30 **Abstract**

31 Top-down atmospheric inversion infers surface-atmosphere fluxes from spatially
32 distributed observations of atmospheric compositions, which is a vital means for
33 quantifying large-scale anthropogenic and natural emissions. In this study, we
34 developed a Regional multi-Air Pollutant Assimilation System (RAPAS v1.0) based on
35 the Weather Research and Forecasting/Community Multiscale Air Quality Modeling
36 System (WRF/CMAQ) model, the three-dimensional variational (3DVAR) algorithm
37 and the ensemble square root filter (EnSRF) algorithm. It is capable of simultaneously
38 assimilating spatially distributed hourly in-situ measurements of CO, SO₂, NO₂, PM_{2.5}
39 and PM₁₀ concentrations to quantitatively optimize gridded emissions of CO, SO₂, NO_x,
40 primary PM_{2.5} (PPM_{2.5}) and coarse PM₁₀ (PMC) on regional scale. RAPAS includes two
41 subsystems, initial field assimilation (IA) subsystem and emission inversion (EI)
42 subsystem, which are used to generate a good chemical initial condition (IC), and
43 conduct inversions of anthropogenic emissions, respectively. A “two-step” inversion
44 scheme is adopted in the EI subsystem in each data assimilation (DA) window, in which
45 the emission is inferred in the first step, and then, it is input into the CMAQ model to
46 simulate the initial field of the next window, meanwhile, it is also transferred to the next
47 window as the prior emission. The chemical IC is optimized through the IA subsystem,
48 and the original emission inventory is only used in the first DA window. Besides, a
49 “super-observation” approach is implemented based on optimal estimation theory to
50 decrease the computational costs and observation error correlations and reduce the
51 influence of representativeness errors.

52 With this system, we estimated the emissions of CO, SO₂, NO_x, PPM_{2.5} and PMC in
53 December and July 2016 over China using the corresponding nationwide surface
54 observations. The 2016 Multi-resolution Emission Inventory for China (MEIC 2016)
55 was used as the prior emission. For December, the system was run from 26 November
56 to 31 December, in which the IA subsystem was run in the first 5 days, and the EI
57 subsystem was run in the following days. In July, the system was run in the same way.
58 The evaluation and sensitivity testing of this system mainly focused on December.

59 Results showed that the simulated concentrations of CO, NO₂, SO₂, PM_{2.5} and PM₁₀
60 with the prior inventory have large systematic biases, with relative biases in the range
61 of -48.2-54.2%. In the IA subsystem, after 3DVAR, the root mean squared error (RMSE)
62 of the simulated concentrations decreased by 50.0-73.2%, and the correlation
63 coefficient (CORR) increased to 0.78-0.92 for the five species. In the EI subsystem,
64 after emission inversions, the RMSE of the simulated concentrations decreased by 40.1-
65 56.3%, and the CORR increased to 0.69-0.87. For the whole mainland China, the
66 uncertainties were reduced by 44.4%, 45.0%, 34.3%, 51.8% and 56.1% for CO, SO₂,
67 NO_x, PPM_{2.5} and PMC, respectively. Overall, compared to the prior emission (MEIC
68 2016), the posterior emissions increased by 129%, 20%, 5%, and 95% for CO, SO₂,
69 NO_x and PPM_{2.5}, respectively, indicating that there was significant underestimation in
70 the MEIC inventory. The posterior PMC emissions, including anthropogenic and
71 natural dust contributions, increased by 1045%. A series of sensitivity tests were
72 conducted with different inversion processes, prior emissions, prior uncertainties, and
73 observation errors. Results showed that the “two-step” scheme clearly outperformed
74 the simultaneous assimilation of ICs and emissions (“one-step” scheme), and the
75 system is rather robust in estimating the emissions using the nationwide surface
76 observations over China. Our study offers a useful tool for accurately quantifying multi-
77 species anthropogenic emissions at large scales and near-real time.

86 **1. Introduction**

87 Due to rapid economic developments and pollution control legislations, an increasing
88 demand to provide updated emission estimates has arisen, especially in areas where
89 anthropogenic emissions are intensive. Accurately estimating source emission
90 quantities and spatiotemporal changes resulting from various regulations is imperative
91 and valuable for understanding air quality responses and crucial for providing timely
92 instructions for the design of future emissions regulations. However, most inventories
93 have been developed based on a bottom-up approach and are usually updated with a
94 few years delay due to the complexity of gathering all statistical information on activity
95 levels and sector-specific emission factors (Ding et al., 2015). The large uncertainty
96 associated with the low temporal and spatial resolution of these datasets also greatly
97 limits the assessment of emission changes. Some studies (Bauwens et al., 2020; Shi and
98 Brasseur, 2020) have evaluated emission changes indirectly through concentration
99 measurements, but air pollution changes are not only dominated by emission changes,
100 but also highly affected by meteorological conditions (Shen et al., 2021).

101 Top-down atmospheric inversion infers surface-atmosphere fluxes from spatially
102 distributed observations of atmospheric compositions. Recent efforts have focused on
103 developing air pollution data assimilation (DA) system to conduct the top-down
104 inversion, which is able to integrate model and multi-source and large amounts of
105 observational information to constrain emission sources. Two major methods, namely,
106 4D-variational data assimilation (4DVAR) and ensemble Kalman filter (EnKF), are
107 widely used in those DA systems. 4DVAR provides a global optimal analysis through
108 minimizing a cost function. It shows implicit flow-dependent background error
109 covariance and can reflect complex nonlinear constraint relationship (Lorenc, 2003).
110 Additionally, the model error can be partly accounted for with a weak constraint
111 4DVAR method through the definition of a systematic error term in a cost function
112 (Derber, 1989). For example, GEOS-Chem and TM5 4DVAR frameworks have been
113 used to estimate CH₄ (Alexe et al., 2015; Schneising et al., 2009; Stanevich et al., 2021;
114 Wecht et al., 2014) and CO₂ fluxes (Basu et al., 2013; Nassar et al., 2011; Wang et al.,

115 2019a) from different satellite retrieval products. Monteil et al. (2013) showed that the
116 global patterns of CH₄ emissions derived from SCIAMACHY (with bias correction)
117 and GOSAT retrievals are in remarkable agreement based on 15 months observations.
118 Additionally, Jiang et al. (2017) used 4DVAR algorithm to estimate global CO emission
119 trends from 2000–2015 using MOPITT retrievals. Kurokawa et al. (2009) and
120 Stavrakou et al. (2008) also used 4DVAR technique to estimate NO_x emission changes.
121 However, the drawback of the 4DVAR method is the additional development of adjoint
122 models that are technically difficult and cumbersome for complex chemical transport
123 models. Instead, EnKF uses the flow-dependent background error covariance generated
124 by ensemble simulations to map the deviations in concentrations to increments of
125 emissions, which is more flexible and easier to implement. Many previous studies have
126 used EnKF techniques to assimilate the single or dual species observations to optimize
127 the corresponding emission species (Chen et al., 2019; Peng et al., 2017; Schwartz et
128 al., 2014; Sekiyama et al., 2010). Multispecies data assimilation has shown the
129 advantage of efficiently reducing the uncertainty in emission inventories and has led to
130 improvements in air quality forecasting (Ma et al., 2019; Miyazaki et al., 2012b), since
131 it would offer additional constraints on emission estimates through the improvements
132 in related atmospheric fields, chemical reactions, and gas-particle transformations
133 (Miyazaki and Eskes, 2013). Barbu et al. (2009) updated sulfur oxide (SO_x) emissions
134 with SO₂ and sulfate aerosol observations and found that simultaneous assimilation of
135 both species had better performance than assimilating one of them alone.

136 The deviation in chemical initial condition (IC) is one of the important sources of error
137 that affects the accuracy of emission inversion, because atmospheric inversion fully
138 attributes the biases in simulated and observed concentrations to the deviations in
139 emissions (Meirink et al., 2006; Peylin et al., 2005). The biases of concentrations would
140 be compensated through unreasonable adjustment of pollution emissions without the
141 optimization of ICs (Tang et al., 2013). Tang et al. (2011) reported that the simultaneous
142 optimizations of the ICs of O₃, NO_x and volatile organic compounds (VOCs) and the
143 emissions of NO_x and VOCs produced an overall better performance in ozone forecasts

144 than the adjustment in emissions only. Similar method of simultaneously optimizing
145 chemical ICs and emissions were also applied to constraining emissions in many
146 previous studies (Ma et al., 2019; Miyazaki et al., 2012a; Peng et al., 2018). Although
147 a large improvement has been achieved, this method still has great limitations because
148 the contributions from the emissions and the chemical ICs to the model's bias are
149 difficult to distinguish (Jiang et al., 2017). In addition, in this method, the constraints
150 of the chemical ICs with observations in each assimilation window make the emission
151 inversions are independent between assimilation windows, means if the emission in one
152 window is overestimated or underestimated, it cannot be transferred to the next window
153 for further correcting and be compensated in the following windows. This may result
154 in a systematic bias in the inverted emissions (Jiang et al., 2021).

155 Since 2013, China has deployed an air pollution monitoring network that publishes
156 nationwide and real-time hourly surface atmospheric observations. This dataset
157 provides an opportunity to improve emission estimates using DA. In this study, a
158 regional multi- air pollutant assimilation system introducing 3DVAR and EnKF DA
159 techniques is constructed to simultaneously assimilate various surface observations
160 (e.g., CO, SO₂, NO₂, O₃, PM_{2.5} and PM₁₀). Considering the possible shortcomings of
161 the simultaneous optimization method (named as “one-step” method in this study) as
162 mentioned by Jiang et al. (2021), we adopted a “two-step” method (Sect. 3) in this system.
163 Unlike the “one-step” method, the ICs of each DA window in the “two-step” method is
164 simulated using the posterior emissions of the pervious DA window. The capability of
165 RAPAS in reanalysis field generation and emission inversion estimation was evaluated.
166 The robustness of the system was also investigated with different prior inventories,
167 uncertainty settings of the prior emission, and observation errors. This paper is
168 organized as follows: in Sect. 2, we introduce the DA system and the observation data,
169 and in Sect. 3, we describe the experimental design. The results of the system
170 performance and sensitivity tests are presented and discussed in Sect. 4, followed by
171 the conclusions in Sect. 5.

172

173 **2. Method and data**

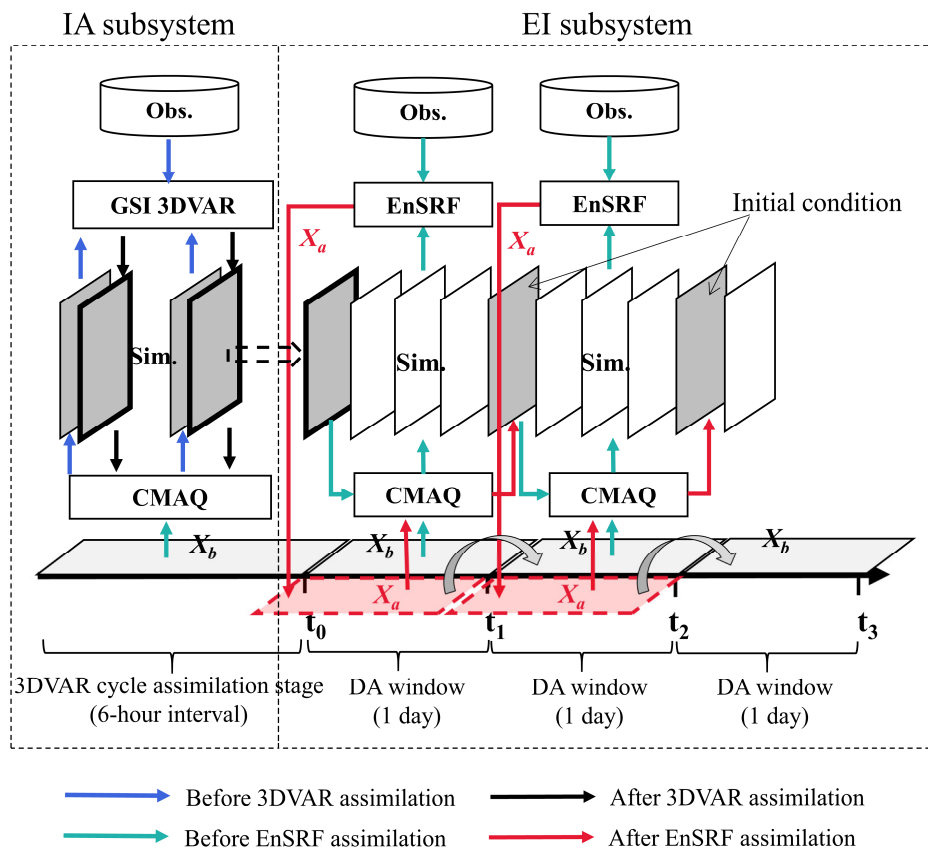

174 **2.1 System description**

175 **2.1.1 Procedure of the assimilation system**

176 A regional air pollutant assimilation system has been preliminarily constructed and
177 successfully applied in our previous studies to optimize gridded CO and NO_x emissions
178 (Feng et al., 2020a; Feng et al., 2020b). Herein, the system was further extended to
179 simultaneously assimilate multiple species (e.g., CO, SO₂, NO₂, O₃, PM_{2.5} and PM₁₀)
180 and officially named as the Regional multi- Air Pollutant Assimilation System
181 (RAPASv1.0). The RAPAS mainly includes three components: a regional chemical
182 transport model (CTM), which is coupled offline and used to simulate the
183 meteorological fields and atmospheric compositions, and the 3DVAR and ensemble
184 square root filter (EnSRF) modules, which are used to optimize chemical ICs (Feng et
185 al., 2018; Jiang et al., 2013b) and anthropogenic emissions (Feng et al., 2020a; Feng et
186 al., 2020b), respectively. The introduction of 3DVAR mainly considers its great
187 performance based on our previous study and lower computational cost during spin-up
188 period in optimizing ICs. Additionally, it has been found that the 3DVAR method can
189 obtain a better initial field than the EnKF method (Schwartz et al., 2014).

190 Based on above three components, the RAPAS is divided into two subsystems, namely
191 the IC assimilation (IA) subsystem (CTM plus 3DVAR) and the emission inversion (EI)
192 subsystem (CTM plus EnSRF). As shown in Figure 1, the IA subsystem is first run to
193 optimize chemical ICs (Kleist et al., 2009; Wu et al., 2002) for the subsequent EI
194 subsystem. In the IA subsystem, we do not need to distinguish the type of sources of
195 the model-observation mismatch error. The EI subsystem runs cyclically with a “two-
196 step” scheme. In the first step, the prior emissions (\mathbf{X}^b) are perturbed and put into the
197 CTM model to simulate chemical concentration ensembles. The simulated
198 concentrations of the lowest model level are then interpolated to the observation space
199 according to the locations and times of the observations using the nearest neighbor
200 interpolation method. The prior emissions (\mathbf{X}^b), simulated observations and real

201 observations are entered into the EnSRF module to generate the optimized emissions
 202 (\mathbf{X}^a). In the second step, the optimized emissions are entered into the CTM model again
 203 to generate the initial fields of the next DA window. Meanwhile, the optimized
 204 emissions are transferred to the next window as the prior emissions. Different from the
 205 “one-step” scheme, this “two-step” scheme needs to run the CTM model twice, which
 206 is time consuming, but it could transfer the potential errors of the inverted emissions in
 207 one DA window to the next for further correction. The benefit of this scheme will be
 208 further presented in Sect. 4.3.

