-}$ ), nitrate ( $\text{NO}_3^-$ ),  
 273 ammonium ( $\text{NH}_4^+$ ), sea salt (SEAS), and fine-mode unspciated aerosols ( $\text{AP}_{2.5}$ ), and  
 274 additional coarse  $\text{PM}_{10}$  (PMC) are extracted as analysis variables, which are updated  
 275 by the  $\text{PM}_{2.5}$  and PMC observations, respectively. Before the calculation of equation (1)  
 276 within the GSI, the analysis variables are bilinearly interpolated in the horizontal  
 277 direction to the observation locations.

278 The computation of background error covariance ( $\mathbf{B}$ ) is generally costly and difficult  
 279 when a high-dimensional numerical model is used. For simplification,  $\mathbf{B}$  is represented  
 280 as a product of spatial correlation matrices and standard deviations (SDs):

$$281 \quad \mathbf{B} = \mathbf{D}\mathbf{C}\mathbf{D}^T \quad (4)$$

$$282 \quad \mathbf{C} = \mathbf{C}_x \otimes \mathbf{C}_y \otimes \mathbf{C}_z \quad (5)$$

283 where  $\mathbf{D}$  is the background error SD matrix,  $\mathbf{C}$  is the background error correlation  
 284 matrix,  $\otimes$  denotes the Kronecker product, and  $\mathbf{C}_x$ ,  $\mathbf{C}_y$ , and  $\mathbf{C}_z$  denote three one-  
 285 dimensional correlation submatrices in the longitude, latitude, and vertical coordinate  
 286 directions, respectively.  $\mathbf{C}_x$  and  $\mathbf{C}_y$  are assumed to be isotropic horizontally such that  
 287 can be represented using a Gaussian function. The correlation between any two points  
 288  $x_i$  and  $x_j$  in the horizontal can be expressed as follows:

$$289 \quad c(x_i, x_j) = e^{-\frac{(x_i-x_j)^2}{2L^2}} \quad (6)$$

290 where  $L$  is the horizontal correlation scale, which is estimated using the proxy of the  
 291 background error (Fig. 3). The vertical correlation matrix  $\mathbf{C}_z$  is directly estimated from  
 292 the model background field since  $\mathbf{C}_z$  is only an  $n_z \times n_z$  (here,  $n_z=15$ ) matrix.

293

294 **Figure 3.** Vertical profiles of standard deviations (top,  $\mu\text{g m}^{-3}$ ), horizontal length scale  
 295 (middle, km) and vertical length scale (bottom, km) for CO, SO<sub>2</sub>, NO<sub>2</sub>, O<sub>3</sub>, sulfate,  
 296 nitrate, ammonium, EC, OC, sea salt, unspciated aerosols (AP<sub>2.5</sub>), PMC, PM<sub>2.5</sub> and  
 297 PM<sub>10</sub>.

298 To estimate these matrices, the “NMC” method is used here to compute **B** for each  
 299 variable by taking the differences between forecasts of different lengths valid at the  
 300 same time (Parrish and Derber, 1992; Rabier et al., 1998). Differences between 24- and  
 301 12-h WRF/CMAQ forecasts of 60 pairs (two pairs a day) of analysis variables valid at  
 302 either 0000 or 1200 UTC over November 2016 are used. The horizontal and vertical  
 303 length scales of the correlation matrices are estimated by recursive filters (Purser et al.,  
 304 2003). The vertical distribution of background error SDs is shown in Fig. 3, which

305 varies with height and species. The vertical profile of the background error SDs  
 306 corresponds to the vertical concentration distribution. This means that higher  
 307 concentrations tend to have larger background error SDs (e.g., CO and nitrate). These  
 308 SDs exhibit a common reduction with height, especially at the top of the boundary layer.  
 309 The horizontal correlation of background error determines the propagation of  
 310 observation information in this direction, while vertical correlation determines the  
 311 vertical extension of such increments. For gaseous pollutants and individual aerosol  
 312 components, excluding nitrate and sea salt, the horizontal length scales decrease with  
 313 increasing heights, while the total particulate matter increases slightly under the  
 314 boundary layer and then decreases slightly over the boundary layer. The ground-level  
 315 scale generally spread 40-45 km for all control variables on average. The vertical length  
 316 scale of most species increases with height near the ground where they are emitted  
 317 (Descombes et al., 2015) and then drops rapidly to the height of the upper stable  
 318 atmosphere, with a scale of 1.4 km.

#### 319 **2.1.4 EnKF assimilation algorithm**

320 In EnKF, the time-dependent uncertainties of the state variables are estimated using a  
 321 Monte Carlo approach through an ensemble. Uncertainty can be propagated with linear  
 322 or nonlinear dynamic models (flow-dependent background error covariance) by simply  
 323 implementing ensemble simulations. The EnSRF algorithm introduced by (Whitaker  
 324 and Hamill, 2002) is used to constrain pollution emissions in this study. EnSRF is a  
 325 deterministic EnKF that obviates the need to perturb observations, which has a higher  
 326 computational efficiency and a better performance (Sun et al., 2009).

327 The perturbation of prior emissions represents the uncertainty. We implement additive  
 328 emission adjustment methods, which are calculated using the following function.

$$329 \quad \mathbf{X}_i^b = \mathbf{X}_0^b + \delta\mathbf{X}_i^b, i = 1, 2, \dots, N \quad (7)$$

330 where  $\mathbf{b}$  represents the background (prior) state,  $i$  is the identifier of the perturbed  
 331 samples,  $N$  is the ensemble size (40 in this study), and  $\delta\mathbf{X}_i^b$  represents the randomly  
 332 perturbed samples that are added to the prior emissions  $\mathbf{X}_0^b$  to produce ensemble

333 samples of the inputs  $\mathbf{X}_i^b$ .  $\delta\mathbf{X}_i^b$  is drawn from Gaussian distributions with a mean of  
 334 zero and the standard deviation of the prior emission uncertainty in each grid. The state  
 335 variables of the emissions include CO, SO<sub>2</sub>, NO<sub>x</sub>, primary PM<sub>2.5</sub> (PPM<sub>2.5</sub>) and PMC.  
 336 We used variable localization to update the analysis, which means that the covariance  
 337 among different state variables is set to zero (Miyazaki et al., 2012b).

338 After obtaining an ensemble of state vectors (prior emissions), ensemble runs of the  
 339 CMAQ model are conducted to propagate these errors in the model with each ensemble  
 340 sample of state vectors. Combined with observational vector  $\mathbf{y}$ , the state vector is  
 341 updated by minimizing the analysis variance:

$$342 \quad \bar{\mathbf{X}}^a = \bar{\mathbf{X}}^b + \mathbf{K}(\mathbf{y} - \mathbf{H}\bar{\mathbf{X}}^b) \quad (8)$$

$$343 \quad \mathbf{K} = \mathbf{P}^b \mathbf{H}^T (\mathbf{H} \mathbf{P}^b \mathbf{H}^T + \mathbf{R})^{-1} \quad (9)$$

$$344 \quad \mathbf{P}^b = \frac{1}{N-1} \sum_{i=1}^N (\mathbf{X}_i^b - \bar{\mathbf{X}}^b) (\mathbf{X}_i^b - \bar{\mathbf{X}}^b)^T \quad (10)$$

$$345 \quad \delta\mathbf{X}_i^a = \delta\mathbf{X}_i^b - \tilde{\mathbf{K}} \mathbf{H} \delta\mathbf{X}_i^b \quad (11)$$

346 While employing sequential assimilation and independent observations,  $\tilde{\mathbf{K}}$  is  
 347 calculated as follows:

$$348 \quad \tilde{\mathbf{K}} = \left(1 + \sqrt{\mathbf{R} / \mathbf{H} \mathbf{P}^b \mathbf{H}^T + \mathbf{R}}\right)^{-1} \mathbf{K} \quad (12)$$

349 where  $\bar{\mathbf{X}}^b$  represents the mean of the ensemble samples;  $\mathbf{P}^b$  is the ensemble-  
 350 estimated background (a priori) error covariance;  $\mathbf{P}^b \mathbf{H}^T$  contains the response of the  
 351 uncertainty in the simulated concentrations to the uncertainty in emissions;  $\mathbf{K}$  is the  
 352 Kalman gain matrix of the ensemble mean depending on the  $\mathbf{P}^b$  and observation error  
 353 covariance  $\mathbf{R}$ , representing the relative contributions to analysis; and  $\tilde{\mathbf{K}}$  is the Kalman  
 354 gain matrix of the ensemble perturbation, which is used to calculate emission  
 355 perturbations after inversions  $\delta\mathbf{X}_i^a$ . The ensemble mean  $\bar{\mathbf{X}}^a$  of the analyzed state is  
 356 taken as the best estimate of the emissions.

