Model evaluation statistics

The unit of atmospheric concentration used in this work is $\mu g \ m^{-3}$. The ppb mixing ratios of gaseous species downloaded from some network websites were converted to mass concentrations via the ideal gas law ($pV = nRT$) and assuming 1 atmosphere pressure:

$$\mu g \ m^{-3} = \frac{\text{ppb} \times M}{0.0821 \times (273.15 + T)}$$

where $T$ is the temperature in °C, $M$ is molecular mass of the gaseous pollutant (g mol$^{-1}$) and 0.0821 L atm K$^{-1}$ mol$^{-1}$ is the ideal gas constant $R$.

The following statistical metrics were calculated to compare model and observation data where $M_i$ and $O_i$ are modelled and observed (i.e. measured) data in a dataset of $n$ such pairs. If a model grid contains more than one measurement site, the average of the measurements is used as $O_i$.

Pearson’s correlation coefficient:

$$R = \frac{\sum_{i=1}^{n}(M_i - \bar{M})(O_i - \bar{O})}{\sqrt{\sum_{i=1}^{n}(M_i - \bar{M})^2} \sqrt{\sum_{i=1}^{n}(O_i - \bar{O})^2}}$$

Mean bias:

$$M_B = \frac{1}{n} \sum_{i=1}^{n} (M_i - O_i) = \bar{M} - \bar{O}$$

Mean absolute error:

$$M_E = \frac{1}{n} \sum_{i=1}^{n} |M_i - O_i|$$

Normalized mean bias:

$$NMB = \frac{\sum_{i=1}^{n}(M_i - O_i)}{\sum_{i=1}^{n} O_i} = \left(\frac{\bar{M}}{\bar{O}} - 1\right)$$

Normalized mean error:

$$NME = \frac{\sum_{i=1}^{n}|M_i - O_i|}{\sum_{i=1}^{n} O_i} = \frac{M_E}{\bar{O}}$$
NOx and SOx emission differences between HTAP and ECLIPSEE inventories

Figure S1. Top: Global annual NOx emissions for 2010 from ECLIPSEE. Bottom: the difference in 2010 annual NOx emissions (mg m⁻²) between ECLIPSEE and HTAP (ECLIPSEE - HTAP). The inset panel provides the maximum, median and mean values of both positive and negative differences across individual emission grids.
Figure S2. Top: Global annual SO\textsubscript{x} emissions for 2010 from ECLIPSE\textsubscript{E}. Bottom: the difference in 2010 annual SO\textsubscript{x} emissions (mg m\textsuperscript{-2}) between ECLIPSE\textsubscript{E} and HTAP (ECLIPSE\textsubscript{E} – HTAP). The inset panel provides the maximum, median and mean values of both positive and negative differences across individual emission grids.
Comparisons of monthly profiles of the HTAP and ECLIPSE\textsubscript{E} emission inventories

Figure S3 presents a global map of annual terrestrial NH\textsubscript{3} emissions from ECLIPSE\textsubscript{E} (i.e. ECLIPSE annual total emission with EDGAR monthly profile) in 2010. The boxes on the map delineate four example regions with measurement networks that are subsequently used to compare model and measurement concentrations spatially and seasonally, as reported in the main paper. Figure S4 compares the spatially-averaged monthly NH\textsubscript{3} emissions of the HTAP and ECLIPSE\textsubscript{E} inventories in 2010 in each of these four global regions.

There is clear seasonality in NH\textsubscript{3} emissions in all four regions. In East Asia, the ECLIPSE\textsubscript{E} inventory has larger NH\textsubscript{3} emissions than the HTAP inventory across all months and has a prominent maximum in spring, in addition to the general elevated emissions in summer projected by both inventories. For Southeast Asia, both the HTAP and ECLIPSE\textsubscript{E} inventories present a distinct peak in NH\textsubscript{3} emissions in March, with the HTAP inventory having larger emissions than the ECLIPSE\textsubscript{E} inventory in most months of the year, particularly in winter (as a consequence of smaller annual variation in the HTAP NH\textsubscript{3} emissions).

In Europe and North America there is generally good coincidence in magnitude and seasonality of NH\textsubscript{3} emissions between the two inventories. In Europe, both inventories project maximum NH\textsubscript{3} emissions in March and April, although the ECLIPSE\textsubscript{E} inventory also projects a second maximum in August. The annual average emissions in Europe are similar, with sometimes one inventory and sometimes the other having higher emission in an individual month. In contrast, in North America, both inventories project maximum NH\textsubscript{3} emissions in July and August and much less pronounced peaks in early spring. In this region it is the HTAP inventory that projects the greatest annual variation, in contrast to East and Southeast Asia where ECLIPSE\textsubscript{E} projects the greatest annual variation. The spring and summer peaks in NH\textsubscript{3} emissions in all four world regions reflect both agricultural activities (the dominant source of NH\textsubscript{3}) and meteorological conditions. Larger NH\textsubscript{3} emissions in spring are associated with intensive manure and synthetic fertilizer application, whilst the rising temperatures throughout the summer favour the volatilisation of NH\textsubscript{3} from all sources.