209

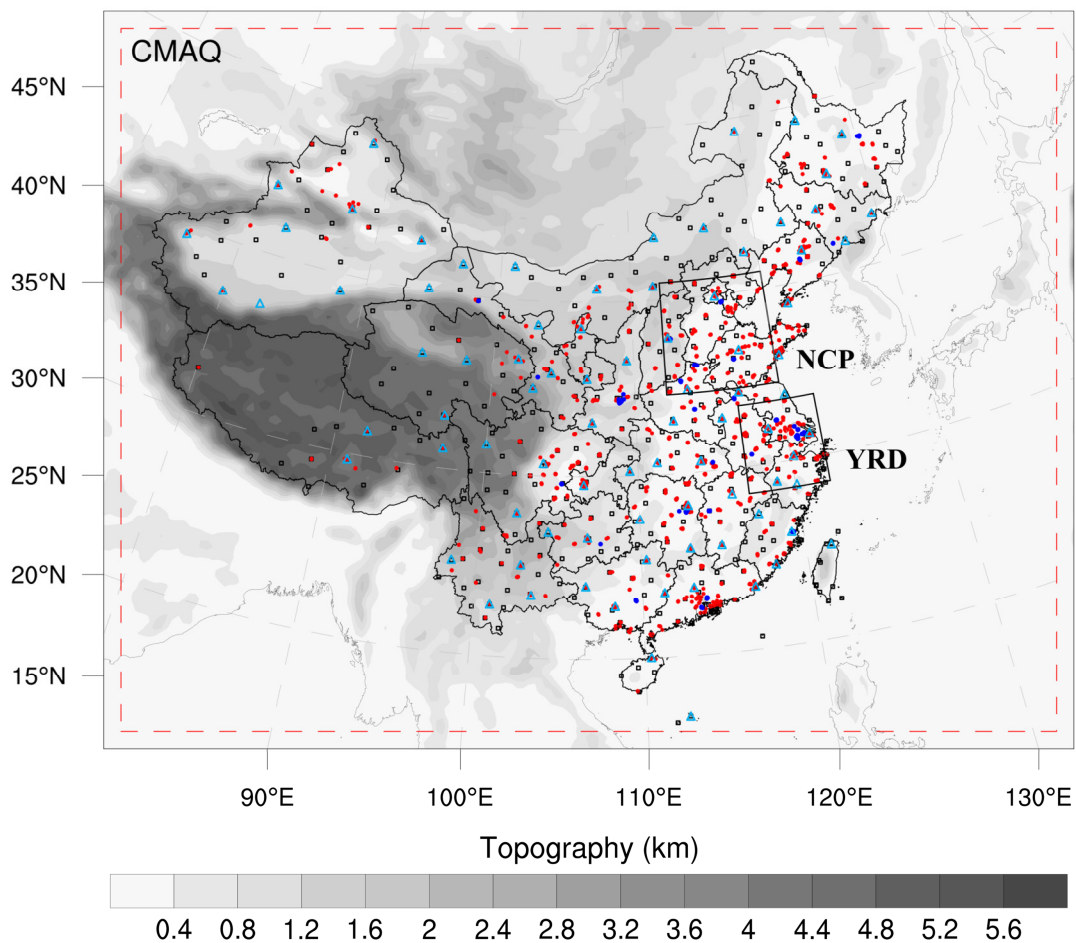

210 **Figure 1.** The composition and flow chart of RAPAS. The \mathbf{x}_a and \mathbf{x}_b represent the
 211 prior and posterior emissions. The 3DVAR assimilation stage lasts 5 days with data
 212 input frequency of 6 hours, and the DA window in the EI subsystem is set to 1 day.

213 **2.1.2 Atmospheric transport model**

214 The regional chemical transport model of WRF/CMAQ was adopted in this study.
 215 CMAQ is a regional 3-D Eulerian atmospheric chemistry and transport model with a

216 “one-atmosphere” design developed in the US Environmental Protection Agency (EPA).
217 It can address the complex interactions among multiple pollutants/air quality issues
218 simultaneously. CMAQ was driven by the WRF model, which is a state of the art
219 mesoscale numerical weather prediction system designed for both atmospheric research
220 and meteorological field forecasting. In this study, WRF version 4.0 and CMAQ version
221 5.0.2 were adopted. The WRF simulations were performed with a 36-km horizontal
222 resolution on 169×129 grids, and it covers the whole of mainland of China (Figure 2).
223 This spatial resolution has been widely adopted in regional simulations and can provide
224 good simulations of the spatiotemporal variations of air pollutants (Mueller and Mallard,
225 2011; Sharma et al. 2016). In the vertical direction, there are 51 sigma levels on sigma-
226 pressure coordinates extending from the surface to 100 hPa. The underlying surface of
227 urban and built-up land was replaced by the MODIS land cover retrieval of 2016 to
228 adapt to the rapid expansion of urbanization. The CMAQ model is run with the same
229 domain but with three grid cells removed from each side of the WRF domain. There are
230 15 layers in the CMAQ vertical coordinate, which were interpolated from the 51 WRF
231 layers.

232 The meteorological initial and lateral boundary conditions are both provided by the
233 Final (FNL) Operational Global Analysis data of the National Center for Environmental
234 Prediction (NCEP) with a $1^\circ \times 1^\circ$ resolution at 6-h intervals. The chemical lateral
235 boundary conditions and chemical ICs in the IA subsystem come from the background
236 profiles. As mentioned above, in the EI subsystem, the chemical IC in the first window
237 is provided by the IA subsystem, and in the following windows, it is forward simulated
238 using optimized emission from the previous window. The Carbon Bond 05 with updated
239 toluene chemistry (CB05tucl) and the 6th generation aerosol module (AERO6) are
240 chosen as the gas-phase and aerosol chemical mechanisms, respectively (Appel et al.,
241 2013; Sarwar et al., 2012). Detailed physical and chemical configurations are listed in
242 Table 1.

243

244 **Figure 2.** Model domain and observation network. The red dashed frame depicts the
 245 CMAQ computational domain; the black squares represent the surface meteorological
 246 measurement sites; the turquoise triangles represent the sounding sites; and the red and
 247 blue dots represent the air pollution measurement sites. Observations of all sites are
 248 assimilated in the 3DVAR subsystem, while observations of city sites where red dots
 249 are averaged are used for assimilation and where green dots are averaged are used for
 250 independent evaluation in EI subsystem; the boxed subregions are the North China
 251 Plain (NCP) and Yangtze River Delta (YRD); and the shaded area depicts the
 252 topography.

253

254

255

256 **Table 1.** Configuration options of WRF/CMAQ

WRF		CMAQ	
Parameter	Scheme	Parameter	Scheme
Microphysics	WSM6	Horizontal/Vertical advection	yamo/wrf
Longwave	RRTM	Horizontal/Vertical diffusion	multiscale/acm2
Shortwave	Goddard	Deposition	m3dry

Cumulus	Kain-Fritsch	Photolysis	phot_inline
Land-surface	Noah	Aerosol module	AERO6
Surface layer	Revised	Cloud module	cloud_acm_ae6
Urban canopy	No	Gas-phase chemistry	CB05tucl

257 **2.1.3 3DVAR assimilation algorithm**

258 The Grid-point Statistical Interpolation (GSI) developed in the US National Centers for
 259 Environmental Prediction (NCEP) was employed in this study. Building upon the work
 260 of Liu et al. (2011), Jiang et al. (2013b) and Feng et al. (2018), we extended it to
 261 simultaneously assimilate multiple species (including CO, SO₂, NO₂, O₃, PM_{2.5}, and
 262 PM₁₀) and first used individual aerosol species of PM_{2.5} as analysis variables within the
 263 GSI/WRF/CMAQ framework. Additional work includes the construction of surface air
 264 pollutant observation operators, the updating of observation errors, and the statistics of
 265 background error covariance for the analysis variables. Moreover, the data interface
 266 was also modified to read/write the CMAQ output/input file directly, which is easy to
 267 implement.

268 In the sense of a minimum analysis error variance, the 3DVAR algorithm optimizes
 269 analysis fields with observations by iterative processes to minimize the cost function
 270 ($J(\mathbf{x})$) defined below:

271
$$J(\mathbf{x}) = \frac{1}{2}(\mathbf{x}_a - \mathbf{x}_b)^T \mathbf{B}^{-1}(\mathbf{x}_a - \mathbf{x}_b) + \frac{1}{2}[H(\mathbf{x}_a) - \mathbf{y}]^T \mathbf{R}^{-1}[H(\mathbf{x}_a) - \mathbf{y}], \quad (1)$$

272 where \mathbf{x}_a is a vector of the analysis field; \mathbf{x}_b denotes the background field; \mathbf{y} is the
 273 vector of observations; \mathbf{B} and \mathbf{R} are the background and observation error covariance
 274 matrices, respectively, representing the relative contributions to analysis; and H is the
 275 observation operator that maps the model variables to the observation space.

276 The analysis variables are the 3D mass concentrations of the pollution compositions
 277 (e.g., CO and sulfate) at each grid point. Hourly mean surface pollution observations
 278 within a 1 hour window of the analysis are assimilated. To assimilate the surface
 279 pollution observations, model-simulated compositions are first diagnosed at the
 280 observation locations. For gas concentrations that are directly used as analysis variables,
 281 data units need to be converted from ppm or ppb to mg m^{-3} or $\mu\text{g m}^{-3}$ to match with
 282 observations. The model-simulated $\text{PM}_{2.5}$ and PM_{10} concentrations at the ground level
 283 are diagnosed as follows:

$$284 \quad \text{PM}_{2.5} = f_i \times \text{PM}_i + f_j \times \text{PM}_j + f_k \times \text{PM}_k = \text{OC} + \text{EC} + \text{SO}_4^{2-} + \text{NO}_3^- + \text{NH}_4^+ +$$

$$285 \quad \text{SEAS} + \text{AP}_{2.5} \quad (2)$$

$$286 \quad \text{PM}_{10} = \text{PM}_i + \text{PM}_j + \text{PM}_k = \text{PM}_{2.5} + \text{PMC} \quad (3)$$

287 where f_i , f_j , and f_k are the $\text{PM}_{2.5}$ fractions of the Aitken, accumulation, and coarse
 288 modes, respectively. These ratios are recommended as the concentrations of $\text{PM}_{2.5}$ and
 289 fine mode aerosols (i.e., Aitken plus accumulation) could differ because the $\text{PM}_{2.5}$
 290 particles include small tails from the coarse mode in the CMAQ model (Binkowski and
 291 Roselle, 2003; Jiang et al., 2006). PM_i , PM_j , and PM_k represent the mass
 292 concentrations of the 3 modes in the CMAQ model. Seven aerosol species of $\text{PM}_{2.5}$,
 293 including organic carbon (OC), elemental carbon (EC), sulfate (SO_4^{2-}), nitrate (NO_3^-),
 294 ammonium (NH_4^+), sea salt (SEAS), and fine-mode unspciated aerosols ($\text{AP}_{2.5}$), and
 295 additional coarse PM_{10} (PMC) are extracted as analysis variables, which are updated
 296 by the $\text{PM}_{2.5}$ and PMC observations, respectively. Before the calculation of equation (1)
 297 within the GSI, the analysis variables are bilinearly interpolated in the horizontal
 298 direction to the observation locations.

299 The computation of background error covariance (\mathbf{B}) is generally costly and difficult
 300 when a high-dimensional numerical model is used. For simplification, \mathbf{B} is represented
 301 as a product of spatial correlation matrices and standard deviations (SDs):

$$302 \quad \mathbf{B} = \mathbf{D}\mathbf{C}\mathbf{D}^T \quad (4)$$

$$303 \quad \mathbf{C} = \mathbf{C}_x \otimes \mathbf{C}_y \otimes \mathbf{C}_z \quad (5)$$

304 where \mathbf{D} is the background error SD matrix, \mathbf{C} is the background error correlation
 305 matrix, \otimes denotes the Kronecker product, and \mathbf{C}_x , \mathbf{C}_y , and \mathbf{C}_z denote three one-
 306 dimensional correlation submatrices in the longitude, latitude, and vertical coordinate
 307 directions, respectively. \mathbf{C}_x and \mathbf{C}_y are assumed to be isotropic horizontally such that
 308 can be represented using a Gaussian function. The correlation between any two points
 309 x_i and x_j in the horizontal can be expressed as follows:

$$310 \quad c(x_i, x_j) = e^{-\frac{(x_i-x_j)^2}{2L^2}} \quad (6)$$

311 where L is the horizontal correlation scale, which is estimated using the proxy of the
 312 background error (Figure 3). The vertical correlation matrix \mathbf{C}_z is directly estimated
 313 from the model background field since \mathbf{C}_z is only an $n_z \times n_z$ (here, $n_z=15$) matrix.

314

315 **Figure 3.** Vertical profiles of standard deviations (top, $\mu\text{g m}^{-3}$), horizontal length scale
 316 (middle, km) and vertical length scale (bottom, km) for CO, SO₂, NO₂, O₃, sulfate,
 317 nitrate, ammonium, EC, OC, sea salt, unspciated aerosols (AP_{2.5}), PMC, PM_{2.5} and
 318 PM₁₀.

319 To estimate these matrices, the “NMC” method is used here to compute **B** for each
 320 variable by taking the differences between forecasts of different lengths valid at the
 321 same time (Parrish and Derber, 1992; Rabier et al., 1998). Differences between 24- and
 322 12-h WRF/CMAQ forecasts of 60 pairs (two pairs a day) of analysis variables valid at
 323 either 0000 or 1200 UTC over November 2016 are used. The horizontal and vertical
 324 length scales of the correlation matrices are estimated by recursive filters (Purser et al.,
 325 2003). The vertical distribution of background error SDs is shown in Figure 3, which

326 varies with height and species. The vertical profile of the background error SDs
327 corresponds to the vertical concentration distribution. This means that higher
328 concentrations tend to have larger background error SDs (e.g., CO and nitrate). These
329 SDs exhibit a common reduction with height, especially at the top of the boundary layer.
330 The horizontal correlation of background error determines the propagation of
331 observation information in this direction, while vertical correlation determines the
332 vertical extension of such increments. For gaseous pollutants and most individual
333 aerosol components, the horizontal length scales increase with height, while for the total
334 particulate matter (i.e., PM_{2.5} and PM₁₀), the scales increase with height in the boundary
335 layer and decrease with height in the free troposphere. The ground-level scale generally
336 spreads 40-45 km for all control variables on average. The vertical length scale of most
337 species increases first and then decreases with height, which may be related to the
338 vertical mixing (Kahnert, 2008) and stack emissions at about 200 m height.

339 **2.1.4 EnKF assimilation algorithm**

340 In EnKF, the time-dependent uncertainties of the state variables are estimated using a
341 Monte Carlo approach through an ensemble. Uncertainty can be propagated with linear
342 or nonlinear dynamic models (flow-dependent background error covariance) by simply
343 implementing ensemble simulations. The EnSRF algorithm introduced by Bierman
344 (1977) and Maybeck (1979) is used to constrain pollution emissions in this study.
345 EnSRF is a deterministic EnKF that obviates the need to perturb observations, which
346 has a higher computational efficiency and a better performance (Sun et al., 2009).

347 The perturbation of prior emissions represents the uncertainty. We implement additive
348 emission adjustment methods, which are calculated using the following function.

$$349 \quad \mathbf{X}_i^b = \mathbf{X}_0^b + \delta\mathbf{X}_i^b, i = 1, 2, \dots, N \quad (7)$$

350 where \mathbf{b} represents the background (prior) state, i is the identifier of the perturbed
351 samples, N is the ensemble size, which was set to 40 in consideration of a tradeoff
352 between the computation cost and inversion accuracy (Figure S1), and $\delta\mathbf{X}_i^b$ represents
353 the randomly perturbed samples that are added to the prior emissions \mathbf{X}_0^b to produce

354 ensemble samples of the inputs \mathbf{X}_i^b . $\delta\mathbf{X}_i^b$ is drawn from Gaussian distributions with a
 355 mean of zero and the standard deviation of the prior emission uncertainty in each grid.
 356 The state variables of the emissions include CO, SO₂, NO_x, primary PM_{2.5} (PPM_{2.5}) and
 357 PMC. We used variable localization to update the analysis, which means that the
 358 covariance among different state variables was not considered, and the emission of one
 359 species was only constrained with its corresponding air pollutant observation. This
 360 method has been widely used in chemical data assimilation systems to avoid spurious
 361 correlations among species. (Ma et al., 2019; Miyazaki et al., 2012b).