357 With large volumes of site observations that are recorded at a much higher resolution  
 358 than the model grid spacing, there would be significant correlated or fully consistent  
 359 model-data mismatch errors in one cluster, resulting in excessive adjustments and  
 360 deteriorated model performances (Houtekamer and Mitchell, 2001). To reduce the  
 361 horizontal observation error correlations and the influence of representativeness errors,  
 362 a “super-observation” approach combining multiple noisy observations located within  
 363 the same grid and assimilation window is developed based on optimal estimation theory  
 364 (Miyazaki et al., 2012a). Previous studies have demonstrated the necessity of data-  
 365 thinning and dealiasing errors (Feng et al., 2020b; Zhang et al., 2009a). The super-  
 366 observation  $y_{new}$ , super-observation error  $r_{new}$  and corresponding simulation  $x_{new,i}$   
 367 of the  $i$ th sample are calculated as follows:

$$368 \quad 1/r_{new}^2 = \sum_{j=1}^m 1/r_j^2 \quad (13)$$

$$369 \quad y_{new} = \sum_{j=1}^m w_j y_j / \sum_{j=1}^m w_j \quad (14)$$

$$370 \quad x_{new,i} = \sum_{j=1}^m w_j x_{ij} / \sum_{j=1}^m w_j \quad (15)$$

371 where  $j$  is the identifier of  $m$  observations within a super-observation grid;  $r_j$  is the  
 372 observational error of actual  $j$ th observation  $y_j$ ;  $x_{ij}$  represents a simulated  
 373 concentration using the  $i$ th prior emission sample corresponding to the  $j$ th observation;  
 374 and  $w_j = 1/r_j^2$  is the weighting factor. The super-observation error decreases as the  
 375 number of observations used within a super-observation increases. This method has  
 376 been used in our previous inversions using surface-based (Feng et al., 2020b) and  
 377 satellite-based (Jiang et al., 2021) observations.

378 In this study, the DA window is set to 1 day because the model needs a longer time to  
 379 integrate emission information into the concentration ensembles (Ma et al., 2019). In  
 380 addition, due to the complexity of hourly emissions, it is very difficult to simulate  
 381 hourly concentrations that can match the observations well. Although a longer DA

382 window could allow more observations to constrain the emission change of one grid,  
383 the spurious correlation signals of EnKF would attenuate observation information with  
384 time (Bruhwiler et al., 2005; Jiang et al., 2021). Kang et al. (2012) and Zhang et al.  
385 (2015) also pointed out that the emission inversion with a long window (e.g., 1 to 3  
386 weeks) is not as accurate as that obtained with a short DA window (e.g., 6 hours to 1  
387 week). Therefore, daily mean simulations and observations are used in the EnSRF  
388 algorithm, and daily emissions are optimized in this system.

389 EnKF is subject to spurious correlations due to the limited number of ensembles when  
390 it is applied in high-dimensional atmospheric models, which can cause rank  
391 deficiencies in the estimated background error covariance and filter divergence, and  
392 further degrade analyses and forecasts (Wang et al., 2020). Covariance localization is  
393 performed to reduce spurious correlations caused by the finite ensemble size  
394 (Houtekamer and Mitchell, 2001). Covariance localization preserves the meaningful  
395 impact of observations on state variables within a certain distance (cutoff radius) but  
396 limits the detrimental impact of observations on remote state variables. The localization  
397 function of Gaspari and Cohn function (Gaspari and Cohn, 1999) is used in this system,  
398 which is a piecewise continuous fifth-order polynomial approximation of a normal  
399 distribution. The optimal localization scale is related to the ensemble size, assimilation  
400 window, dynamic system, and lifetime of a chemical species in the atmosphere. CO,  
401 SO<sub>2</sub> and PM<sub>2.5</sub> are rather stable in atmosphere, with lifetime more than 1 day. According  
402 to the averaged wind speed (3.3 m/s, Table 4) and the length of DA window, their  
403 localization scales are set to 300 km. In addition, NO<sub>2</sub> is rather active, with a lifetime  
404 of approximately 10 hours in winter (de Foy et al., 2015), and PMC, which is mainly  
405 from local sources, its residence time in the atmosphere is also short due to the rapid  
406 deposition rate (Clements et al., 2014; Clements et al., 2016; Hinds, 1982). Their  
407 localization scales are set to 150 km and 250 km, respectively.

## 408 **2.2 Prior emissions and uncertainties**

409 The anthropogenic emissions over China are taken from the 2016 Multi-resolution  
410 Emission Inventory for China (MEIC 2016) (Zheng et al., 2018), while those over the

411 other regions of East Asia are obtained from the mosaic Asian anthropogenic emission  
412 inventory (MIX) (Li et al., 2017). The spatial resolutions of both the MEIC and MIX  
413 inventories are  $0.25^\circ \times 0.25^\circ$ , and they are both downscaled to match the model grid  
414 spacing (36 km). The spatial distributions of the CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC  
415 emissions are shown in Fig. 10. The daily emission inventory, which is arithmetic  
416 averaged from the combined monthly emission inventory, is directly used in the EI  
417 subsystem and employed as the prior emission of the first DA window in the EI  
418 subsystem (Fig. 1). MEIC 2012 is used as an alternative a priori over China to  
419 investigate the impact of different prior emissions on the optimized emissions. The  
420 Model of Emissions of Gases and Aerosols from Nature (MEGAN) (Guenther et al.,  
421 2012) is used to calculate time-dependent biogenic emissions. It is also driven by the  
422 WRF model in this study. Biomass burning emissions are not included because they  
423 have little impact across China during the study period (Zhang et al., 2020).

424 During the cycling inversions, the inverted emissions of different members converge  
425 gradually, and the ensemble-estimated error covariance matrix is very likely to be  
426 underestimated. To avoid this, considering the compensation of model errors and  
427 comparable emission uncertainties from one day to the next, we impose the same  
428 uncertainty on emissions at each DA window. As mentioned above, the optimized  
429 emissions of the current DA window are transferred to the next DA window as prior  
430 emissions. The technology-based emission inventory developed by Zhang et al. (2009b),  
431 basically using the same method as MEIC, shows that the emissions of PMC and PPM<sub>2.5</sub>  
432 have the largest uncertainties, followed by CO, and finally SO<sub>2</sub> and NO<sub>x</sub>. Therefore, the  
433 uncertainties in this study are set to 40%, 40%, 30%, 25%, and 25%. However, previous  
434 studies have shown that the inversely estimated CO and PMC emissions could exceed  
435 100% higher than the bottom-up emissions (MEIC) in certain areas (Feng et al., 2020b;  
436 Ma et al., 2019). According to the extent of underestimation, we set an uncertainty of  
437 100% for both the CO and PMC emissions at the beginning of the three DA windows  
438 to quickly converge the emissions. The mean emission analysis is generally minimally  
439 sensitive to the uncertainty setting in our cycle assimilation method (Feng et al., 2020;

440 Gurney et al., 2004; Miyazaki et al., 2012) because the inversion errors of the current  
441 window could be transferred to the next window for further optimization (Sect. 4.3).