![Global annual NH\textsubscript{3} emissions (mg m\textsuperscript{-2}) for 2010 from the ECLIPSE\textsubscript{E} inventory as implemented in the EMEP MSC-W model simulations in this work. The grey boxes show four regions in which monthly emission profiles of the ECLIPSE\textsubscript{E} and HTAP inventories are compared.](image-url)
Comparisons between use of HTAP and ECLIPSE\textsubscript{E} emission inventories: \(\text{NH}_4^+\) concentration

The influences of the two emission inventories on model simulated surface concentration differs according to consideration of primary or secondary component and varies from one region to another. In general, concentrations of primary pollutants are more influenced by the local emissions, while secondary species are much less so. Fig. S5 compares the modelled \(\text{NH}_4^+\) concentrations using the two emission inventories for the grids in which there are also available measurements from the monitoring networks.

The differences in \(\text{NH}_4^+\) concentrations in simulations using the two emission inventories are smaller than for \(\text{NH}_3\) (Fig. 4), as shown by concentrations that are closer to 1:1 in all regions. For example, whilst modelled \(\text{NH}_3\) concentrations in China derived using the ECLIPSE\textsubscript{E} inventory are on average 56% higher than those derived using the HTAP inventory, the \(\text{NH}_4^+\) concentrations are very similar. The annual average \(\text{NH}_4^+\) concentrations (based on network locations) in China are 7.30 and 7.15 \(\mu\text{g m}^{-3}\) for HTAP and ECLIPSE\textsubscript{E} respectively, which is a difference of only 2%. The regression equation of \(\text{NH}_4^+\) concentrations from the model simulations with the two inventories across the full set of measurement network locations considered in this work is excellent \((y = 0.92x + 0.01, R = 0.98\text{, Fig. S5})\). This indicates good global consistency for the WRF-EMEP modelling system across a wide variation of primary \(\text{NH}_3\), \(\text{NO}_2\) and \(\text{SO}_2\) emissions in different global...
regions. It can be noted, however, that model simulations with both HTAP and ECLIPSE\textsubscript{E} inventories yield slightly higher concentrations than measurements at lower concentrations (below 5 \(\mu\text{g m}^{-3}\)) but lower concentrations than measurements at higher concentration ranges. This reflects a fundamental difference between modelled and measured data. The modelled value represents the average concentration over a grid of several 10s km in horizontal dimension, whereas the measured values only represent the concentration at the specific location of the measurement. Since the latter are readily impacted by local sources and sinks, they will generally have a greater range in values which are averaged out in the former. Measurements are also sometimes deliberately sited in locations of anticipated high pollutant concentration that may be reduced by grid averaging in relatively spatially coarse global model simulations.

![Figure S5](image)

Figure S5. Comparisons of annual average surface concentrations of \(\text{NH}_4^+\) for 8 monitoring networks in 2010 – NNDMN from China as East Asia, EANET as Southeast Asia, NAMN and AGANet (UK) and EMEP/CCC plotted together here as Europe, and the EPA and AMoN (USA) and NAPS (Canada) plotted together here as North America – and for all networks combined (“global”). The upper row of plots is modelled versus measured using the HTAP emission inventory. The middle row is modelled versus measured using the ECLIPSE\textsubscript{E} emission inventory. The lower row is the modelled data for the two inventories plotted against each other for the same set of model grids that contain measurement sites. In each plot, N is the total number of scatter points, \(R\) is the Pearson correlation coefficient, the black dashed line is the 1:1 line and the coloured solid line is the trend line corresponding to the equation presented.
Comparison of temporal variation of modelled NH$_4^+$ concentrations with measurements

Figure S6. Monthly averaged measured (left panels) and modelled (right panels) NH$_4^+$ concentrations in 2015 for NNDMN, EANET, AGANet (UK) and EMEP/CCC monitoring networks. The box extends from the lower to upper quartile values of the data, with an orange line at the median and a green point at the mean. The whiskers represent 5% and 95% percentiles.
Comparison of modelled precipitation and wet deposition with measurements

Figure S7. Scatter plots of model-measurement comparisons of 2015 annual wet deposition variables for oxidized N (as NO$_3^-$) for four measurement networks: NNDMN, EANET, EMEP/CCC and US NTN. Left panels are annual precipitation. Middle panels are precipitation-weighted annual average NO$_3^-$ concentration in precipitation. Right panels are annual total wet deposition of NO$_3^-$ In each plot, the coloured line is the least squares regression and the black dashed line is the 1:1 line.
Table S1. Summary statistics of model comparison with measurements (referred to here as ‘O’ for observation) for annual precipitation amount (Prec Amount, mm), precipitation-weighted annual mean concentration of NO₃ (Prec Conc, mgN L⁻¹), and wet deposition of oxidized N (WDEP, mgN m⁻²) for four measurement networks in 2015. N is the number of measurement sites. R is Pearson’s coefficient. Fac2 fraction is the proportion of data points that are within a factor of 2. Mean_O and Mean_M of Prec Conc are annual averages of observation and model respectively. Mean_O and Mean_M of Prec Amount and WDEP are annual totals. NMB is normalized mean bias, NME is normalized mean error.