362 After obtaining an ensemble of state vectors (prior emissions), ensemble runs of the
 363 CMAQ model are conducted to propagate these errors in the model with each ensemble
 364 sample of state vectors. Combined with observational vector \mathbf{y} , the state vector is
 365 updated by minimizing the analysis variance:

$$366 \quad \bar{\mathbf{X}}^a = \bar{\mathbf{X}}^b + \mathbf{K}(\mathbf{y} - \mathbf{H}\bar{\mathbf{X}}^b) \quad (8)$$

$$367 \quad \mathbf{K} = \mathbf{P}^b \mathbf{H}^T (\mathbf{H} \mathbf{P}^b \mathbf{H}^T + \mathbf{R})^{-1} \quad (9)$$

$$368 \quad \mathbf{P}^b = \frac{1}{N-1} \sum_{i=1}^N (\mathbf{X}_i^b - \bar{\mathbf{X}}^b) (\mathbf{X}_i^b - \bar{\mathbf{X}}^b)^T \quad (10)$$

$$369 \quad \delta\mathbf{X}_i^a = \delta\mathbf{X}_i^b - \tilde{\mathbf{K}} \mathbf{H} \delta\mathbf{X}_i^b \quad (11)$$

370 While employing sequential assimilation and independent observations, $\tilde{\mathbf{K}}$ is
 371 calculated as follows:

$$372 \quad \tilde{\mathbf{K}} = \left(1 + \sqrt{\mathbf{R} / (\mathbf{H} \mathbf{P}^b \mathbf{H}^T + \mathbf{R})}\right)^{-1} \mathbf{K} \quad (12)$$

373 where $\bar{\mathbf{X}}^b$ represents the mean of the ensemble samples; \mathbf{H} is the observation
 374 operator that maps simulated concentrations from model space to observation space;
 375 $\mathbf{y} - \mathbf{H}\bar{\mathbf{X}}^b$ reflects the differences between the simulated and observed concentrations;
 376 \mathbf{P}^b is the ensemble-estimated background (a priori) error covariance; $\mathbf{P}^b \mathbf{H}^T$ contains
 377 the response of the uncertainty in the simulated concentrations to the uncertainty in
 378 emissions; \mathbf{K} is the Kalman gain matrix of the ensemble mean depending on the \mathbf{P}^b

379 and observation error covariance \mathbf{R} , representing the relative contributions to analysis;
 380 and $\tilde{\mathbf{K}}$ is the Kalman gain matrix of the ensemble perturbation, which is used to
 381 calculate emission perturbations after inversions $\delta\mathbf{X}_t^a$. The ensemble mean $\overline{\mathbf{X}^a}$ of the
 382 analyzed state is taken as the best estimate of the emissions.

383 With large volumes of site observations that are recorded at a much higher resolution
 384 than the model grid spacing, there would be significant correlated or fully consistent
 385 model-data mismatch errors in one cluster, resulting in excessive adjustments and
 386 deteriorated model performances (Houtekamer and Mitchell, 2001). To reduce the
 387 horizontal observation error correlations and the influence of representativeness errors,
 388 a “super-observation” approach combining multiple noisy observations located within
 389 the same grid and assimilation window is developed based on optimal estimation theory
 390 (Miyazaki et al., 2012a). Previous studies have demonstrated the necessity of data-
 391 thinning and dealiasing errors (Feng et al., 2020b; Zhang et al., 2009a). The super-
 392 observation y_{new} , super-observation error r_{new} and corresponding simulation $x_{new,i}$
 393 of the i th sample are calculated as follows:

$$394 \quad 1/r_{new}^2 = \sum_{j=1}^m 1/r_j^2 \quad (13)$$

$$395 \quad y_{new} = \sum_{j=1}^m w_j y_j / \sum_{j=1}^m w_j \quad (14)$$

$$396 \quad x_{new,i} = \sum_{j=1}^m w_j x_{ij} / \sum_{j=1}^m w_j \quad (15)$$

397 where j is the identifier of m observations within a super-observation grid; r_j is the
 398 observational error of actual j th observation y_j ; x_{ij} represents a simulated
 399 concentration using the i th prior emission sample corresponding to the j th observation;
 400 and $w_j = 1/r_j^2$ is the weighting factor. The super-observation error decreases as the
 401 number of observations used within a super-observation increases. This method has
 402 been used in our previous inversions using surface-based (Feng et al., 2020b) and

403 satellite-based (Jiang et al., 2021) observations.

404 In this study, the DA window was set to 1 day because the model needs a longer time
405 to integrate emission information into the concentration ensembles (Ma et al., 2019).
406 Due to the “super-observation” approach, only one assimilation is needed in one
407 assimilation window. In addition, due to the complexity of hourly emissions, it is very
408 difficult to simulate hourly concentrations that can match the observations well.
409 Although a longer DA window could allow more observations to constrain the emission
410 change of one grid, the spurious correlation signals of EnKF would attenuate
411 observation information with time (Bruhwiler et al., 2005; Jiang et al., 2021). Kang et
412 al. (2012) conducted OSSEs and demonstrated that due to the errors of transport and
413 increase the spurious correlation, a longer DA window (e.g., 3 weeks) would cause the
414 analysis system to blur out the essential emission information far away from the
415 observation. Therefore, daily mean simulations and observations are used in the EnSRF
416 algorithm, and daily emissions are optimized in this system.

417 EnKF is subject to spurious correlations due to the limited number of ensembles when
418 it is applied in high-dimensional atmospheric models, which can cause rank
419 deficiencies in the estimated background error covariance and filter divergence, and
420 further degrade analyses and forecasts (Wang et al., 2020). Covariance localization is
421 performed to reduce spurious correlations caused by the finite ensemble size
422 (Houtekamer and Mitchell, 2001). Covariance localization preserves the meaningful
423 impact of observations on state variables within a certain distance (cutoff radius) but
424 limits the detrimental impact of observations on remote state variables. The localization
425 function of Gaspari and Cohn function (Gaspari and Cohn, 1999) is used in this system,
426 which is a piecewise continuous fifth-order polynomial approximation of a normal
427 distribution. The optimal localization scale is related to the ensemble size, assimilation
428 window, dynamic system, and lifetime of a chemical species in the atmosphere. CO,
429 SO₂ and PM_{2.5} are rather stable in atmosphere, with a lifetime more than 1 day.
430 According to the averaged wind speed (3.3 m/s, Table 4) and the length of DA window,
431 their localization scales are set to 300 km. In addition, NO₂ is rather reactive, with a

432 lifetime of approximately 10 hours in winter (de Foy et al., 2015), and PMC, which is
433 mainly from local sources, its residence time in the atmosphere is also short due to the
434 rapid deposition rate (Clements et al., 2014; Clements et al., 2016; Hinds, 1982). Their
435 localization scales are set to 150 km and 250 km, respectively.

436 **2.2 Prior emissions and uncertainties**

437 The anthropogenic emissions over China were taken from the 2016 Multi-resolution
438 Emission Inventory for China (MEIC 2016) (Zheng et al., 2018), while those over the
439 other regions of East Asia were obtained from the mosaic Asian anthropogenic emission
440 inventory (MIX) (Li et al., 2017). The spatial resolutions of both the MEIC and MIX
441 inventories are $0.25^\circ \times 0.25^\circ$, and they are both downscaled to match the model grid
442 spacing of 36 km. The spatial distributions of the CO, SO₂, NO_x, PPM_{2.5} and PMC
443 emissions are shown in Figure 12. The daily emission inventory, which was arithmetic
444 averaged from the combined monthly emission inventory, was directly used in the EI
445 subsystem and employed as the prior emission of the first DA window in the EI
446 subsystem (Figure 1). During the simulations, the daily emissions were further
447 converted to hourly emissions. For all the species emitted from area sources, we
448 converted them to hourly using a same diurnal profile (Figure S2), and for the point
449 source, we assumed that there was no diurnal change. MEIC 2012 was used as an
450 alternative a priori over China to investigate the impact of different prior emissions on
451 the optimized emissions. The Model of Emissions of Gases and Aerosols from Nature
452 (MEGAN) (Guenther et al., 2012) was used to calculate time-dependent biogenic
453 emissions. It was also driven by the WRF model in this study. Biomass burning
454 emissions were not included because they have little impact across China during the
455 study period (Zhang et al., 2020).

456 During the inversion cycles, the inverted emissions of different members converge
457 gradually, and the ensemble-estimated error covariance matrix is arithmetically likely
458 to be underestimated. To avoid this, considering the compensation of model errors and
459 comparable emission uncertainties from one day to the next, we impose the same
460 uncertainty on emissions at each DA window. As mentioned above, the optimized

461 emissions of the current DA window are transferred to the next DA window as prior
462 emissions. The technology-based emission inventory developed by Zhang et al. (2009b),
463 basically using the same method as MEIC, shows that the emissions of PMC and PPM_{2.5}
464 have the largest uncertainties, followed by CO, and finally SO₂ and NO_x. Therefore, the
465 uncertainties in this study are set to 40%, 40%, 30%, 25%, and 25%. However, previous
466 studies have shown that the inversely estimated CO and PMC emissions could exceed
467 100% higher than the bottom-up emissions (MEIC) in certain areas (Feng et al., 2020b;
468 Ma et al., 2019). According to the extent of underestimation, we set an uncertainty of
469 100% for both the CO and PMC emissions at the beginning of the three DA windows
470 to quickly converge the emissions. The mean emission analysis is generally minimally
471 sensitive to the uncertainty setting in our assimilation cycle method (Feng et al., 2020;
472 Gurney et al., 2004; Miyazaki et al., 2012a) because the inversion errors of the current
473 window could be transferred to the next window for further optimization (Sect. 4.3).

474 **2.3 Observation data and errors**

475 Hourly averaged surface CO, SO₂, NO₂, O₃, PM_{2.5} and PM₁₀ observations from 1504
476 national control air quality stations were assimilated in this system, which were
477 obtained from the Ministry of Ecology and Environment of the People's Republic of
478 China (<http://106.37.208.233:20035/>, last access: 25 June 2020). These sites are
479 distributed over most of central and eastern China and become denser near metropolitan
480 areas (see Figure 2). Value-range and time-continuity checks were performed to ensure
481 data quality. Value-range checks were mainly performed to eliminate unrealistic or
482 unrepresentative observations. Only observations within the subjectively selected
483 threshold range were assimilated (Table 2). A time-continuity check was performed to
484 eliminate gross outliers and a sudden anomaly using a function of $\max(|O(t) -$
485 $O(t \pm 1)|) \leq f(t)$, where $O(t)$ and $O(t \pm 1)$ represent observations at time t and
486 $t \pm 1$, respectively, and $f(t) = T_a + T_b \times O_t$. That means that both concentration
487 differences between time t and time $t+1$ and $t-1$ should be less than $f(t)$. T_b is fixed
488 to 0.15, and the section of T_a is given in Table 2, which is determined empirically
489 according to the time series change of concentration at each site. It should be noted that,

490 to avoid potential cross-correlations, we assimilated PM_{2.5} and PMC. Additionally, in
 491 the EI subsystem, the observations within each city were averaged to thin the data
 492 density, reduce the error correlation and increase the spatial representation (Houtekamer
 493 and Mitchell, 2001; Houtekamer and Zhang, 2016). Finally, 336 city sites are available
 494 across the mainland of China, in which 311 cities' data were selected for assimilation
 495 and the remaining 25 were selected for independent validation (Figure 2). In the IA
 496 subsystem, due to the small horizontal correlation scale (Figure 3), to obtain more
 497 extensive observation constraints, all site observations were assimilated to provide a
 498 good IC for the next emission inversion.

499 The observation error covariance matrix (\mathbf{R}) includes both measurement and
 500 representation errors. The measurement error ε_0 is defined as follow:

$$501 \quad \varepsilon_0 = ermax + ermin \times \Pi_0 \quad (16)$$

502 where *ermax* is a base error, and Π_0 denotes the observed concentration. These
 503 parameters for different species are listed in Table 2, which are determined according
 504 to Chen et al. (2019), Feng et al., (2018) and Jiang et al. (2013b).

505 The representative error depends on the model resolution and the characteristics of the
 506 observation locations, which were calculated using the equations of Elbern et al. (2007)
 507 defined as follows:

$$508 \quad \varepsilon_r = \gamma \varepsilon_0 \sqrt{\Delta l / L} \quad (17)$$

509 where γ is a tunable parameter (here, $\gamma=0.5$), Δl is the grid spacing (36 km), and L
 510 indicates the radius (here, 3 km for simplification) of influence area of an observation.

511 The total observation error (r) is defined as follows:

$$512 \quad r = \sqrt{\varepsilon_0^2 + \varepsilon_r^2} \quad (18)$$

513

514

515 **Table 2.** Parameters of quality control and measurement error

Parameter	CO mg m ⁻³	SO ₂ μg m ⁻³	NO ₂ μg m ⁻³	O ₃ μg m ⁻³	PM _{2.5} μg m ⁻³	PMC μg m ⁻³
value-range	0.1-12	1-800	1-250	1-250	1-800	1-900
time-continuity (T_a)	2.5	160	70	80	180	180
ermax	0.05	1	1	1	1.5	1.5
ermin	0.5%	0.5%	0.5%	0.5%	0.75%	0.75%

516

517 **3 Experimental design**

518 RAPAS was conducted according to the procedure and settings described in Sect. 2.
519 December is one of the months with most severe air pollution, while July is one of the
520 least polluted months in China. Therefore, this study mainly tested the performance of
521 the RAPAS system in these two months. For December, the IA subsystem was run from
522 26 to 31 November 2016 with a 6-hour interval cycling assimilation to optimize ICs
523 (ICDA). A better IC at 0000 UTC on December 1 can be obtained by 5-day high-
524 frequency cycling assimilation and atmospheric mixing. Then the EI subsystem was
525 run for December 2016 with a 1-day assimilation window to optimize emissions
526 (EMDA). For July, the system also operated in the same way as for December. It needs
527 to be noted that due to the stronger atmospheric oxidation, the lifetime of NO₂ in July
528 is significantly shorter than that in December, thus we adopted a smaller localization
529 scale for NO₂ (80 km). Both assimilation experiments use the combined prior emission
530 inventories of 2016 as described in Sect. 2.2, and the emission base year coincides with
531 the research stage. An Observing Systems Simulation Experiment (OSSE) was
532 conducted to evaluate the performance of the RAPAS system, which has been widely
533 used in previous assimilation systems development (Daley, 1997). In the OSSE
534 experiment, we used the MEIC 2016 inventory as a “true” emission, and reduced the
535 “true” emission by 30% over the mainland of China as a prior emission. The simulations
536 simulated using the “true” emission and sampled according to the locations and times

537 of the real observations were used as artificial observations. The observation errors are
538 the same as those in EMDA. To evaluate the IC improvements from the IA subsystem,
539 an experiment without 3DVAR (NODA) is conducted with the same meteorological
540 fields and physical and chemistry parameterization settings as those of the ICDA. To
541 evaluate the posterior emissions of the EI subsystem, two parallel forward modeling
542 experiments are performed for December 2016, namely, a control experiment (CEP)
543 with prior (MEIC 2016) emissions and a validation experiment (VEP) with posterior
544 emissions. Both experiments use the same initial field at 0000 UTC on December 01
545 generated through the IA subsystem. Similar to the above, the only differences between
546 CEP and VEP are emissions. Table 3 gives a summary of different emission inversion
547 experiments conducted in this study.