### 442 **2.3 Observation data and errors**

443 Hourly averaged surface CO, SO<sub>2</sub>, NO<sub>2</sub>, O<sub>3</sub>, PM<sub>2.5</sub> and PM<sub>10</sub> observations from 1504  
444 national control air quality stations are assimilated in this system, which were obtained  
445 from the Ministry of Ecology and Environment of the People's Republic of China  
446 (<http://106.37.208.233:20035/>). These sites distribute over most of central and eastern  
447 China and become denser near metropolitan areas (see Fig. 2). Value-range and time-  
448 continuity checks are performed to ensure data quality. Value-range checks are mainly  
449 performed to eliminate unrealistic or nonspatially representative observations. Only  
450 observations within the subjectively selected threshold range are assimilated (Table 2).  
451 A time-continuity check is performed to eliminate gross outliers and a sudden anomaly  
452 using a function of  $|O(t) - O(t \pm 1)| \leq f(t)$ , where  $O(t)$  and  $O(t \pm 1)$  represent  
453 observations at time  $t$  and  $t+1$ , respectively, and  $f(t) = T_a + T_b \times O_t$ .  $T_b$  is fixed to  
454 0.15, and the section of  $T_a$  is given in Table 2, which is determined empirically  
455 according to the time series change of concentration at each site. It should be noted that,  
456 to avoid potential cross-correlations, we assimilated PM<sub>2.5</sub> and PMC. Additionally, in  
457 the EI subsystem, the observations within each city are averaged to thin the data density  
458 and reduce the error correlation (Houtekamer and Mitchell, 2001; Houtekamer and  
459 Zhang, 2016). Finally, 336 city sites are available across the mainland of China, in  
460 which 311 cities' data are selected for assimilation and the remaining 25 are selected  
461 for independent validation (Fig. 2). In the IA subsystem, due to the small horizontal  
462 correlation scale (Fig. 3), to obtain more extensive observation constraints, all site  
463 observations are assimilated to provide a "perfect" IC for the next emission inversion.

464 The observation error covariance matrix ( $\mathbf{R}$ ) includes both measurement and  
465 representation errors. The measurement error  $\varepsilon_0$  is defined as follow:

$$466 \quad \varepsilon_0 = ermax + ermin \times \Pi_0 \quad (16)$$

467 where  $ermax$  is a base error, and  $\Pi_0$  denotes the observed concentration. These

468 parameters for different species are listed in Table 2, which are determined according  
 469 to Chen et al. (2019), Feng et al., (2018) and Jiang et al. (2013).

470 The representative error depends on the model resolution and the characteristics of the  
 471 observation locations, which is calculated using the equations of Elbern et al. (2007)  
 472 defined as follows:

$$473 \quad \varepsilon_r = \gamma \varepsilon_0 \sqrt{\Delta l / L} \quad (17)$$

474 where  $\gamma$  is a tunable parameter (here,  $\gamma=0.5$ ),  $\Delta l$  is the grid spacing (36 km), and  $L$   
 475 indicates the radius (here, 3 km for simplification) of influence area of an observation.  
 476 The total observation error ( $r$ ) is defined as follows:

$$477 \quad r = \sqrt{\varepsilon_0^2 + \varepsilon_r^2} \quad (18)$$

478 **Table 2.** Parameters of quality control and measurement error

Parameter	CO mg m <sup>-3</sup>	SO <sub>2</sub> μg m <sup>-3</sup>	NO <sub>2</sub> μg m <sup>-3</sup>	O <sub>3</sub> μg m <sup>-3</sup>	PM <sub>2.5</sub> μg m <sup>-3</sup>	PMC μg m <sup>-3</sup>
value-range	0.1-12	1-800	1-250	1-250	1-800	1-900
time-continuity ( $T_a$ )	2.5	160	70	80	180	180
ermax	0.05	1	1	1	1.5	1.5
ermin	0.5%	0.5%	0.5%	0.5%	0.75%	0.75%

### 479 **3 Experimental design**

480 RAPAS is conducted according to the procedure and settings described in Sect. 2. The  
 481 IA subsystem is run from 26 to 31 November 2016 with a 6-hour interval cycling  
 482 assimilation to optimize ICs (ICDA). A better IC at 0000 UTC on December 1 can be  
 483 obtained by 5-day high-frequency cycling assimilation and atmospheric mixing. Then  
 484 the EI subsystem is run for December 2016 with a 1-day assimilation window to  
 485 optimize emissions (EMDA). Both assimilation experiments use the combined prior  
 486 emission inventories of 2016 as described in Sect. 2.2, and the emission base year  
 487 coincides with the research stage. To evaluate the IC improvements from the IA

488 subsystem, an experiment without 3DVAR (ICNO) is conducted with the same  
489 meteorological fields and physical and chemistry parameterization settings as those of  
490 the ICDA. To evaluate the posterior emissions of the EI subsystem, two parallel forward  
491 modeling experiments are performed for December 2016, namely, a control experiment  
492 (CEP) with prior (MEIC 2016) emissions and a validation experiment (VEP) with  
493 posterior emissions. Both experiments use the same initial field at 0000 UTC on  
494 December 01 generated through the IA subsystem. Similar to the above, the only  
495 differences between CEP and VEP are emissions. Table 3 gives a summary of these  
496 different simulation experiments.

497 To investigate the robustness of our system, 7 sensitivity tests (from EMS1 to EMS7,  
498 see Table 3) are performed. These experiments are all based on EMDA. In EMS1, rather  
499 than forward simulated using the optimized emissions of the previous DA window in  
500 EMDA, the initial fields of each DA window are optimized using the 3DVAR algorithm  
501 directly and the observations at the corresponding moment as mentioned in Sect. 2.3.  
502 The objective of this experiment is to investigate the advantages of the “two-step”  
503 calculation scheme in the EI subsystem as introduced in Sect. 2.1. EMS2 uses MEIC  
504 2012 as the original prior emission in China, aiming to investigate the impact of  
505 different prior inventories on the estimates of emissions. Four other experiments,  
506 namely EMS3-6, aim to test the impact of different prior uncertainty settings, in which,  
507 the prior uncertainties are reduced by -50% and -25%, and increased by 25% and 50%,  
508 respectively. EMS7 aims to evaluate the impact of observation errors on emission  
509 estimates, in which all the observation errors are magnified twice. Seven forward  
510 modeling experiments (VEP1, VEP2, ..., VEP7) are also performed with posterior  
511 emissions of EMS1 to EMS7 to evaluate their performances, respectively.

512

513

514

515

516 **Table 3.** Experiments conducted in this study

Exp. Type	Exp. Name	Period	Initial field	Emission	IA	EI
Assimilation	ICDA	26-31 November	previous 6-hr interval cycling forecast	MEIC 2016 for November	YES	NO
	EMDA	1-31 December	0000 UTC on December 1, taken from ICDA	MEIC 2016 for December (the first DA window), optimized emissions of the previous window (other DA windows)	NO	YES
Sensitivity	EMS1	1-31 December	Forecast with prior emissions in the previous window	The same as EMDA	YES	YES
	EMS2	1-31 December	The same as EMDA	The same as EMDA, but for EMIC 2012	NO	YES
	EMS3-6	1-31 December	The same as EMDA	The same as EMDA, but with a $\pm 25\%$ or $\pm 50\%$ of default uncertainty	NO	YES
	EMS7	1-31 December	The same as EMDA	The same as EMDA, but with a +100% of default observation errors	NO	YES
Verification	ICNO	26-31 November	The same as ICDA	The same as ICDA	NO	NO
	CEP	1-31 December	The same as EMDA	MEIC 2016 for December	NO	NO
	VEP	1-31 December	The same as EMDA	Posterior emissions of EMDA	NO	NO
	VEP1-7	1-31 December	The same as EMDA	Posterior emissions of EMS1-7	NO	NO

517 **4 Results**518 **4.1 Evaluations**519 **4.1.1 Simulated meteorological fields**