548 To investigate the robustness of our system, 8 sensitivity tests (from EMS1 to EMS8,
549 see Table 3) are performed. These experiments are all based on EMDA. In EMS1, rather
550 than forward simulated using the optimized emissions of the previous DA window in
551 EMDA, the initial fields of each DA window were first taken from forward simulation
552 with the prior emissions of the previous DA window, and then optimized using the
553 3DVAR algorithm and the observations at the corresponding moment as mentioned in
554 Sect. 2.3. The objective of this experiment is to investigate the advantages of the “two-
555 step” calculation scheme in the EI subsystem as introduced in Sect. 2.1. EMS2 uses
556 MEIC 2012 as the original prior emission in China, aiming to investigate the impact of
557 different prior inventories on the estimates of emissions. Four other experiments,
558 namely EMS3-6, aim to test the impact of different prior uncertainty settings, in which,
559 the prior uncertainties are reduced by -50% and -25%, and increased by 25% and 50%,
560 respectively. EMS7 aims to evaluate the impact of observation errors on emission
561 estimates, in which all the observation errors are magnified twice. The last EMS8
562 experiment aims to evaluate the impact of IC optimization of the first window on
563 emission estimates, in which the ICs were taken from a 5-day spin-up simulation. Eight
564 forward modeling experiments (VEP1, VEP2, ..., VEP8) were also performed with
565 posterior emissions of EMS1 to EMS8 to evaluate their performances, respectively.

566 **Table 3.** Emission inversion and sensitivity experiments conducted in this study

Exp. Type	Exp. Name	Period	IC of the first DA Window	ICs of the subsequent DA window	Emission
Assimilation	EMDA	1-31 December	0000 UTC on December 1, taken from ICDA	Forecast with posterior emissions in the previous window	MEIC 2016 for December (the first DA window), optimized emissions of the previous window (other DA windows)
	OSSE	1-31 December	The same as EMDA	The same as EMDA	The same as EMDA, but with a decrease of 30% for CO, SO ₂ , NO _x , PPM _{2.5} , and PMC
Sensitivity	EMS1	1-31 December	The same as EMDA	Forecast with prior emissions in the previous window and 3DVAR assimilation	The same as EMDA
	EMS2	1-31 December	The same as EMDA	The same as EMDA	The same as EMDA, but for EMIC 2012
	EMS3-6	1-31 December	The same as EMDA	The same as EMDA	The same as EMDA, but with a $\pm 25\%$ or $\pm 50\%$ of default uncertainty
	EMS7	1-31 December	The same as EMDA	The same as EMDA	The same as EMDA, but with a +100% of default observation errors
	EMS8	1-31 December	0000 UTC on December 1, taken from ICNO	The same as EMDA	The same as EMDA

568

569

570 **4 Results**

571 **4.1 Evaluations**

572 **4.1.1 Simulated meteorological fields**

573 In the RAPAS system, the inversion approach attributes all the biases between the
574 simulated and observed concentrations to the emissions. The meteorological fields
575 dominate the physical and chemical processes of the air pollutants in the atmosphere,
576 and thus their simulation accuracy would significantly affect the estimates of emissions
577 in this study. To quantitatively evaluate the performance of the WRF simulations, the
578 mean bias (BIAS), root mean square error (RMSE), and correlation coefficient (CORR)
579 were calculated against the surface meteorological observations measured at 400
580 stations and the planetary boundary layer height (PBLH) calculated using the sounding
581 data at 92 sites. The surface observations were obtained from the National Climate Data
582 Center (NCDC) integrated surface database (<http://www.ncdc.noaa.gov/oa/ncdc.html>,
583 last access: 25 October 2021), and the sounding data were obtained from the website of
584 the University of Wyoming (<http://weather.uwyo.edu/upperair/sounding.html>, last
585 access: 10 March 2022). The sounding data are in 12 hours interval. The observed
586 PBLH were calculated using the sound data through the bulk Richardson number
587 method (Richardson et al., 2013). The spatial distribution of the meteorological stations
588 is shown in Figure 2. The simulated temperature at 2 m (T2), relative humidity at 2 m
589 (RH2), wind speed at 10 m (WS10), and PBLH from 26 November to 31 December
590 2016 are evaluated against the observations. Table 4 summarizes the statistical results
591 of the evaluations of the simulated meteorological parameters. Overall, the T2, RH2
592 and PBLH are slightly underestimated, with biases of -0.1 °C, -3.8% and -41.1 m,
593 respectively. The CORRs are approximately 0.98 for T2, 0.94 for RH2 and 0.90 for
594 PBLH, showing good consistency between the observations and simulations. The
595 WS10 is overestimated, with a bias of 0.7 m/s and an RMSE of 0.8 m/s, but is better
596 than many other studies (Chen et al., 2016; Jiang et al., 2012a; Jiang et al., 2012b).
597 Therefore, WRF can generally reproduce the meteorological conditions sufficiently in

598 terms of their temporal variation and magnitude over China, which is adequate for our
 599 inversion estimation.

600 **Table 4.** Statistics comparing the simulated and observed 10-m wind speed (WS10), 2-
 601 m temperature (T2), and 2-m relative humidity (RH2), and planetary boundary layer
 602 height (PBLH).

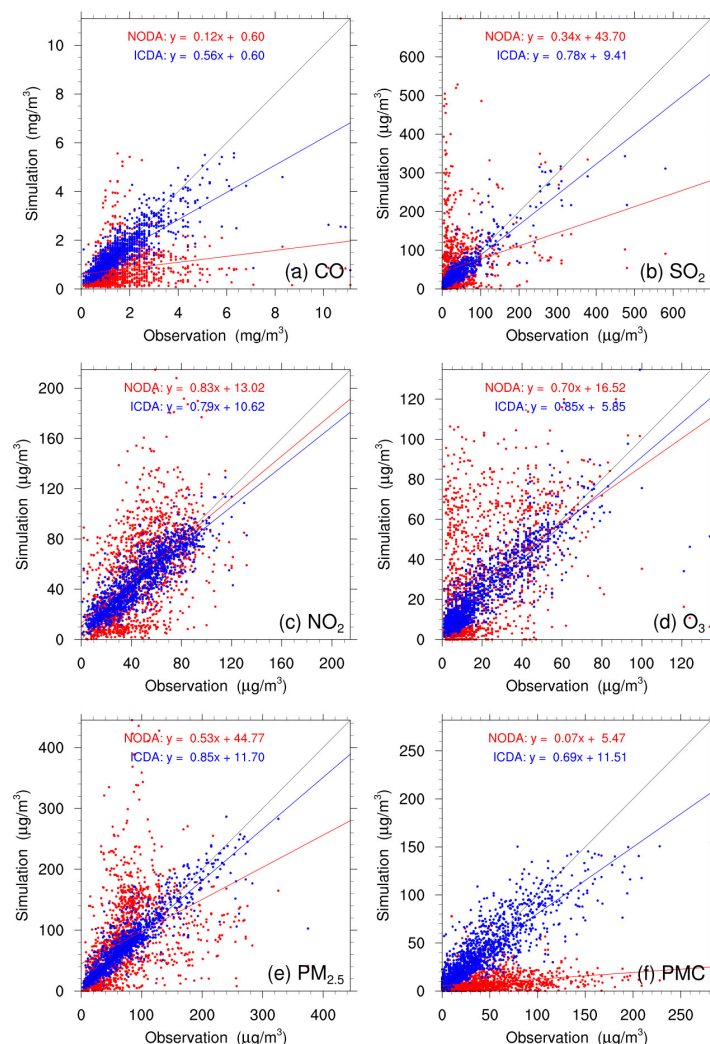

Variable Met.	No. of sites	Mean Obs.	Mean Sim.	BIAS	RMSE	CORR
WS10 (m/s)	400	2.6	3.3	0.7	0.8	0.72
T2 (°C)	400	2.9	2.8	-0.1	0.7	0.98
RH2 (%)	400	66.3	62.6	-3.8	5.2	0.94
PBLH (m)	92	267.5	226.4	-41.1	50.4	0.90

603 * BIAS, mean bias; RMSE, root mean square error; CORR, correlation coefficient

604 4.1.2 Initial fields

605 Figure 4 shows the evaluations of the analyzed concentrations of the 6 species against
 606 surface observations. For comparison, the evaluations of the simulations without
 607 3DVAR (NODA) are also shown in Figure 4. The simulations of the NODA experiment
 608 (red dots) are scattered on both sides of a central line, as large systematic biases remain
 609 across many measurement sites. Conversely, the ICDA experiment (blue dots) shows
 610 much better agreement with observations than those from NODA. The statistics show
 611 that there are large systematic biases in the NODA simulations, with large RMSEs and
 612 small CORRs for all species, especially for CO and PMC. After the assimilation of
 613 surface observations, the RMSE of CO decreases to 0.7 mg m^{-3} , and those of SO_2 , NO_2 ,
 614 O_3 , $\text{PM}_{2.5}$ and PMC decrease to 22.0, 12.0, 9.6, 20.5 and $19.6 \text{ } \mu\text{g m}^{-3}$, respectively, with
 615 respective reduction rates of 50.0%, 73.1%, 61.0%, 64.7%, 69.5%, and 60.8%
 616 compared to the ones of the NODA (Table 5). The CORRs of ICDA increase by 290.0%,
 617 291.3%, 55.4%, 87.2%, 130.0% and 214.8% to 0.78, 0.90, 0.87, 0.88, 0.92 and 0.85,
 618 respectively. These statistics indicate the initial fields of the ground level have been
 619 significantly improved. However, due to the lack of observations, we still do not know

620 the simulation bias in the upper-middle boundary layer. Although concentrations at high
621 altitudes can be constrained by ground-based observations through vertical correlations,
622 the effect is limited, so the bias is still non-negligible.

623

634 * BIAS, mean bias; RMSE, root mean square error; CORR, correlation coefficient

635 4.1.3 Posterior emissions

636 Due to mismatched spatial scales, it is difficult to directly evaluate the optimized
 637 emissions against observations. Generally, we indirectly validate them by comparing
 638 the forward simulated concentrations using the posterior emissions against atmospheric
 639 measurements (e.g., Jiang et al. (2014), Jin et al. (2018), and Peters et al. (2007)). Figure
 640 5 shows the spatial distributions of the mean biases between the simulated gaseous
 641 pollutants using prior and posterior emissions and assimilated observations. In the CEPs,
 642 for each species, the distribution of biases is similar to the increments in background
 643 fields constrained through 3DVAR as shown in Figure S3. For example, almost all sites
 644 have large negative biases for CO, while for SO₂ and NO₂, positive biases are mainly
 645 distributed over the North China Plain (NCP), Yangtze River Delta (YRD), Sichuan
 646 Basin (SCB) and Central China, and negative biases are over the rest of the areas. After
 647 constraining with observations, the biases of all the 3 gaseous air pollutants are

648 significantly reduced in most sites. For CO, the biases at 62% of the sites decreased to
649 absolute values less than 0.2 mg m^{-3} , and for SO₂ and NO₂, the biases at 52% and 47%
650 of the sites were within $\pm 4 \text{ } \mu\text{g m}^{-3}$. However, large negative biases are still observed in
651 part of western Chinas, indicating that the uncertainties of the posterior emissions are
652 still large in western China, which may be attributed to the large biases in prior
653 emissions and to the relatively limited observation. Overall, the statistics show that
654 there are different levels of improvements at 92%, 85% and 85% of the total 311
655 assimilation sites for CO, SO₂ and NO₂, respectively. The small amount of sites with
656 worse performance may be related to the overadjusted emissions by EI or contradictory
657 adjustments caused by opposite biases in adjacent areas.

658 Table 6 lists the statistical results of the evaluations averaged over the whole mainland
659 of China. For CO, the mean bias is -0.8 mg m^{-3} with the prior emissions, while it
660 substantially reduces to -0.1 mg m^{-3} with a reduction rate of 89.6% when simulating
661 with the posterior emissions. Additionally, the RMSE decreases by 48.1% from 1.08 to
662 0.56 mg m^{-3} , and the CORR increases by 76.1% from 0.46 to 0.81. For SO₂ and NO₂,
663 the regional mean biases slightly increase as the positive/negative biases among
664 different sites might be offset. However, the RMSEs decrease to 17.7 and $12.3 \text{ } \mu\text{g m}^{-3}$,
665 respectively, which are 58.3% and 50.8% lower than those of CEPs, and the CORRs
666 increase by 125.6% and 35.4%, both reaching up to 0.88, indicating that EI has
667 significantly improved the NO_x and SO₂ emission estimates.

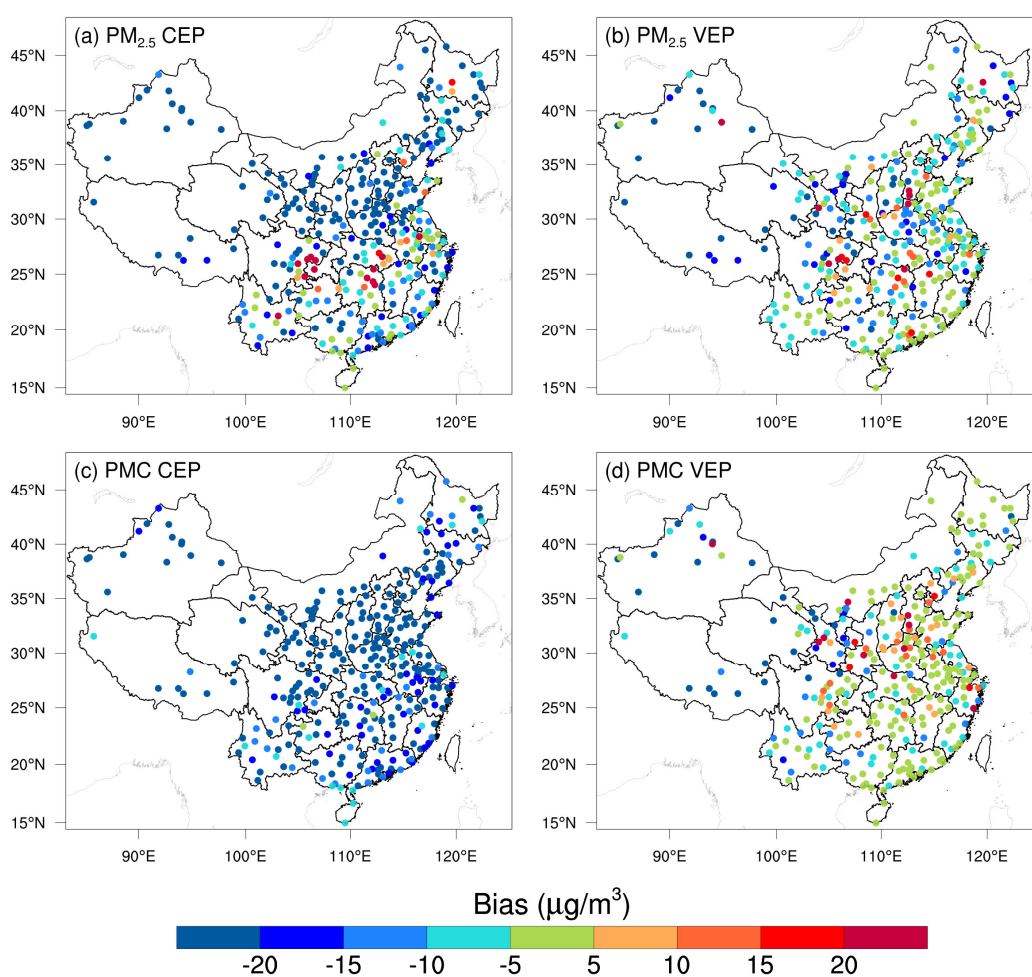

668

669 **Figure 5.** Spatial distribution of the BIAS of the simulated (a, b) CO, (c, d) SO₂ and (e,
 670 f) NO₂ with prior (left, CEP) and posterior (right, VEP) emissions. CO unit: mg m⁻³;
 671 SO₂ and NO₂ units: µg m⁻³.