520 In the RAPAS system, the inversion approach attributes all the biases between the

521 simulated and observed concentrations to the emissions. The meteorological fields  
 522 dominate the physical and chemical processes of the air pollutants in the atmosphere,  
 523 and thus their simulation accuracy would significantly affect the estimates of emissions  
 524 in this study. To quantitatively evaluate the performance of the WRF simulations, the  
 525 mean bias (BIAS), root mean square error (RMSE), and correlation coefficient (CORR)  
 526 were calculated against the surface meteorological observations measured at 400  
 527 stations, which were obtained from the National Climate Data Center (NCDC)  
 528 integrated surface database (<http://www.ncdc.noaa.gov/oa/ncdc.html>). The spatial  
 529 distribution of the meteorological stations (blue dots) is shown in Fig. 2. The simulated  
 530 temperature at 2 m (T2), relative humidity at 2 m (RH2), and wind speed at 10 m (WS10)  
 531 from 26 November to 31 December 2016 are evaluated against the observations. Table  
 532 4 summarizes the statistical results of the evaluations of the simulated meteorological  
 533 parameters. Overall, the T2 and RH2 are slightly underestimated, with biases of -0.1 °C  
 534 and -3.8%, respectively. The CORRs are approximately 0.98 for T2 and 0.94 for RH2,  
 535 showing good consistency between the observations and simulations. The WS10 is  
 536 overestimated, with a bias of 0.7 m/s and an RMSE of 0.8 m/s, but is better than many  
 537 other studies (Chen et al., 2016; Jiang et al., 2012a; Jiang et al., 2012b). Therefore,  
 538 WRF can generally reproduce the meteorological conditions sufficiently in terms of  
 539 their temporal variation and magnitude over China, which is adequate for our inversion  
 540 estimation.

541 **Table 4.** Statistics comparing the simulated and observed 10-m wind speed (WS10,  
 542 m/s), 2-m temperature (T2, °C), and 2-m relative humidity (RH2, %) averaged over all  
 543 400 stations.

Variable Met.	Mean Obs.	Mean Sim.	BIAS	RMSE	CORR
WS10 (m/s)	2.6	3.3	0.7	0.8	0.72
T2 (°C)	2.9	2.8	-0.1	0.7	0.98
RH2 (%)	66.3	62.6	-3.8	5.2	0.94

544 \* BIAS, mean bias; RMSE, root mean square error; CORR, correlation coefficient

#### 545 **4.1.2 Initial fields**

546 Figure 4 shows the evaluations of the analyzed concentrations of the 6 species against  
547 surface observations. For comparison, the evaluations of the simulations without  
548 3DVAR (ICNO) are also shown in Fig. 4. The simulations of the ICNO experiment  
549 (red dots) are scattered on both sides of a central line, as large systematic biases remain  
550 across many measurement sites. Conversely, the ICDA experiment (blue dots) shows  
551 much better agreement with observations than those from ICNO. The statistics show  
552 that there are large systematic biases in the ICNO simulations, with large RMSEs and  
553 small CORRs for all species, especially for CO and PMC. After the assimilation of  
554 surface observations, the RMSE of CO decreases to  $0.7 \text{ mg m}^{-3}$ , and those of  $\text{SO}_2$ ,  $\text{NO}_2$ ,  
555  $\text{O}_3$ ,  $\text{PM}_{2.5}$  and PMC decrease to 22.0, 12.0, 9.6, 20.5 and  $19.6 \text{ } \mu\text{g m}^{-3}$ , respectively, with  
556 respective reduction rates of 50.0%, 73.1%, 61.0%, 64.7%, 69.5%, and 60.8%  
557 compared to the ones of the ICNO (Table 5). The CORRs of ICDA increase by 290.0%,  
558 291.3%, 55.4%, 87.2%, 130.0% and 214.8% to 0.78, 0.90, 0.87, 0.88, 0.92 and 0.85,  
559 respectively. These statistics indicate that the initial fields can be adjusted effectively  
560 by our IA subsystem.

561

562 **Figure 4.** Scatter plots of simulated versus observed (a) CO, (b) SO<sub>2</sub>, (c) NO<sub>2</sub>, (d) O<sub>3</sub>,  
 563 (e) PM<sub>2.5</sub> and (f) PMC mass concentrations at 0000 UTC on December 1 initializations  
 564 from the background (red) and analysis (blue) fields.

565

570 \* BIAS, mean bias; RMSE, root mean square error; CORR, correlation coefficient

### 571 4.1.3 Posterior emissions

572 Due to mismatched spatial scales, it is difficult to directly evaluate the optimized  
 573 emissions against observations. Generally, we indirectly validate them by comparing  
 574 the forward simulated concentrations using the posterior emissions against atmospheric  
 575 measurements (e.g., Jiang et al. (2014), Jin et al. (2018), and Peters et al. (2007)). Figure  
 576 5 shows the spatial distributions of the mean biases between the simulated gaseous  
 577 pollutants using prior and posterior emissions and assimilated observations. In the CEPs,  
 578 for each species, the distribution of biases is similar to the increments in background  
 579 fields constrained through 3DVAR as shown in Fig. S1. For example, almost all sites  
 580 have large negative biases for CO, while for SO<sub>2</sub> and NO<sub>2</sub>, positive biases are mainly  
 581 distributed over the North China Plain (NCP), Yangtze River Delta (YRD), Sichuan  
 582 Basin (SCB) and Central China, and negative biases are over the rest areas. After  
 583 constraining with observations, the biases of all the 3 gaseous air pollutants are

584 significantly reduced in most sites. For CO, the biases at 62% of the sites decreased to  
585 absolute values less than  $0.2 \text{ mg m}^{-3}$ , and for SO<sub>2</sub> and NO<sub>2</sub>, the biases at 52% and 47%  
586 of the sites were within  $\pm 4 \text{ } \mu\text{g m}^{-3}$ . However, large negative biases are still observed in  
587 part of western Chinas, indicating that the uncertainties of the posterior emissions are  
588 still large in western China, which may be attributed to the large biases in prior  
589 emissions and to the relatively limited observation. Overall, the statistics show that  
590 there are different levels of improvements at 92%, 85% and 85% of the total 311  
591 assimilation sites for CO, SO<sub>2</sub> and NO<sub>2</sub>, respectively. The small amount of sites with  
592 worse performance may be related to the overadjusted emissions by EI or contradictory  
593 adjustments caused by opposite biases in adjacent areas.

594 Table 6 lists the statistical results of the evaluations averaged over the whole mainland  
595 of China. For CO, the mean bias is  $-0.8 \text{ mg m}^{-3}$  with the prior emissions, while it  
596 substantially reduces to  $-0.1 \text{ mg m}^{-3}$  with a reduction rate of 89.6% when simulating  
597 with the posterior emissions. Additionally, the RMSE decreases by 48.1% from 1.08 to  
598  $0.56 \text{ mg m}^{-3}$ , and the CORR increases by 76.1% from 0.46 to 0.81. For SO<sub>2</sub> and NO<sub>2</sub>,  
599 the regional mean biases slightly increase as the positive/negative biases among  
600 different sites might be offset. However, the RMSEs decrease to 17.7 and  $12.3 \text{ } \mu\text{g m}^{-3}$ ,  
601 respectively, which are 58.3% and 50.8% lower than those of CEPs, and the CORRs  
602 increase by 125.6% and 35.4%, both reaching up to 0.88, indicating that EI has  
603 significantly improved the NO<sub>x</sub> and SO<sub>2</sub> emission estimates.

604

605 **Figure 5.** Spatial distribution of the BIAS of the simulated (a, b) CO, (c, d) SO<sub>2</sub> and (e,  
 606 f) NO<sub>2</sub> with prior (left, CEP) and posterior (right, VEP) emissions. CO unit: mg m<sup>-3</sup>;  
 607 SO<sub>2</sub> and NO<sub>2</sub> units: µg m<sup>-3</sup>.

608 Figure 6 shows the spatial distributions of the mean biases of simulated PM<sub>2.5</sub> and PMC  
 609 evaluated against the assimilated observations. Similarly, the CEP simulations do not  
 610 perform well. There are widespread underestimations across the country, with mean  
 611 biases of -24.0 and -32.4 µg m<sup>-3</sup>. After data assimilation, the performance of VEP  
 612 simulations is significantly improved. The biases decrease by 72.1% and 90.4% to -6.7  
 613 and -3.1 µg m<sup>-3</sup>, the RMSEs decrease by 41.2% and 40.7% to 29.6 and 24.6 µg m<sup>-3</sup>, and  
 614 the CORRs increase by 35.9% and 176.0% to 0.87 and 0.69 for PM<sub>2.5</sub> and PMC,  
 615 respectively. Overall, 89.6% and 97.2% of the assimilation sites are improved for PM<sub>2.5</sub>

616 and PMC, respectively. However, compared with the results of the 3 gaseous pollutants,  
 617 there are sites with large biases scattered throughout the whole domain. Besides the  
 618 potential overadjusted or contradictory adjustments of emissions as in the 3 gas species,  
 619 it may be also related to the complex precursors and the nonlinear responses to its  
 620 precursors for  $PM_{2.5}$ , and the fact that we do not simulate the time variation of dust  
 621 blowing caused by wind speed for PMC due to the lack of land cover data that is  
 622 compatible with the CMAQ dust module and agricultural activities data to identify dust  
 623 source regions.

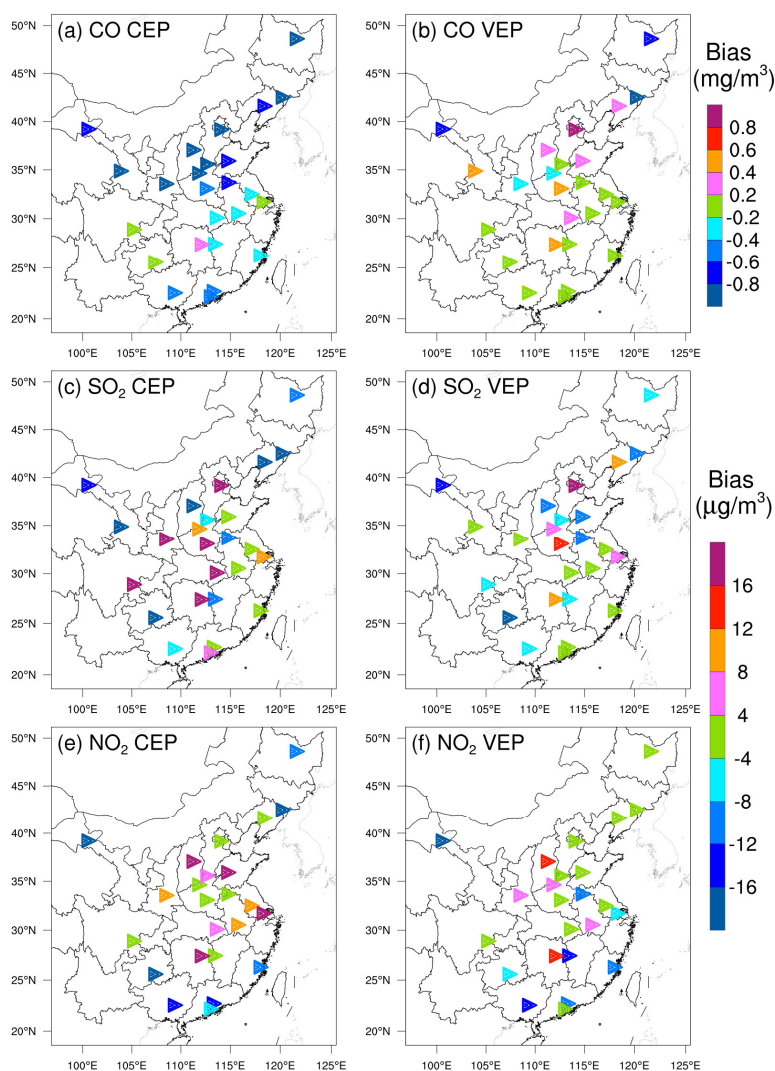

624

625 **Figure 6.** Same as in Fig. 5 but for  $PM_{2.5}$  and PMC.

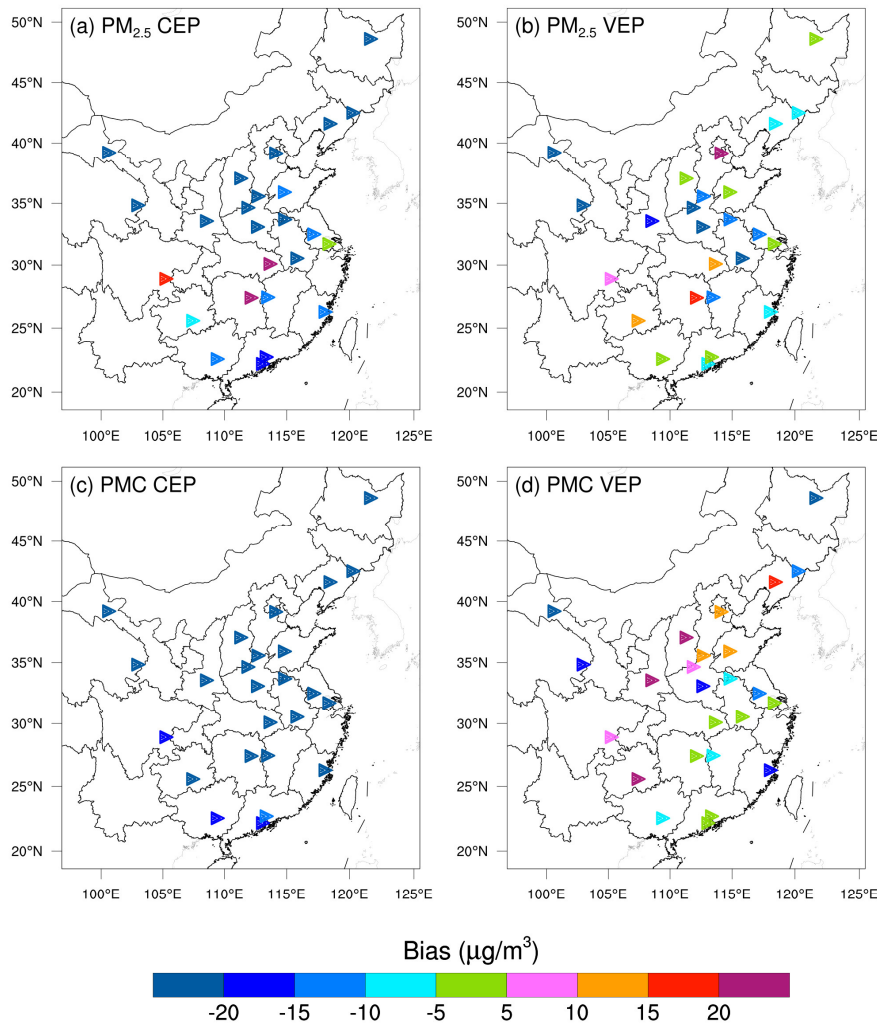

626 Figure 7 and Fig. 8 show the spatial distributions of the biases calculated against the  
 627 independent observations for the 5 species. With posterior emissions, the decreasing

628 ratios of RMSEs range from 26.7% to 42.0%, and the CORRs increase by 13.7-59.0%  
 629 to 0.62-0.87. Overall, the biases at the independent sites are similar or slightly worse  
 630 than those at the assimilated sites, which is reasonable since the closer to the assimilated  
 631 site the independent sites are, the more constraints of observation information can be  
 632 obtained, and the improvements in optimized state variables of the model are more  
 633 significant. For example, generally, the transmission distance of  $\text{NO}_2$  is relatively short,  
 634 and remote cities with small emission correlations to the cities with assimilated  
 635 observations are relatively less constrained, resulting in only a 26.7% decrease in the  
 636 RMSE.

637  
 638

**Figure 7.** As in Fig. 5 but for the independent validation.

639

640

**Figure 8.** As in Fig. 6 but for the independent validation.

641 Compared with the previous studies, Tang et al. (2013) conducted inversion of CO  
 642 emissions over Beijing and the surrounding areas, the improvements (Table 6) in the  
 643 RMSE (37-48% vs. 30-51%) and the CORR (both studies  $\sim 0.81$ ) are comparable, but  
 644 the biases here could decrease by 90-97%, which is much greater than their 48-64%  
 645 reductions. Additionally, Chen et al. (2019) showed that the RMSE of simulated SO<sub>2</sub>  
 646 with updated SO<sub>2</sub> emissions decreased by 4.2-52.2% for different regions, and the  
 647 CORR only increased to 0.69 at most. The improvement is relatively smaller than our  
 648 results, which may be due to the insufficient adjustment of emissions caused by the  
 649 underestimated ensemble spread through the inflation method. The better performance  
 650 in this study may be related to our inversion process that makes the optimized emissions

651 of the current DA window propagate to the next DA window for further correction.