672 Figure 6 shows the spatial distributions of the mean biases of simulated PM_{2.5} and PMC
 673 evaluated against the assimilated observations. Similarly, the CEP simulations do not
 674 perform well. There are widespread underestimations across the country, with mean
 675 biases of -24.0 and -32.4 µg m⁻³. After data assimilation, the performance of VEP
 676 simulations is significantly improved. The biases decrease by 72.1% and 90.4% to -6.7
 677 and -3.1 µg m⁻³, the RMSEs decrease by 41.2% and 40.7% to 29.6 and 24.6 µg m⁻³, and
 678 the CORRs increase by 35.9% and 176.0% to 0.87 and 0.69 for PM_{2.5} and PMC,
 679 respectively. Overall, 89.6% and 97.2% of the assimilation sites are improved for PM_{2.5}

680 and PMC, respectively. However, compared with the results of the 3 gaseous pollutants,
 681 there are sites with large biases scattered throughout the whole domain. Besides the
 682 potential overadjusted or contradictory adjustments of emissions as in the 3 gas species,
 683 It may also be related to the complex precursors and complex homogeneous and
 684 heterogeneous chemical reactions and transformation processes of secondary PM_{2.5},
 685 and the fact that we do not simulate the time variation of dust blowing caused by wind
 686 speed for PMC due to the lack of land cover data that is compatible with the CMAQ
 687 dust module and agricultural activities data to identify dust source regions.

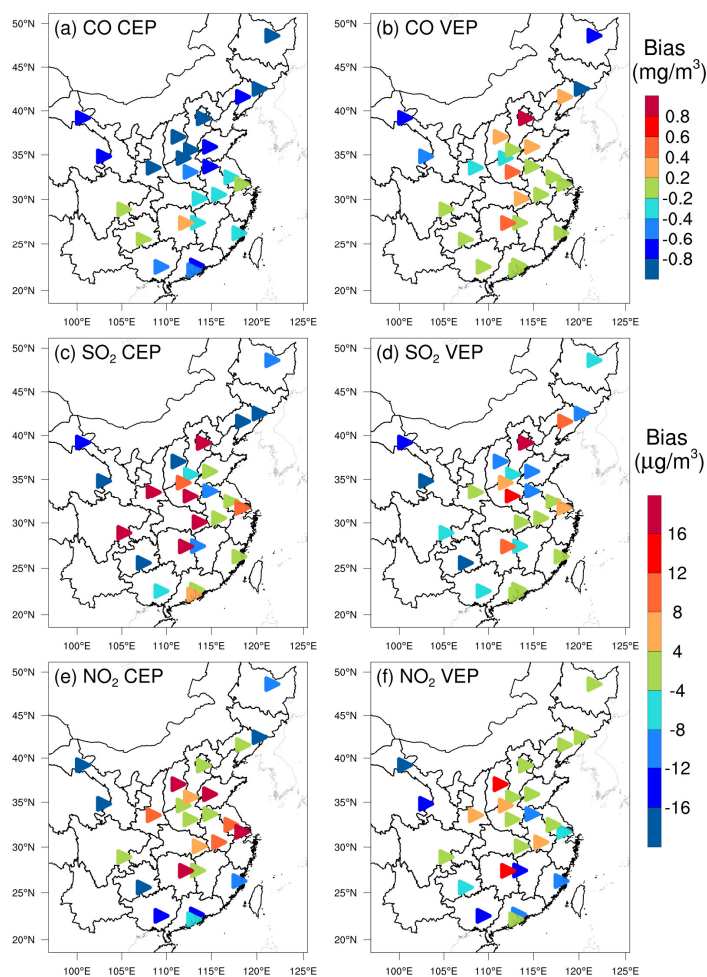

688

689 **Figure 6.** Same as in Figure 5 but for PM_{2.5} and PMC.

690 Figure 7 and Figure 8 show the spatial distributions of the biases calculated against the
 691 independent observations for the 5 species. With posterior emissions, the decreasing

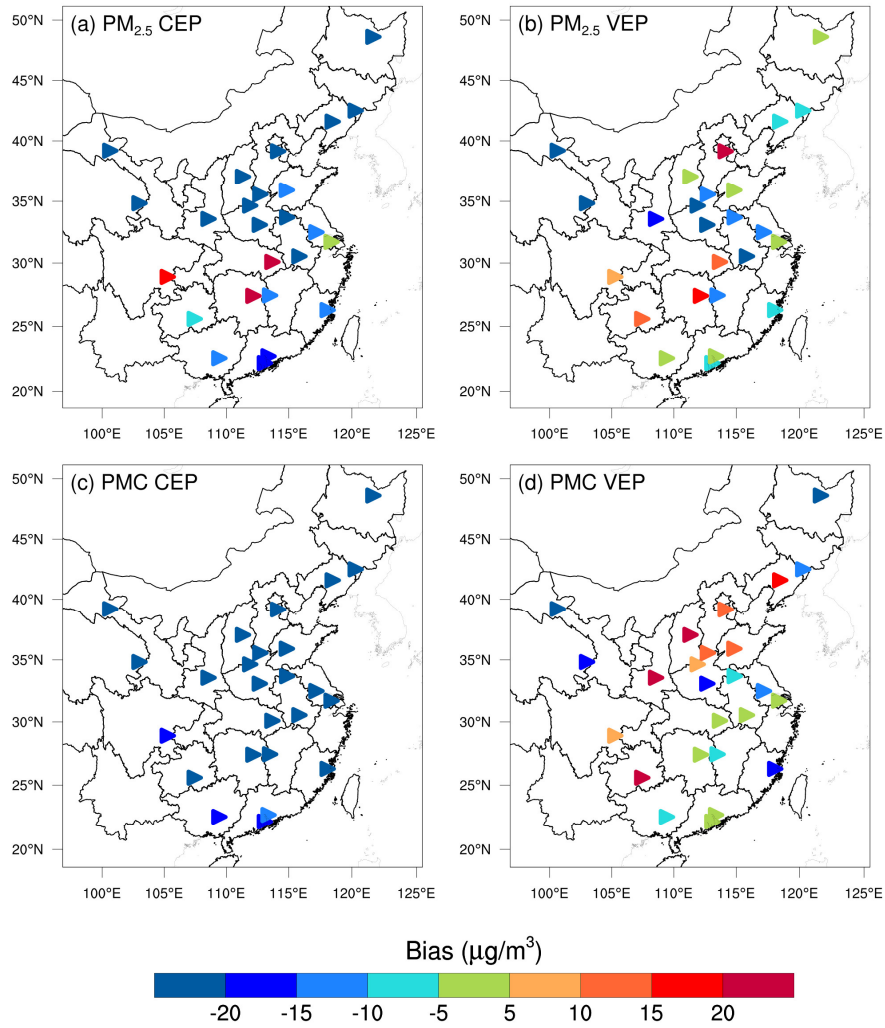

692 ratios of RMSEs range from 26.7% to 42.0%, and the CORRs increase by 13.7-59.0%
 693 to 0.62-0.87. Overall, the biases at the independent sites are similar or slightly worse
 694 than those at the assimilated sites, which is reasonable since the closer to the assimilated
 695 site the independent sites are, the more constraints of observation information can be
 696 obtained, and the improvements in optimized state variables of the model are more
 697 significant. For example, generally, the transmission distance of NO₂ is relatively short,
 698 and remote cities with small emission correlations to the cities with assimilated
 699 observations are relatively less constrained, resulting in only a 26.7% decrease in the
 700 RMSE.

701

702

Figure 7. As in Figure 5 but for the independent validation.

703

704

Figure 8. As in Figure 6 but for the independent validation.

705 Compared with the previous studies, Tang et al. (2013) conducted inversion of CO
 706 emissions over Beijing and the surrounding areas, the improvements (Table 6) in the
 707 RMSE (37-48% vs. 30-51%) and the CORR (both studies ~ 0.81) are comparable, but
 708 the biases here could decrease by 90-97%, which is much greater than their 48-64%
 709 reductions. Additionally, Chen et al. (2019) showed that the RMSE of simulated SO₂
 710 with updated SO₂ emissions decreased by 4.2-52.2% for different regions, and the
 711 CORR only increased to 0.69 at most. The improvement is relatively smaller than our
 712 results, which may be due to the insufficient adjustment of emissions caused by the
 713 underestimated ensemble spread through the inflation method. The better performance
 714 in this study may be related to our inversion process that makes the optimized emissions

715 of the current DA window propagate to the next DA window for further correction.

716 **Table 6.** Statistics comparing the pollution concentrations from the simulations with
 717 prior (CEP) and posterior (VEP) emissions against assimilated and independent
 718 observations, respectively. CO unit: mg m⁻³; others units: μg m⁻³.

719 * BIAS, mean bias; RMSE, root mean square error; CORR, correlation coefficient

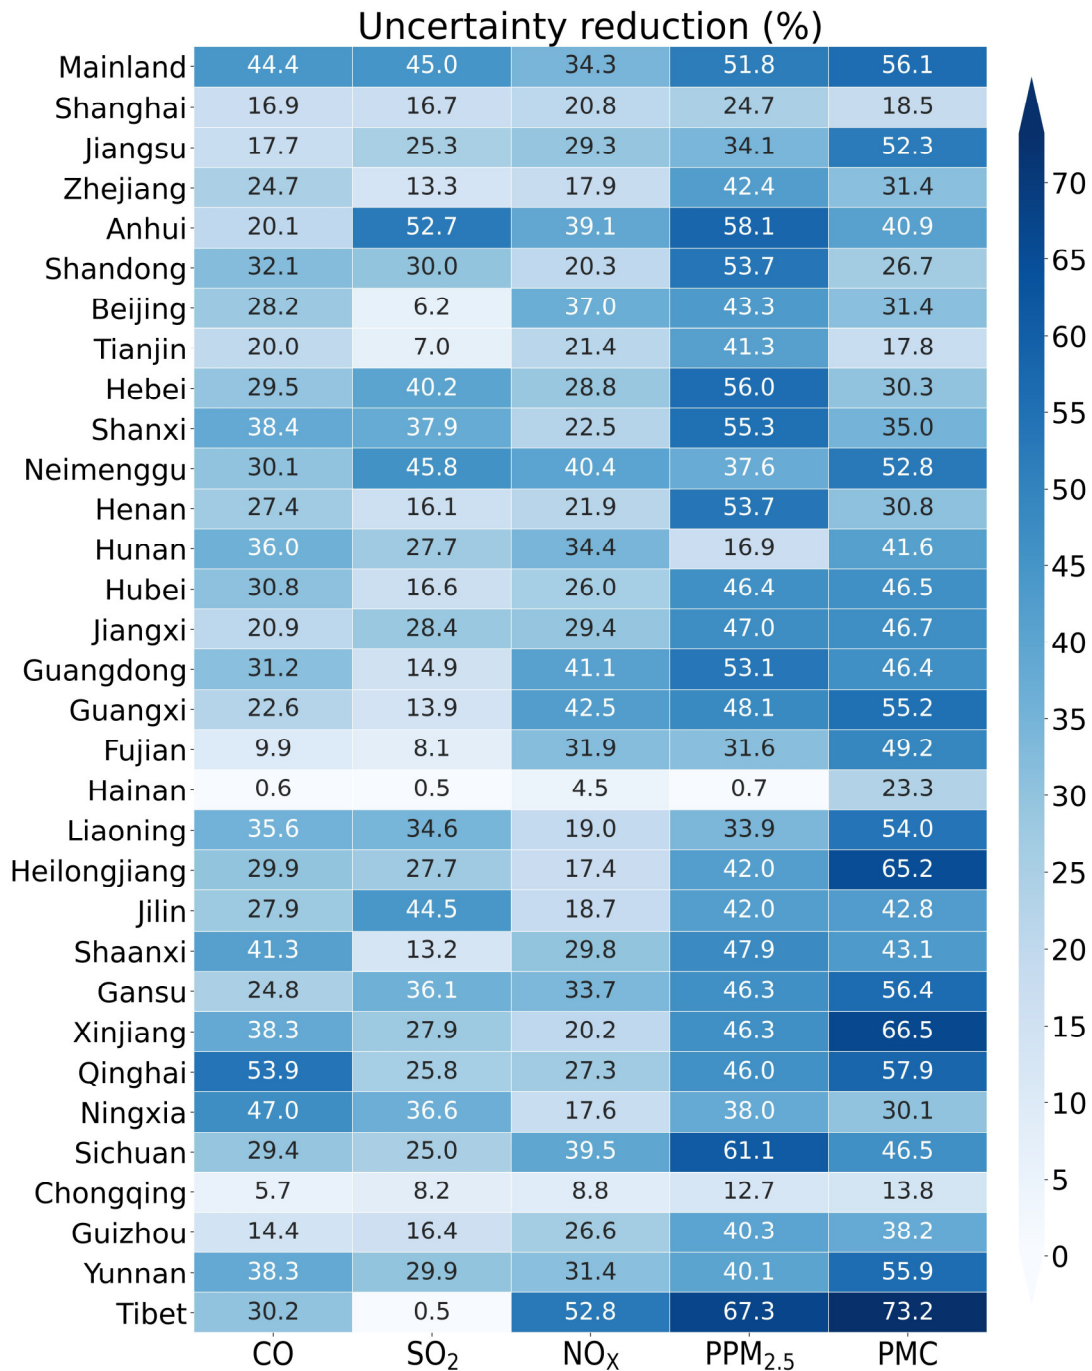

720 4.1.4 Uncertainty reduction

721 The uncertainty reduction rate (UR) is another important quantity to evaluate the
 722 performance of RAPAS and the effectiveness of in-situ observations in this system
 723 (Chevallier et al., 2007; Jiang et al., 2021; Takagi et al., 2011). Following Jiang et al.
 724 (2021), the UR is calculated as

$$725 \quad UR = \left(1 - \frac{\sigma_{posterior}}{\sigma_{prior}}\right) \times 100 \quad (19)$$

726 where $\sigma_{posterior}$ and σ_{prior} are the posterior and prior uncertainties, respectively,
 727 which were calculated using the standard deviations of the prior and posterior
 728 perturbations (Text S3). Figure 9 shows the URs averaged in each province and the
 729 whole mainland China. The URs vary with species, and among the 5 species of
 730 emissions, the uncertainties of the PPM_{2.5} and PMC are greatly reduced, while the UR
 731 of NO_x emission is lowest, that is because the URs are closely related to the magnitude

732 settings of prior uncertainties (Jiang et al., 2021). For the whole mainland China, the
733 uncertainties are reduced by 44.4%, 45.0%, 34.3%, 51.8% and 56.1% for CO, SO₂, NO_x,
734 PPM_{2.5} and PMC, respectively. For one species, it also varies across provinces. The
735 URs are usually related to observation coverage, which means that the more observation
736 constraints there are, the more the URs decrease. Additionally, the URs may also relate
737 to emission distributions. Generally, the URs are more significant in the provinces
738 where the observations and emissions are both relatively concentrated (e.g., Tibet),
739 while they are much lower in where the emissions are scattered or relatively uniform,
740 but the observations are only in large cities, even though there are many more
741 observations than other provinces.

742

743 **Figure 9.** Time-averaged posterior emission uncertainty reduction (%) indicated by the
 744 standard deviation reduction of total emissions per province calculated by prior and
 745 posterior ensembles.