652 **Table 6.** Statistics comparing the pollution concentrations from the simulations with  
 653 prior (CEP) and posterior (VEP) emissions against assimilated and independent  
 654 observations, respectively. CO unit: mg m<sup>-3</sup>; others units: μg m<sup>-3</sup>.

Species	Mean Obs.	Mean Sim.		BIAS		RMSE		CORR	
		CEP	VEP	CEP	VEP	CEP	VEP	CEP	VEP
Against assimilated observations

#### 656 4.1.4 Uncertainty reduction

657 The uncertainty reduction rate (UR) is another important quantity to evaluate the  
 658 performance of RAPAS and the effectiveness of in-situ observations in this system  
 659 (Chevallier et al., 2007; Jiang et al., 2021; Takagi et al., 2011). Following Jiang et al.  
 660 (2021), the UR is calculated as

$$661 \quad UR = \left(1 - \frac{\sigma_{posterior}}{\sigma_{prior}}\right) \times 100 \quad (19)$$

662 where  $\sigma_{posterior}$  and  $\sigma_{prior}$  are the posterior and prior uncertainties, respectively.  
 663 Figure 9 shows the URs averaged in each province and the whole mainland China. The  
 664 URs vary with species, and among the 5 species of emissions, the uncertainties of the  
 665 PPM<sub>2.5</sub> and PMC are greatly reduced, while the UR of NO<sub>x</sub> emission is lowest, that is  
 666 because the URs are closely related to the magnitude settings of prior uncertainties  
 667 (Jiang et al., 2021). For the whole mainland China, the uncertainties are reduced by

668 44.4%, 45.0%, 34.3%, 51.8% and 56.1% for CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC,  
669 respectively. For one species, it also varies across provinces. The URs are usually  
670 related to observation coverage, which means that the more observation constraints  
671 there are, the more the URs decrease. Additionally, the URs may also relate to emission  
672 distributions. Generally, the URs are more significant in the provinces where the  
673 observations and emissions are both relatively concentrated (e.g., Tibet), while they are  
674 much lower in where the emissions are scattered or relatively uniform, but the  
675 observations are only in large cities, even though there are many more observations  
676 than other provinces.

677

678 **Figure 9.** Time-averaged posterior emission uncertainty reduction (%) indicated by the  
 679 standard deviation reduction of total emissions per province calculated by prior and  
 680 posterior ensembles.

681 **4.2 Inverted emissions**

682 Figure 10 shows the spatial distribution of the temporal averaged prior and posterior  
 683 emissions and their differences. Higher emissions are mainly concentrated in central

684 and eastern China, especially in the NCP, YRD, and PRD, and lower emissions occur  
685 across Northwest and Southern China. Compared with the prior emissions, posterior  
686 CO emissions are considerably increased across most areas of mainland China,  
687 especially in northern China, with an overall increase of 129%. Notable  
688 underestimation of the prior emissions is also confirmed by previous inversion  
689 estimations (Feng et al., 2020b; Tang et al., 2013; Wu et al., 2020) and model  
690 evaluations (Kong et al., 2019a). For SO<sub>2</sub>, the emission increases mainly occur in  
691 Northeast China, Shanxi, Ningxia, Gansu, Fujian, Jiangxi and Yunnan provinces. In  
692 SCB, Central China, YRD, and part of NCP, the emissions are significantly reduced.  
693 For national total, the SO<sub>2</sub> emission is increased by 20%. For NO<sub>x</sub>, although the  
694 increment of national total emissions is small, only about 5%, large deviations still exist  
695 on regional scale. Obviously, the emissions in the NCP and YRD are reduced, while in  
696 the other regions, the emissions of most cities are increased. The changes in PPM<sub>2.5</sub>  
697 emission are similar to SO<sub>2</sub>. Compared with the prior emission, the posterior PPM<sub>2.5</sub>  
698 emissions are decreased over central China, SCB and YRD, while the ones in southern  
699 and northern China are increased, especially in Shanxi, Shaanxi, Gansu and southern  
700 Hebei province. Overall, the relative increase is 95%. For PMC, the posterior emissions  
701 are increased over the whole mainland China, with national mean relative increase  
702 exceeding 1000%. Larger emission increments mainly occur in the areas where have  
703 significant anthropogenic emissions of CO and PPM<sub>2.5</sub>, indicating that the large  
704 underestimations of PMC emissions in the prior inventory may be mainly attributed to  
705 the underestimations of anthropogenic activities. In addition, without dust may be  
706 another reason, since no wind blowing dust scheme was applied in this study as  
707 mentioned above. Large PMC emission increment are also found in Ma et al (2019).  
708 Detailed estimation of posterior emissions and relative changes compared to prior  
709 emissions in each province and the whole mainland China is given in Table S1. Note  
710 that the differences, excluding PMC, between the prior and posterior emissions mainly  
711 reflect the deficiencies of the prior emissions because the times of the prior emissions  
712 and the observations are completely consistent in this study.

713

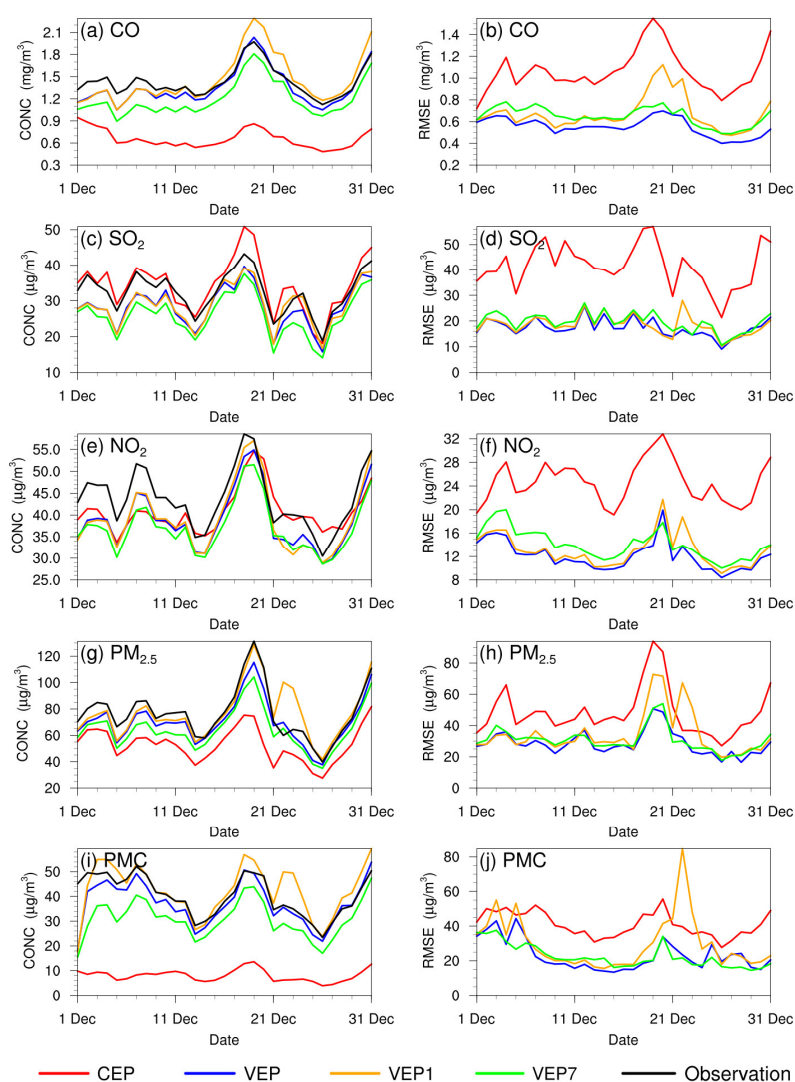

714 **Figure 10.** Spatial distribution of the time-averaged prior emissions (left column, MEIC  
 715 2016), posterior emissions (middle column), and differences (right column, posterior  
 716 minus prior).