746 **4.1.5 Evaluation using chi-squared statistics**

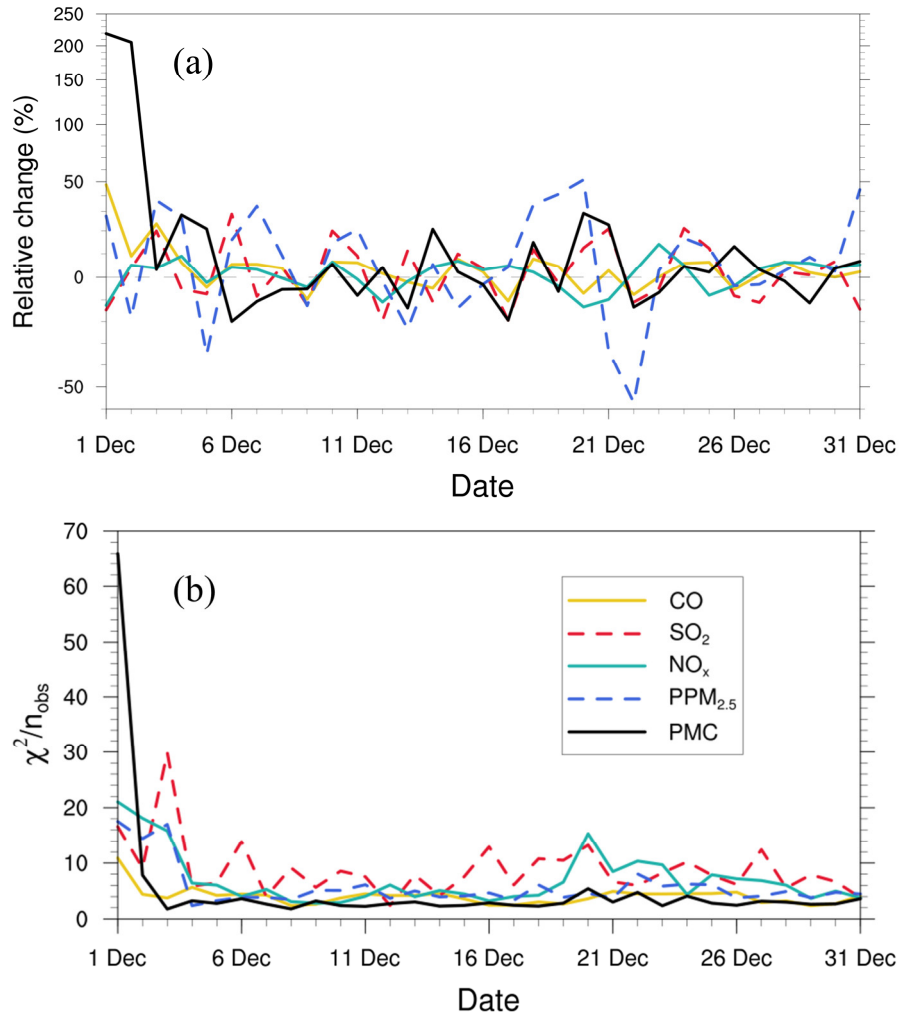

747 To diagnose the performance of the EnKF analysis, the chi-squared (χ^2) statistics was
 748 calculated, which is generally used to test whether the prior ensemble mean RMSE with

749 respect to the observations is consistent with the prior “total spread” (square root of the
 750 sum of ensemble variance and observation error variance). Following Zhang et al.
 751 (2015), for the t th window, χ^2 is defined as

$$752 \quad \chi_t^2 = (\mathbf{y} - \mathbf{H}\overline{\mathbf{X}^b})^T (\mathbf{H}\mathbf{P}^b\mathbf{H}^T + \mathbf{R})^{-1} (\mathbf{y} - \mathbf{H}\overline{\mathbf{X}^b}) \quad (20)$$

753 Figure 10 shows the time series of the relative changes between the prior and posterior
 754 emissions and the χ^2 statistics. There are relatively large adjustments of emissions in
 755 the first three windows, especially for PMC. After that, the optimality of the five species
 756 reaches a more optimal state with successive emission inversion cycle. The χ^2 statistics
 757 shows a similar variation characteristics with the daily changes in the emissions. The
 758 χ^2 value is slightly greater than 1, indicating that the uncertainties from error covariance
 759 statistics do not fully account for the error in the ensemble simulations. A similar
 760 situation also appeared in Chen et al. (2019). Further investigations should be
 761 conducted to generate larger spreads by accounting for the influence of model errors.
 762 Since we imposed a same uncertainty of prior emission at each DA window to partially
 763 compensate for the influence of model errors, χ^2 statistics showed small fluctuations,
 764 indicating that the system updates emissions consistently and stably.

765

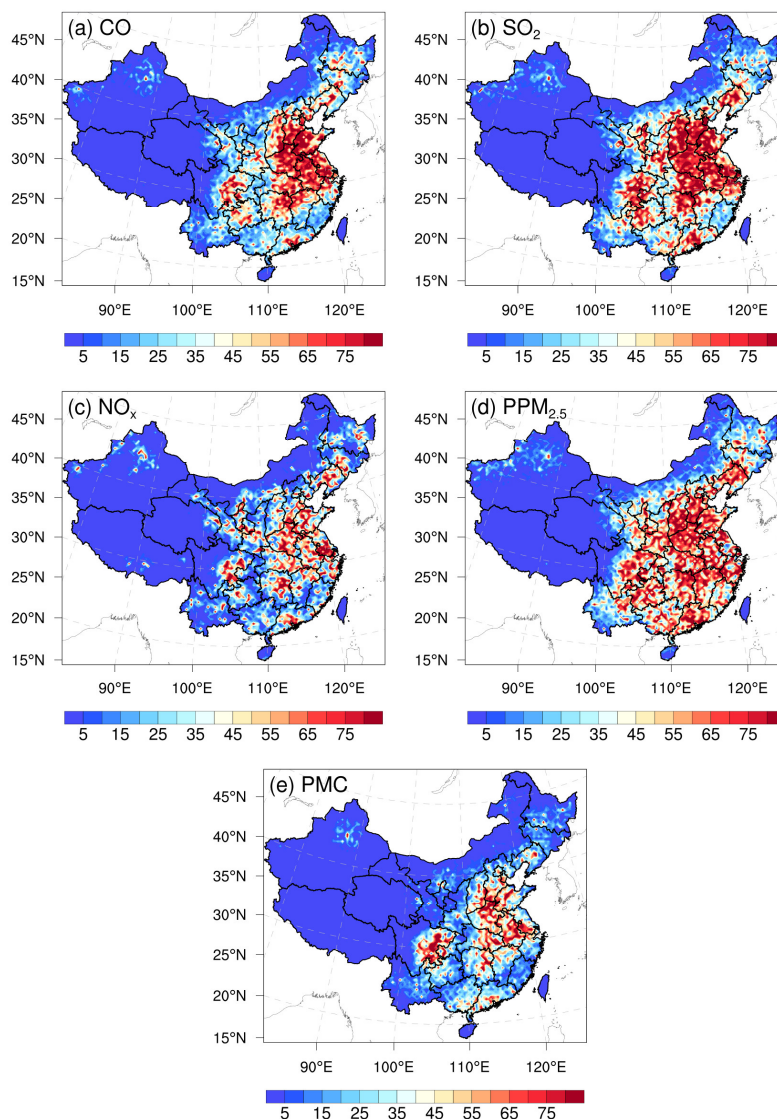

766

767 **Figure 10.** Relative changes (a) in a posteriori emission estimates of CO, SO₂, NO_x,
 768 PPM_{2.5} and PMC, and χ^2 statistics (b) of these state vectors in each window.

769 **4.1.6 Evaluation using OSSE**

770 Figure 11 shows the spatial distribution of the error reduction in the posterior emissions
 771 of the five species. It can be found that after inversion, in most areas, the emission errors
 772 can be reduced by more than 80%, especially in the central and eastern regions with
 773 dense observation sites, while in remote areas far away from cities, due to the sparse
 774 observation sites, the emission errors are still not well adjusted. Overall, the error
 775 reduction rates of CO, SO₂, NO_x, PPM_{2.5}, and PMC are 78.4%, 86.1%, 78.8%, 77.6%,
 776 and 72.0%, respectively, indicating that with the ground in-situ observations in China,
 777 RAPAS can significantly reduce emission errors, thus has good performance in

779

780 **Figure 11** Spatial distribution of the error reduction (%) of posterior emissions in the
 781 OSSE.

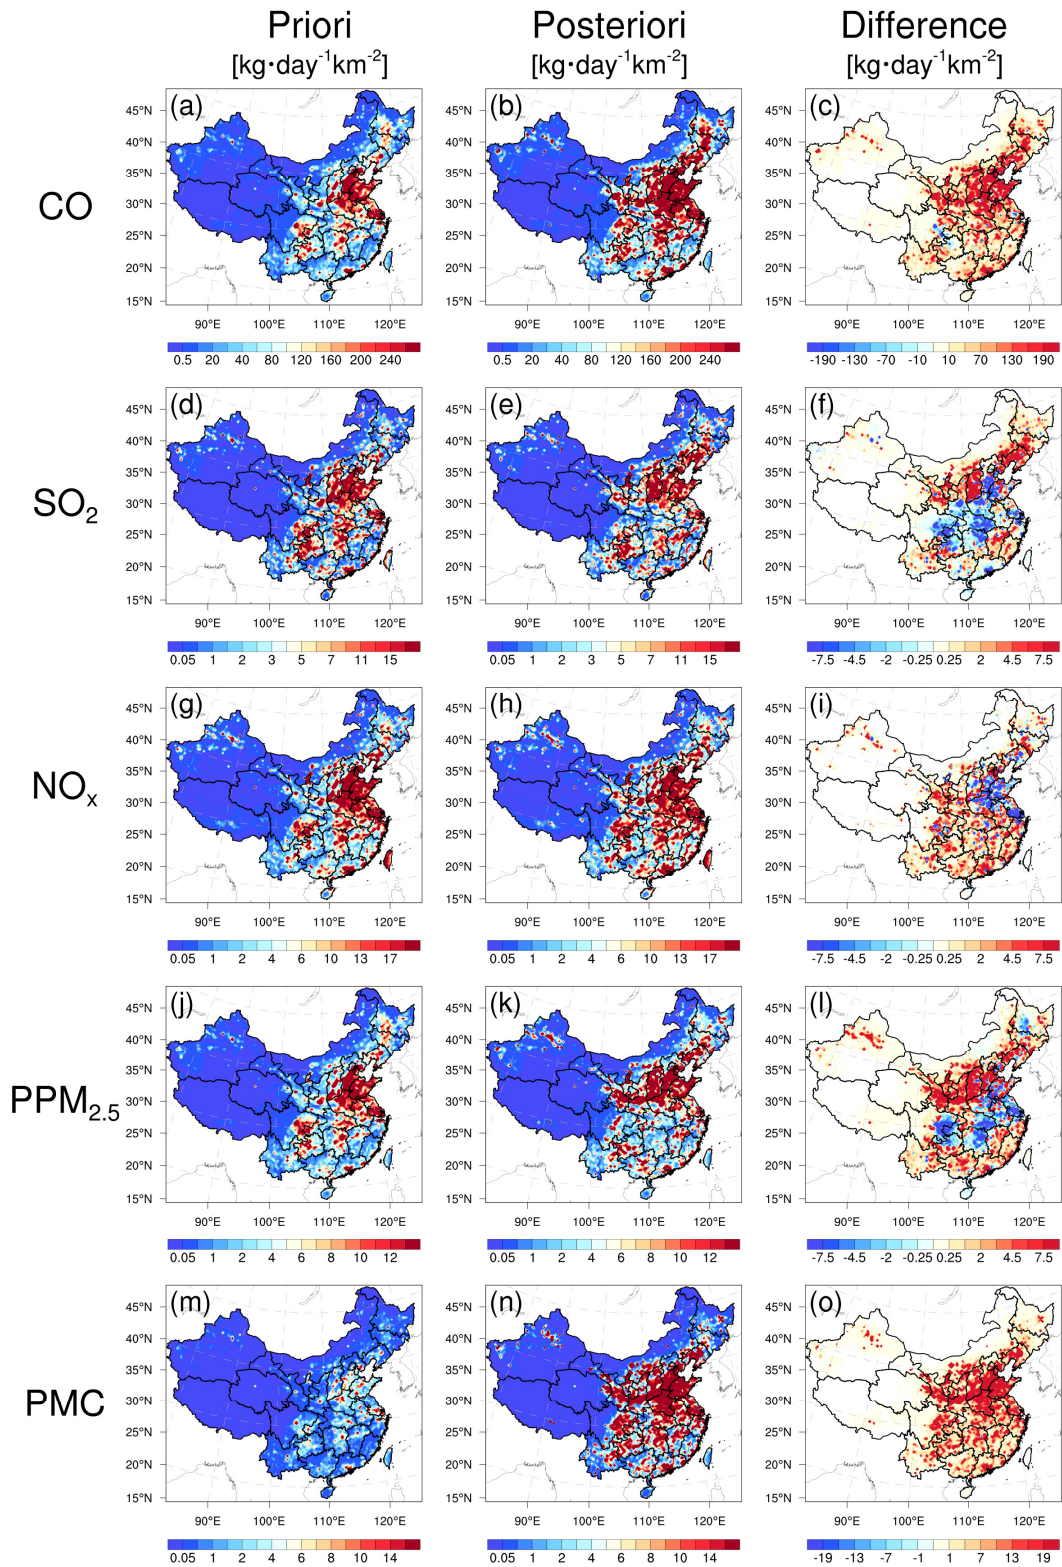

782 4.2 Inverted emissions

783 Figure 12 shows the spatial distribution of the temporal averaged prior and posterior
 784 emissions and their differences of the emissions in December 2016. It should be noted
 785 that the emissions outside China were masked, since the observation sites are all within
 786 China in this study, there is little change in the emissions outside China. Higher
 787 emissions are mainly concentrated in central and eastern China, especially in the NCP,
 788 YRD, and PRD, and lower emissions occur across Northwest and Southern China.

789 Compared with the prior emissions, posterior CO emissions are considerably increased
790 across most areas of mainland China, especially in northern China, with an overall
791 increase of 129%. Notable underestimation of the prior emissions is also confirmed by
792 previous inversion estimations (Feng et al., 2020b; Tang et al., 2013; Wu et al., 2020)
793 and model evaluations (Kong et al., 2019b). For SO₂, the emission increases mainly
794 occur in Northeast China, Shanxi, Ningxia, Gansu, Fujian, Jiangxi and Yunnan
795 provinces. In SCB, Central China, YRD, and part of NCP, the emissions are
796 significantly reduced. For national total, the SO₂ emission is increased by 20%. For
797 NO_x, although the increment of national total emissions is small, only about 5%, large
798 deviations still exist on regional scale. Obviously, the emissions in the NCP and YRD
799 are reduced, while in the other regions, the emissions of most cities are increased. The
800 changes in PPM_{2.5} emission are similar to SO₂. Compared with the prior emission, the
801 posterior PPM_{2.5} emissions are decreased over central China, SCB and YRD, while the
802 ones in southern and northern China are increased, especially in Shanxi, Shaanxi, Gansu
803 and southern Hebei province. Overall, the relative increase is 95%. For PMC, the
804 posterior emissions are increased over the whole mainland China, with national mean
805 relative increase exceeding 1000%. Larger emission increments mainly occur in the
806 areas where have significant anthropogenic emissions of CO and PPM_{2.5}, indicating
807 that the large underestimations of PMC emissions in the prior inventory may be mainly
808 attributed to the underestimations of anthropogenic activities. In addition, the absence
809 of natural dust is another reason, as the wind-blown dust scheme was not applied in this
810 study. Overall, PM₁₀ emissions (PPM_{2.5}+PMC) increased by 318%. If we assume that
811 all the increment in PM₁₀ emissions is all from natural dust, that means the contribution
812 of natural dust accounts for 75% of total PM₁₀ emissions, which is consistent with the
813 source apportionment of PM₁₀ of 75% in Changsha in Central China (Li et al., 2010).
814 Large PMC emission increment are also found in Ma et al (2019).

815 Detailed estimation of posterior emissions and relative changes compared to prior
816 emissions in each province and the whole mainland China is given in Table S1. The
817 evaluation results for July show that the emission uncertainty can still be significantly

818 reduced, and the performance of the system in July is comparable to that in December
819 (Table S2). Additionally, the seasonal variation of emissions can be well reflected
820 (Figures S4 and S5), which means that our system can perform well at different times
821 of the year. Note that the differences, excluding PMC, between the prior and posterior
822 emissions mainly reflect the deficiencies of the prior emissions because the times of the
823 prior emissions and the observations are completely consistent in this study.

824

825 **Figure 12.** Spatial distribution of the time-averaged prior emissions (left column, MEIC

826 2016), posterior emissions (middle column), and differences (right column, posterior

827 minus prior).

828 4.3 Sensitivity tests

829 4.3.1 Impact of prior inventories

830 Various prior inventories have great differences in space allocation and emission
831 magnitude. Inversion results can be sensitive to a priori emissions if the observation is
832 insufficient (Gurney et al., 2004; He et al., 2018). MEIC 2012 is used as an alternative
833 a priori in EMS2 to investigate the impact of different prior emissions on the posterior.
834 Figure 13 shows the time series of the relative differences in daily posterior emissions
835 of the five species between the EMDA (base) and EMS2 experiments. Overall, the
836 differences between the two posterior emissions gradually decrease over time. At the
837 beginning, the differences in the CO, SO₂, NO_x, PPM_{2.5} and PMC between the two
838 inventories (i.e., MEIC 2012 vs MEIC 2016) are 17.5%, 114.5%, 30.8%, 46.0% and
839 72.0%, respectively, while during the last ten days, the differences of the two posterior
840 emissions have decreased to 2.5%, 4.5%, 4.5%, -8.9% and 3.0%, respectively. In
841 addition, it also could be found that the species that has larger emission differences at
842 the beginning take a longer time (namely more DA steps) to achieve convergence. The
843 quick convergence of PMC emission is attributed to the large prior uncertainty of 100%
844 used in the first 3 DA windows. Different from the other species, there are significant
845 negative deviations of PPM_{2.5} emissions between the two experiments. That may be
846 due to the positive deviations in the precursors of PM_{2.5} (i.e., SO₂ and NO_x), which will
847 lead to a larger amount of secondary production. To balance the total PM_{2.5}
848 concentration, the PPM_{2.5} emissions will be reduced. We compare the PM_{2.5}
849 concentrations simulated by the two optimized inventories and find that they are almost
850 the same (Figure S6). Overall, this indicates that the observation in China is sufficient
851 in inferring the emissions, and our system is rather robust. Meanwhile, it also suggests
852 that the monthly posterior emissions shown in Sect. 4.2 are still underestimated to a
853 certain extent.

854

855 **Figure 13.** Relative differences in CO, SO₂, NO_x, PPM_{2.5} and PMC emissions (% the
 856 ratio of absolute difference to EMDA) between the EMDA and EMS2 experiments.

857

858 4.3.2 Impact of prior uncertainties settings

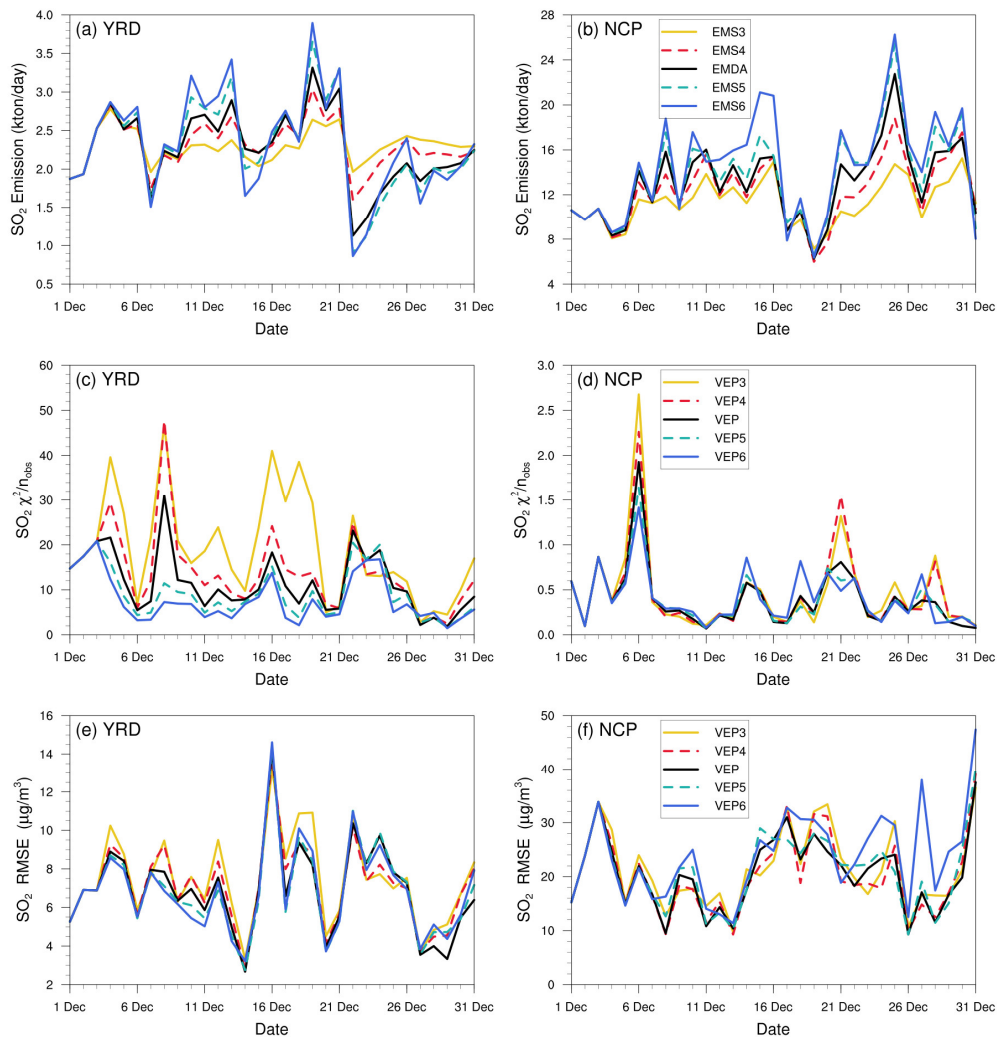

859 The uncertainty of prior emissions determines how closely the analysis is weighted
 860 toward the background and observation, but information about prior uncertainties is
 861 generally not readily available. To evaluate the possible influence of prior uncertainties
 862 on the optimized emissions, we increased/reduced the uncertainties after 3 days of
 863 cycling, namely starting at 0000 UTC, 3 December, by 25% and 50 % in EMS3 (-50%),
 864 EMS4 (-25%), EMS5 (+25%) and EMS6 (+50%), respectively. Table 7 summarizes the
 865 emission changes with different prior uncertainties settings in EMS3-6 experiments. To
 866 better understand the response of the system to the emission uncertainty settings, Figure
 867 14 shows the time series of SO₂ emission changes, the Chi-square statistics and the
 868 RMSEs of simulated SO₂ with emissions updated in the EMDA and EMS3-6
 869 experiments over the YRD and NCP (Figure 2). Compared with the EMDA, when the
 870 uncertainties are decreased (increased), the emissions of the 5 species decrease
 871 (increase) accordingly. That is because the posterior emissions of the 5 species are
 872 larger than the prior emissions, and as shown in Figure 14a-d, larger uncertainty will

873 lead to a faster convergence, resulting in larger posterior emissions. It also could be
874 found from Figure 14 that a faster convergence will indeed reduce the RMSE of the
875 simulated concentration with the posterior emissions in the early stage of the
876 experiment, but in the later stage of the experiment, there are no significant differences
877 for the RMSE and Chi-square statistics among the different experiments. However, the
878 day-to-day changes in emissions can also cause slight fluctuations. In addition, it shows
879 that when greater uncertainties are set, the day-to-day changes in emissions are also
880 more drastic, resulting in a larger RMSE as shown in NCP. Moreover, those significant
881 day-to-day variations of estimated emissions may not be in line with the actual situation.
882 Due to the spatial-temporal inhomogeneity of emissions, the differences of Chi-square
883 statistics between the YRD and NCP show that it may be necessary to apply different a
884 priori uncertainties according to different regions (Chen et al., 2019). Therefore, when
885 using an EnKF system for emission estimation, we have to be very careful about the
886 setting of these errors. Overall, the uncertainties chosen in EMDA aim to minimize the
887 deviation of the concentration fields and maintain the stability of inversion.

888 **Table 7.** Relative differences in CO, SO₂, NO_x, PPM_{2.5} and PMC emissions (% , the
889 ratio of absolute difference to EMDA) between the EMDA and EMS3-6 experiments.

Species	EMS3	EMS4	EMS5	EMS6
CO	-8.6	-4	3	5.2
SO ₂	-14	-5.7	3.6	6.8
NO _x	-6.5	-3	2.8	4.5
PPM _{2.5}	-16.5	-7.8	4.6	8.7
PMC	-18.5	-8.2	7.3	13.1

890

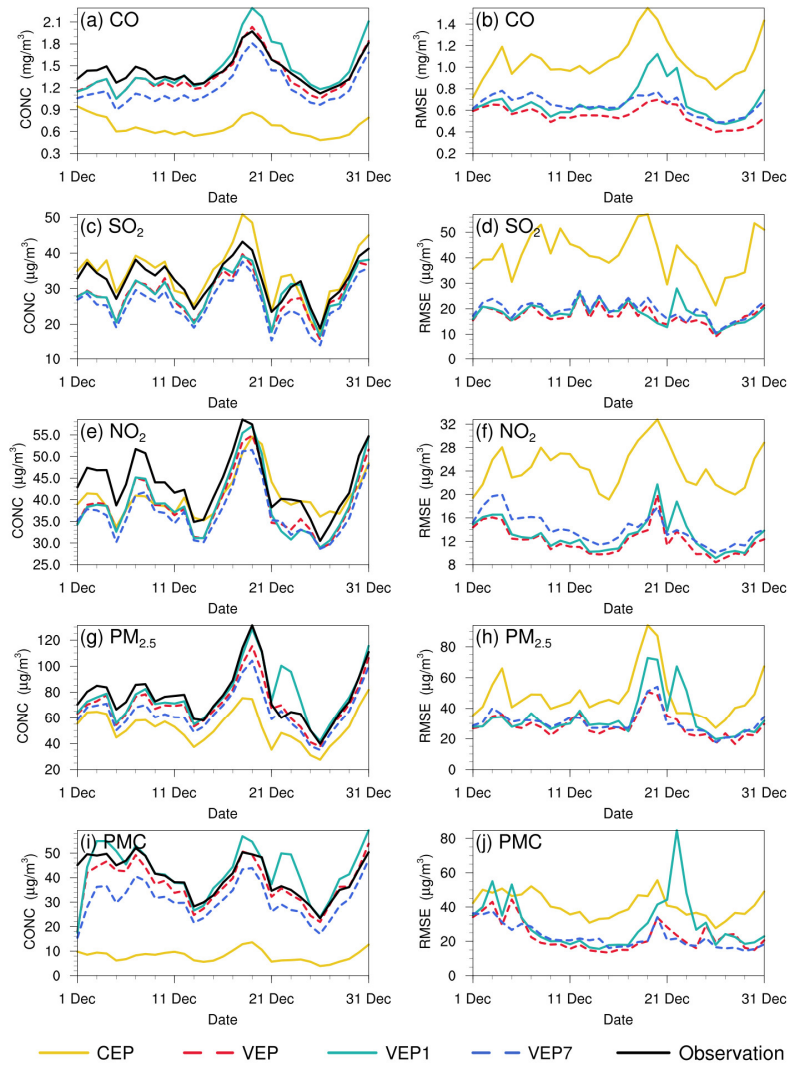

891

892 **Figure 14.** Time-series of SO₂ emission changes, the Chi-square statistics and the
 893 RMSE of simulated SO₂ with updated SO₂ emissions in the EMDA and EMS3-6
 894 experiments over the Yangtze River Delta (YRD) and North China Plain (NCP).

895 4.3.3 Impact of observation error settings

896 Another factor that determines the relative weights of the observation and background
 897 in the analysis is observation errors. A proper estimate of the observation error is also
 898 important in regard to the filter performance, but observation errors are not provided
 899 with the dataset. The observation error is usually set to a fixed value (Ma et al., 2019),
 900 a specific proportion of the observation value (Tang et al., 2013) or the value calculated
 901 by combining measurement error with representative error as used in this study.
 902 Generally, the performance of the data assimilation is quite sensitive to the specification

903 of observation error (Tang et al., 2013). To evaluate the influence of observation error
904 on the optimized emissions, a sensitivity experiment (EMS7) with doubled observation
905 error was conducted. Overall, the spatial distribution of emissions after optimization is
906 almost the same as that of the EMDA experiment, but the increment is lower (Figure
907 S7), resulting in a weaker estimate of the national total emission for each species. That
908 is because that the observation error becomes large, the system will be more convinced
909 of the prior emission and reduce the effect of observation information. Figure 15 shows
910 the time series of simulated and observed daily concentrations and their RMSEs
911 verified against the assimilated sites. The simulations in VEP7 usually perform worse,
912 with larger biases and RMSEs than those of VEP (Figures S8 and S9), especially in
913 most of western and southern China where posterior emissions are still significantly
914 underestimated. These results usually correspond to sluggish emission changes and
915 large Chi-square statistics (Figure S10), suggesting that too large observation error may
916 substantially impact the estimated emissions.

917

918 **Figure 15.** Time series of the daily concentrations (CONC, left) and root mean square
 919 error (RMSE, right) obtained from CEP, VEP, VEP1, and VEP7. The simulations were
 920 verified against the assimilated sites.

921 **4.3.4 Impact of the IC optimization of the first window**

922 Many studies have shown that there would be large emission discrepancies resulting
 923 from the IC errors (Jiang et al., 2013a; Miyazaki et al., 2017; Tang et al., 2013), which
 924 means that if the IC is not optimized, the errors of concentrations would be compensated
 925 through the adjustment of emissions. To evaluate the impact of the IC optimization of
 926 the first window on the emission inversions, the EMS8 experiment without the IA step
 927 was conducted. Figure 16 shows the time series of the relative differences in daily

928 posterior emissions of the five species between the EMDA and EMS8 experiments. It
 929 can be found that the optimization of IC has great impact on the emission inversions of
 930 long-lived species (i.e., CO). The overall difference in the inverted CO emissions
 931 between the two experiments is about 5.3%, and in the first few windows, the maximum
 932 difference can reach 26.1%. For the short-lived species, the IC optimization has little
 933 impact on the emission, for example, the averaged emission differences of SO₂, NO_x
 934 and PMC in the two experiments are 0.3%, 0.3% and 0.9%, respectively. For PPM2.5,
 935 it is affected not only by the primary emission, but also by the complex chemistry of its
 936 precursors. Therefore, the difference between the two experiments fluctuates at a
 937 certain extent, with overall difference of 2%. It is worth noting that with the gradual
 938 disappearance of the benefit of IC assimilation, the two experiments can reach a unified
 939 state after some windows. For CO, the impact of IA on emission inversion lasts about
 940 half a month. These results indicate that removing the bias of IC of the first DA window
 941 is essential for subsequent inverse analysis (Jiang et al., 2017).

942

943 **Figure 16.** Relative differences in CO, SO₂, NO_x, PPM2.5 and PMC emissions (% the
 944 ratio of absolute difference to EMDA) between the EMDA and EMS8.