## 717 4.3 Sensitivity tests

### 718 4.3.1 The advantages of “two-step” scheme

719 Adjusting the ICs and emissions simultaneously (i.e., “one-step” scheme) has been  
720 applied to constrain prior emissions in many previous studies (Evensen, 2009; Kong et  
721 al., 2019b). To investigate the impact of different methods on the optimized emissions,  
722 a sensitivity test (EMS1) is performed, in which the initial fields of each DA window  
723 are optimized using the 3DVAR algorithm directly. Compared with our “two-step”  
724 method (EMDA), the posterior emissions of EMS1 are increased by 7%, 1.4%, 0.6%,  
725 22.2%, and 17.2% for CO, SO<sub>2</sub>, NO<sub>x</sub>, PM<sub>2.5</sub> and PMC, respectively. As mentioned  
726 previously, in the “two-step” scheme, the optimized emission can be sufficiently fed  
727 back to the concentration field and fully mixed in the atmosphere (1 day), and the error  
728 transfer makes the system consistently and stably updated. If the emission in one  
729 window is overestimated, in this way, it could be compensated in the next window with  
730 lower estimates. In contrast, when initial fields assimilating with observations  
731 simultaneously at each window, the overestimation will not be corrected and will  
732 accumulate to the end. We also evaluate the posterior emissions of EMS1 using the  
733 same method as shown in Sect. 4.1.3. Figure 11 shows the time series of simulated and  
734 observed daily concentrations and their RMSEs verified against the assimilated sites.  
735 Overall, compared to the base experiment (EMDA), the performance of EMS1 is  
736 significantly worse, with RMSEs of CO, SO<sub>2</sub>, NO<sub>2</sub>, PM<sub>2.5</sub> and PMC increasing from  
737 0.56 mg m<sup>-3</sup>, 17.7, 12.3, 29.6, and 24.6 μg m<sup>-3</sup> to 0.69 mg m<sup>-3</sup>, 18.8, 13.3, 36.8, and 33.3  
738 μg m<sup>-3</sup>, respectively. Additionally, it can be seen from the figure that the results of the  
739 two experiments are relatively close at the beginning and during the heavy pollution  
740 period (16-21 December). However, after that, the simulated results with “one-step”  
741 inversion emissions are significantly higher than the observations, and these large  
742 biases continue until the end. The results verified against the independent sites also  
743 show a similar situation (Fig. S2). The reason may be that during the period of heavy  
744 pollution, the WRF-CMAQ (off-line model) does not consider the feedback process of  
745 meteorology and chemistry, resulting in low simulations. Therefore, the system will

746 compensate for the underestimated concentrations caused by the model error through  
 747 more emissions, resulting in the overestimation of emissions. The accumulation of  
 748 emission error in each independent window further leads to the overestimation of  
 749 concentration after the end of high pollution, especially for species with a long lifetime  
 750 (e.g., CO). On the contrary, this overestimation will be corrected quickly in the  
 751 subsequent inversion using the “two-step” inversion scheme in this study, so as to  
 752 ensure the stability of the system. It should be noted that the model performance  
 753 depends on many factors but does not affect the advantage of the “two-step” scheme.

754  
 755 **Figure 11.** Time series of the daily concentrations (CONC, left) and root mean square  
 756 error (RMSE, right) obtained from CEP, VEP, VEP1, and VEP3. The simulations were  
 757 verified against the assimilated sites.

### 758 **4.3.2 Impact of prior inventories**

759 Various prior inventories have great differences in space allocation and emission  
760 magnitude. Inversion results can be sensitive to a priori emissions if the observation is  
761 insufficient (Gurney et al., 2004; He et al., 2018). MEIC 2012 is used as an alternative  
762 a priori in EMS2 to investigate the impact of different prior emissions on the posteriori.  
763 Figure 12 shows the time series of the relative differences in daily posterior emissions  
764 of the five species between the EMDA (base) and EMS2 experiments. Overall, the  
765 differences between the two posterior emissions gradually decrease over time. At the  
766 beginning, the differences in the CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC between the two  
767 inventories (i.e., MEIC 2012 vs MEIC 2016) are 17.5%, 114.5%, 30.8%, 46.0% and  
768 72.0%, respectively, while during the last ten days, the differences of the two posterior  
769 emissions have decreased to 2.5%, 4.5%, 4.5%, -8.9% and 3.0%, respectively. In  
770 addition, it also could be found that the species that has larger emission differences at  
771 the beginning take a longer time (namely more DA steps) to achieve convergence. The  
772 quick convergence of PMC emission is attributed to the large prior uncertainty of 100%  
773 used in the first 3 DA windows. Different from the other species, there are significant  
774 negative deviations of PPM<sub>2.5</sub> emissions between the two experiments. That may be  
775 due to the positive deviations in the precursors of PM<sub>2.5</sub> (i.e., SO<sub>2</sub> and NO<sub>x</sub>), which will  
776 lead to a larger amount of secondary production. To balance the total PM<sub>2.5</sub>  
777 concentration, the PPM<sub>2.5</sub> emissions will be reduced. We compare the PM<sub>2.5</sub>  
778 concentrations simulated by the two optimized inventories and find that they are almost  
779 the same (Fig. S3). Overall, this indicates that the observation in China is sufficient in  
780 inferring the emissions, and our system is rather robust. Meanwhile, it also suggests  
781 that the monthly posterior emissions shown in Sect. 4.2 are still underestimated to a  
782 certain extent.

783

784 **Figure 12.** Relative differences in CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC emissions (% the  
 785 ratio of absolute difference to EMDA) between the EMDA and EMS2 experiments.

786

### 787 4.3.3 Impact of prior uncertainties settings

788 The uncertainty of prior emissions determines how closely the analysis is weighted  
 789 toward the background and observation, but information about prior uncertainties is  
 790 generally not readily available. To evaluate the possible influence of prior uncertainties  
 791 on the optimized emissions, we increased/reduced the uncertainties after 3 days of  
 792 cycling, namely starting at 0000 UTC, 3 December, by 25% and 50 % in EMS3 (-50%),  
 793 EMS4 (-25%), EMS5 (+25%) and EMS6 (+50%), respectively. Table 7 summarizes the  
 794 emission changes with different prior uncertainties settings in EMS3-6 experiments. To  
 795 better understand the response of the system to the emission uncertainty settings, Fig.  
 796 13 shows the time series of SO<sub>2</sub> emission changes and the RMSEs of simulated SO<sub>2</sub>  
 797 with emissions updated in the EMDA and EMS3-6 experiments over the YRD and NCP  
 798 (Fig. 2). Compared with the EMDA, when the uncertainties are decreased (increased),  
 799 the emissions of the 5 species decrease (increase) accordingly. That is because the  
 800 posterior emissions of the 5 species are larger than the prior emissions, and as shown  
 801 in Fig. 13, larger uncertainty will lead to a faster convergence, resulting in larger

802 posterior emissions. It also could be found from Fig. 13 that a faster convergence will  
 803 indeed reduce the RMSE of the simulated concentration with the posterior emissions in  
 804 the early stage of the experiment, but in the later stage of the experiment, there are no  
 805 significant differences for the RMSE among the different experiments. In addition, it  
 806 shows that when greater uncertainties are set, the day-to-day changes in emissions are  
 807 also more drastic, resulting in a larger RMSE as shown in NCP. Moreover, those  
 808 significant day-to-day variations of estimated emissions may not be in line with the  
 809 actual situation. Overall, the uncertainties chosen in EMDA aim to minimize the  
 810 deviation of the concentration fields and maintain the stability of inversion.

811 **Table 7.** Relative differences in CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC emissions (% the  
 812 ratio of absolute difference to EMDA) between the EMDA and EMS3-6 experiments.