945 4.3.5 The advantages of “two-step” scheme

946 Adjusting the ICs and emissions simultaneously (i.e., “one-step” scheme) has been
947 applied to constrain prior emissions in many previous studies (Evensen, 2009; Kong et
948 al., 2019a). To investigate the impact of different methods on the optimized emissions,
949 a sensitivity test (EMS1) was performed, in which the initial fields of each DA window
950 were optimized using the 3DVAR algorithm directly. Compared with our “two-step”
951 method (EMDA), the posterior emissions of EMS1 are increased by 7%, 1.4%, 0.6%,
952 22.2%, and 17.2% for CO, SO₂, NO_x, PM_{2.5} and PMC, respectively. Overall, there is no
953 significant difference between the two methods for NO_x and SO₂, but for CO, it can be
954 clearly seen that the difference increases with the inversion (Figure S11). As mentioned
955 previously, in the “two-step” scheme, the unresolved posterior emission error will be
956 fed back to the initial field of the next window through sufficient mixed simulation
957 within one day for timely optimization. Meanwhile, the system always maintains the
958 mass balance of pollutants. In this way, the system updates emissions more consistently
959 and stably. If the emission in one window is overestimated, in this way, it could be
960 compensated in the next window with lower estimates. In contrast, when initial fields
961 assimilating with observations simultaneously at each window, the overestimation will
962 not be corrected and will accumulate to the end. We also evaluate the posterior
963 emissions of EMS1 using the same method as shown in Sect. 4.1.3. Overall, compared
964 to the base experiment (EMDA), the performance of EMS1 is significantly worse, with
965 RMSEs of CO, SO₂, NO₂, PM_{2.5} and PMC increasing from 0.56 mg m⁻³, 17.7, 12.3,
966 29.6, and 24.6 μg m⁻³ to 0.69 mg m⁻³, 18.8, 13.3, 36.8, and 33.3 μg m⁻³, respectively
967 (Figure 15). Additionally, it can be seen from the figure that the results of the two
968 experiments are relatively close at the beginning and during the heavy pollution period
969 (16-21 December). However, after that, the simulated results with “one-step” inversion
970 emissions are significantly higher than the observations, and these large biases continue
971 until the end. The results verified against the independent sites also show a similar
972 situation (Figure S8). The reason may be that during the period of heavy pollution, the
973 WRF-CMAQ (off-line model) does not consider the feedback process of meteorology

974 and chemistry, resulting in low simulations. Therefore, the system will compensate for
975 the underestimated concentrations caused by the model error through more emissions,
976 resulting in the overestimation of emissions. The accumulation of emission error in each
977 independent window further leads to the overestimation of concentration after the end
978 of high pollution, especially for species with a long lifetime (e.g., CO). On the contrary,
979 this overestimation will be corrected quickly in the subsequent inversion using the
980 “two-step” inversion scheme in this study (Figure S11), so as to ensure the stability of
981 the system. Additionally, the other “one-step” experiment, taking MEIC 2012 as prior
982 emissions, was conducted. However, the relative differences (Figure S12) in posterior
983 emissions between this experiment and the EMS1 did not converge like that between
984 EMDA and EMS2 with “two-step” scheme (Figure 13), which further demonstrates the
985 advantages of the “two-step” scheme. It should be noted that the model performance
986 depends on many factors but does not affect the advantage of the “two-step” scheme.

987 **4.4 Discussion**

988 Optimal state estimation using an EnKF relies on the assumption of unbiased Gaussian
989 prior error, which is not guaranteed in such highly nonlinear and large biases systems
990 In this study, some pollutants (e.g., CO, PMC) have very large simulated biases, thus if
991 a small uncertainty is adopted, the emission bias cannot be fully reduced, while if a
992 very large uncertainty is adopted, then the degree of freedom of adjustment is too large,
993 and the inverted daily emissions will fluctuate abnormally. Therefore, we only set a
994 larger prior uncertainty in the first three windows, adopted a moderate uncertainty in
995 the following windows, and used a “two-step” inversion scheme and cyclic iteration to
996 gradually correct the emission errors. Figure 10(a) shows the time series of the relative
997 differences between the prior and posterior emissions in each window. There are the
998 relatively large adjustments for the emissions in the first three windows, especially for
999 PMC, but the adjustment ranges of the five species after the first 3 windows are
1000 basically within the uncertainty range (e.g., $\pm 25\%$), indicating that with this scheme,
1001 the EnKF method used in this system still has a good performance in emission inversion.

1002 The model-data mismatch error not only comes from the emissions, but also from the
1003 inherent model errors arising from model structure, discretization, parameterizations
1004 and the biases in the simulated meteorological fields. Neglecting model errors would
1005 attribute all uncertainties to emissions, and lead to considerable biases in the estimated
1006 emissions. In the version of CMAQ model used in this study, there is no heterogeneous
1007 reactions (Quan et al., 2015; Wang et al., 2017), the parameterization scheme for the
1008 formation of secondary organic aerosol (SOA) is imperfect (Carlton et al., 2008; Jiang
1009 et al., 2012; Yang et al., 2019), no feedback between chemistry and meteorology is
1010 considered, and we used an idea profile for chemical lateral boundary conditions. All
1011 of the above problems can lead to underestimated concentrations of pollutants, which
1012 in turn require more emissions to compensate, leading to overestimations in emissions.
1013 In addition, previous studies have shown that the emission of ammonia in the MEIC
1014 inventory was underestimated (Kong et al., 2019b; Paulot et al., 2014; Zhang et al.,
1015 2018). Due to lack of ammonia observations, our system does not include emission
1016 estimates of ammonia, which means that the concentration of ammonium aerosol was
1017 underestimated in this system, also resulting in an overestimation in the $\text{PPM}_{2.5}$
1018 emission. Wind-blown dust was also not simulated here, thus the PMC emission
1019 inverted in this system do not only come from anthropogenic activities, but also from
1020 natural sources. Although some of these shortcomings could be solved in the future by
1021 updating the CTM model, there will still be errors in each parameterization and each
1022 process. Generally, parameter estimation method was used to reduce the model errors,
1023 in which, some uncertain parameters were included in the augmented state vector and
1024 were optimized synchronously based on the available observations (Brandhorst et al.,
1025 2017; Evensen, 2009). However, it is still quite difficult to identify the key uncertain
1026 parameters of different species in different models, which generally comes not only
1027 from the complex atmospheric chemical model, but also from hundreds of model inputs
1028 (Tang et al., 2013). Another method is bias correction, which treats the model error as
1029 a bias term, and includes it in the augmented state vector (Brandhorst et al., 2017; De
1030 Lannoy et al., 2007; Keppenne et al., 2005). In addition, the weak-constraint 4D-Var

1031 method can also be used to reduce the model errors, which adds a correction term in
1032 the model integration to account for the different sources of model error (Sasaki, 1970).
1033 Although reliable diagnosis of model error is still a challenge at present (Laloyaux et
1034 al., 2020), it should be considered in an assimilation system. We will consider model
1035 errors in our system in the future to obtain better emission estimates.

1036 Independent variable localization was adopted to avoid potential spurious correlations
1037 across different species in this study. However, the transmission scales for different
1038 species in different regions are still different, and a more accurate localization range
1039 could be obtained through backward trajectory analysis. Although Hamer et al. (2015)
1040 successfully used O₃ observations to estimate NO_x and VOC emissions within the 4D-
1041 var framework within an idealised model, O₃ observations are not assimilated to
1042 improve NO_x and VOC emissions using cross-species information due to the strong
1043 nonlinear effects within the O₃-NO_x-VOC relationship (Wang et al., 2019b), in which
1044 the O₃ concentration and NO_x (VOC) emissions are positively correlated in the NO_x
1045 (VOC)-limited region and negatively correlated in the VOC (NO_x)-limited region (Tang
1046 et al., 2011). This work will be followed up by an ongoing work using available VOC
1047 observations. The optimization of the initial fields or emissions of NO₂ may also change
1048 the O₃-NO_x-VOC relationship. Assuming that NO₂ is underestimated, the NO₂
1049 concentration increases after assimilation, but the VOC concentration remains
1050 unchanged, then in the NO_x (VOC)-limited region, the subsequent generation of O₃
1051 will increase (decrease); Conversely, the ozone concentration errors caused by
1052 assimilating NO₂ will also affect the subsequent NO_x emission inversion. Similarly, the
1053 model may not be able to resolve local-scale NO₂ well because of uniform distribution
1054 of concentration over the whole grid. Therefore, the model is shifted towards a NO_x
1055 (VOC)-limited regime in high (low) pollution regions, which negatively impacts results
1056 by perturbing ozone chemistry in unrealistic ways (Inness et al., 2015). To evaluate the
1057 influence of O₃-NO_x-VOC relationship change and model resolution on inversion, we
1058 also further conducted a nested emission inversion on a densely observed area (the
1059 Yangtze River Delta, China) with a grid spacing of 12 km (Feng et al., 2022). The study

1060 period is the same as this study. Results showed that the NO_x emissions in the Yangtze
1061 River Delta retrieved at two resolutions are almost the same (14.7 kt/day vs. 13.4
1062 kt/day), with a difference of 8.8%, indicating that the emissions can be adjusted
1063 effectively by RAPAS. As shown previously, the concentrations after DA are obviously
1064 underestimated in western China, indicating that the inverted emissions over these
1065 regions still have large uncertainties because of the sparsity of observations that are
1066 spatially insufficient for sampling the inhomogeneity of emissions. Therefore, further
1067 investigations with joint assimilation of multisource observations (e.g., satellite) are
1068 also underway.

1069 When comparing the performances of the “two-step” and “one-step” schemes, for the
1070 “one-step” scheme, we use a combination assimilation method, namely 3DVAR for the
1071 optimizations of initial fields and EnKF for emission inversions in each DA window,
1072 which is similar as Jiang et al., (2017), but different from most previous studies
1073 (Miyazaki et al., 2017; Tang et al., 2013). Because most previous “one-step”
1074 assimilation studies used only one method (i.e., EnKF). This combination method may
1075 cause the comparison less than perfect. However, it should be noted that, even using
1076 the same method (such as EnKF) to optimize the emission of the current window and
1077 the initial field of the next window simultaneously (Peng et al., 2018), the initial field
1078 estimation errors will still be mixed in the simulated concentration field, resulting in
1079 unreasonable emission compensation in the next window. In “one-step” scheme, the
1080 essence is to build a good initial field in the high levels. Schwartz et al. (2014) compared
1081 the performances of EnKF and 3DVAR in optimizing initial fields, and found that
1082 3DVAR method can obtain a better initial field than EnKF method. Therefore, we
1083 believe that in this comparison, a combinatorial assimilation approach used in the “one-
1084 step” scheme is an acceptable approach, and the conclusion is credible, that the “two-
1085 step” scheme has better performances than the “one-step” scheme in emission estimates.
1086 NO_x is mainly emitted by transportation (Li et al., 2017), which can better reflect the
1087 level of economic activities to a certain extent. Weekly emission changes were also
1088 explored to verify the performance of the system in depicting emission changes (Figure

1089 S13). Although the “weekend effect” of emissions in China is not significant (Wang et
1090 al., 2014; Wang et al., 2015), the posterior NO_x emission changes showed a good
1091 agreement with the observations. In our previous studies (Feng et al., 2020a; Feng et
1092 al., 2020b), the system was successfully applied to optimize NO_x and CO emissions,
1093 respectively. The inverted emission changes were also in line with the time points of
1094 epidemic control. Additionally, the emission changes can well reflect the emission
1095 migration from developed regions or urban areas to developing regions or surrounding
1096 areas over recent years, which were consistent with the emission control strategies in
1097 China. Although the system does not consider the model error, resulting in a certain
1098 difference between the posterior emission and the actual emission, the spatiotemporal
1099 changes in posterior emissions are relatively reasonable, which can be used to monitor
1100 emission changes and make emission regulations.

1101 **5 Summary and conclusions**

1102 In this study, we developed a Regional multi-Air Pollutant Assimilation System
1103 (RAPASv1.0) based on the WRF/CMAQ model, 3DVAR and EnKF algorithm. RAPAS
1104 can quantitatively optimize gridded emissions of CO, SO₂, NO_x, PPM_{2.5} and PMC on
1105 regional scale by simultaneously assimilating hourly in-situ measurements of CO, SO₂,
1106 NO₂, PM_{2.5} and PM₁₀. This system includes two subsystems, namely the IA subsystem
1107 and the EI subsystem, which optimizes the chemical ICs, and infers the anthropogenic
1108 emissions, respectively.

1109 Taking the 2016 Multi-resolution Emission Inventory for China (MEIC 2016) in
1110 December as a priori, the emissions of CO, SO₂, NO_x, PPM_{2.5} and PMC in December
1111 2016 were inferred through assimilating the corresponding nationwide observations
1112 over China. The optimized ICs and posterior emissions were examined against the
1113 assimilated and independent observations through parallel forward simulation
1114 experiments with and without DA. Sensitivity tests are also performed to investigate
1115 the impact of different inversion processes, prior emissions, prior uncertainties and
1116 observation errors on the emission estimates.

1117 The results show that RAPAS has a good performance in assimilating ground in-situ
1118 observations, with the calculated emission uncertainties reduced by 44.4%, 45.0%,
1119 34.3%, 51.8% and 56.1% for CO, SO₂, NO_x, PPM_{2.5} and PMC, respectively. It can also
1120 significantly improve the simulations, the RMSEs of the simulated concentrations with
1121 posterior emissions decreased by 40.1-56.3%, and the CORRs increased from 0.26-0.66
1122 to 0.69-0.87 for different species. The OSSE experiment shows that the error of
1123 posterior CO, SO₂, NO_x, PPM_{2.5}, and PMC could be reduced by 78.4%, 86.1%, 78.8%,
1124 77.6%, and 72.0%, respectively. Overall, compared with the prior emissions (MEIC
1125 2016), the posterior emissions increased by 129%, 20%, 5% and 95% for CO, SO₂, NO_x
1126 and PPM_{2.5}, respectively. The posterior PMC emissions, which included anthropogenic
1127 and natural dust contributions, increased by 1045%. The sensitivity tests with different
1128 inversion processes show that the “two-step” scheme in emission inversion outperforms
1129 the joint adjustment of ICs and emissions (“one-step” scheme), especially after heavy
1130 pollution. The sensitivity tests with different prior inventories show the observation in
1131 China is sufficient in inferring the emissions, and our system is less dependent on prior
1132 inventories. Additionally, the sensitivity tests with different prior uncertainties indicate
1133 that when the posterior emissions are larger than the prior emissions, the emissions
1134 decrease/increase with the decreases/increases of uncertainties because of the different
1135 convergence rates. These results demonstrate the advantage of the two-step method in
1136 emission inversion in that the inversion errors of the last window could be transferred
1137 to the current window for further optimization and the robustness of the emissions
1138 estimated from RAPAS using the nationwide observations over China. It should be
1139 noted that the system usually responds slowly to too small a priori uncertainty or too
1140 large observation error, which may result in large errors in the estimated emissions.

1141 In summary, the comprehensive evaluation and sensitivity tests reveal that RAPAS
1142 could serve as a useful tool for accurately quantifying the spatial and temporal changes
1143 of multi-species emissions at regional scales and near-real time, which will be helpful
1144 for the air pollution control in China, and the other regions around the world with dense
1145 ground observation networks.

1146 **Code and data availability**

1147 The codes of RAPAS v1.0 are available at <https://doi.org/10.5281/zenodo.5566225>.
1148 The WRF model code is open-source code and can be obtained from the WRF Model
1149 User's Page (<https://www2.mmm.ucar.edu/wrf/users>, last access: 25 April 2021). The
1150 CMAQ model is available through an open license as well (<https://www.epa.gov/cmaq>,
1151 last access: 25 April 2021). The observation and emission data used in this paper are
1152 available at <https://doi.org/10.5281/zenodo.4718290> (Feng and Jiang, 2021).

1153

1154 **Author contribution**

1155 SF, FJ, ZW and ZJ developed RAPAS v1.0. SF and FJ designed the research. SF
1156 performed model simulations, analyzed data, and prepared the paper with contributions
1157 from all co-authors. FJ supervised the model development project and assisted in
1158 conceptualization and writing. HW, WH, YS, LZ, YZ, CL, and WJ contributed to the
1159 discussion and improvement of the paper.

1160

1161 **Competing interests**

1162 The authors declare that they have no conflict of interest.

1163 **Acknowledgements**

1164 This work is supported by the National Key R&D Program of China (Grant No.
1165 2016YFA0600204), the National Natural Science Foundation of China (Grant No.