Species	EMS3	EMS4	EMS5	EMS6
CO	-8.6	-4	3	5.2
SO <sub>2</sub>	-14	-5.7	3.6	6.8
NO <sub>x</sub>	-6.5	-3	2.8	4.5
PPM <sub>2.5</sub>	-16.5	-7.8	4.6	8.7
PMC	-18.5	-8.2	7.3	13.1

813

814

815 **Figure 13.** Time-series of SO<sub>2</sub> emissions changes and the RMSE of simulated SO<sub>2</sub> with  
 816 updated SO<sub>2</sub> emissions in the EMDA and EMS3-6 experiments over the Yangtze River  
 817 Delta (YRD) and North China Plain (NCP).

#### 818 4.3.4 Impact of observation error settings

819 Another factor that determines the relative weights of the observation and background  
 820 in the analysis is observation errors. A proper estimate of the observation error is also  
 821 important in regard to the filter performance, but observation errors are not provided  
 822 with the dataset. The observation error is usually set to a fixed value (Ma et al., 2019),  
 823 a specific proportion of the observation value (Tang et al., 2013) or the value calculated  
 824 by combining measurement error with representative error as used in this study.  
 825 Generally, the performance of the data assimilation is quite sensitive to the specification  
 826 of observation error (Tang et al., 2013). To evaluate the influence of observation error  
 827 on the optimized emissions, a sensitivity experiment (EMS7) with doubled observation  
 828 error was conducted. Overall, the spatial distribution of emissions after optimization is  
 829 almost the same as that of the EMDA experiment, but the increment is lower (Fig. S4),

830 resulting in a weaker estimate of the national total emission for each species. That is  
831 because that the observation error becomes large, the system will be more convinced of  
832 the prior emission and reduce the effect of observation information. The simulations in  
833 VEP7 usually perform worse, with larger biases and RMSEs than those of VEP (Figs  
834 11, S2 and S5), especially in most of western and southern China where posterior  
835 emissions are still significantly underestimated, suggesting that too large observation  
836 error may substantially impact the estimated emissions.

## 837 **5 Summary and conclusions**

838 In this study, we developed a Regional multi-Air Pollutant Assimilation System  
839 (RAPASv1.0) based on the WRF/CMAQ model, 3DVAR and EnKF algorithm. RAPAS  
840 can quantitatively optimize gridded emissions of CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC on  
841 regional scale by simultaneously assimilating hourly in-situ measurements of CO, SO<sub>2</sub>,  
842 NO<sub>2</sub>, PM<sub>2.5</sub> and PM<sub>10</sub>. This system includes two subsystems, namely the IA subsystem  
843 and the EI subsystem, which optimizes the chemical ICs, and infers the anthropogenic  
844 emissions, respectively.

845 Taking the 2016 Multi-resolution Emission Inventory for China (MEIC 2016) in  
846 December as a priori, the emissions of CO, SO<sub>2</sub>, NO<sub>x</sub>, PPM<sub>2.5</sub> and PMC in December  
847 2016 were inferred through assimilating the corresponding nationwide observations  
848 over China. The optimized ICs and posterior emissions were examined against the  
849 assimilated and independent observations through parallel forward simulation  
850 experiments with and without DA. Sensitivity tests are also performed to investigate  
851 the impact of different inversion processes, prior emissions, prior uncertainties and  
852 observation errors on the emission estimates.

853 The results show that RAPAS can significantly improve the simulations and reduce the  
854 uncertainties of the emissions. For the whole mainland China, the emission  
855 uncertainties reduced by 44.4%, 45.0%, 34.3%, 51.8% and 56.1% for CO, SO<sub>2</sub>, NO<sub>x</sub>,  
856 PPM<sub>2.5</sub> and PMC, respectively, the RMSEs of the simulated concentrations with  
857 posterior emissions decreased by 40.1-56.3%, and the CORRs increased from 0.26-0.66

858 to 0.69-0.87 for different species. Overall, compared with the prior emissions (MEIC  
859 2016), the posterior emissions increased by 129%, 20%, 5% and 95% for CO, SO<sub>2</sub>, NO<sub>x</sub>  
860 and PPM<sub>2.5</sub>, respectively. The posterior PMC emissions, which included anthropogenic  
861 and natural dust contributions, increased by 1045%. The sensitivity tests with different  
862 inversion processes show that the “two-step” scheme in emission inversion outperforms  
863 the joint adjustment of ICs and emissions (“one-step” scheme), especially after heavy  
864 pollution. The sensitivity tests with different prior inventories show the observation in  
865 China is sufficient in inferring the emissions, and our system is less dependent on prior  
866 inventories. Additionally, the sensitivity tests with different prior uncertainties indicate  
867 that when the posterior emissions are larger than the prior emissions, the emissions  
868 decrease/increase with the decreases/increases of uncertainties because of the different  
869 convergence rates. These results demonstrate the advantage of the two-step method in  
870 emission inversion in that the inversion errors of the last window could be transferred  
871 to the current window for further optimization and the robustness of the emissions  
872 estimated from RAPAS using the nationwide observations over China. It should be  
873 noted that the system usually responds slowly to too small a priori uncertainty or too  
874 large observation error, which may result in large errors in the estimated emissions.

875 Independent variable localization was adopted to avoid potential spurious correlations  
876 across different species in this study. However, the transmission scales for different  
877 species in different regions are still different, and a more accurate localization range  
878 could be obtained through backward trajectory analysis. In additionally, O<sub>3</sub>  
879 observations are not assimilated to improve NO<sub>x</sub> and VOC emissions using cross-  
880 species information due to the strong nonlinear effects within the O<sub>3</sub>-NO<sub>x</sub>-VOC  
881 relationship, in which the O<sub>3</sub> concentration and NO<sub>x</sub> (VOC) emissions are positively  
882 correlated in the NO<sub>x</sub> (VOC)-limited region and negatively correlated in the VOC  
883 (NO<sub>x</sub>)-limited region (Tang et al., 2011). This work will be followed up by an ongoing  
884 work using available VOC observations. As shown previously, the concentrations after  
885 DA are obviously underestimated in western China, indicating that the inverted  
886 emissions over these regions still have large uncertainties because of the sparsity of

887 observations that are spatially insufficient for sampling the inhomogeneity of emissions.  
888 Therefore, further investigations with joint assimilation of multisource observations  
889 (e.g., satellite) are also underway.

890 In summary, this study offers a useful tool for accurately quantifying multi-species  
891 anthropogenic emissions at large scales and near-real time, which will serve better for  
892 monitoring emission changes and designing future emissions regulations and pollution  
893 control.

894

### 895 **Code and data availability**

896 The codes of RAPAS v1.0 are available at <https://doi.org/10.5281/zenodo.5566225>.  
897 The WRF model code is open-source code and can be obtained from the WRF Model  
898 User's Page (<https://www2.mmm.ucar.edu/wrf/users>, last access: 25 April 2021). The  
899 CMAQ model is available through an open license as well (<https://www.epa.gov/cmaq> ,  
900 last access: 25 April 2021). The observation and emission data used in this paper are  
901 available at <https://doi.org/10.5281/zenodo.4718290> (Feng and Jiang, 2021).

902

### 903 **Author contribution**

904 SF, FJ, ZW and ZJ developed RAPAS v1.0. SF and FJ designed the research. SF  
905 performed model simulations, analyzed data, and prepared the paper with contributions  
906 from all co-authors. FJ supervised the model development project and assisted in  
907 conceptualization and writing. HW, WH, YS, LZ, YZ, CL, and WJ contributed to the  
908 discussion and improvement of the paper.

909

### 910 **Competing interests**

911 The authors declare that they have no conflict of interest.

## 912 **Acknowledgements**

913 This work is supported by the National Key R&D Program of China (Grant No.  
914 2016YFA0600204), the National Natural Science Foundation of China (Grant No.  
915 41907378), and the Nanjing University Innovation and Creative Program for Ph.D.  
916 candidate (Grant No. CXCY19-60). We are grateful to the High Performance  
917 Computing Center (HPCC) of Nanjing University for doing the numerical calculations  
918 in this paper on its blade cluster system, and thank the MEIC team for providing the  
919 prior anthropogenic emissions (<http://www.meicmodel.org/>).
