Abstract. We present MISTRA-v9.0, a one dimensional (1D) atmospheric chemistry model. The model includes a detailed particle description with regards to the microphysics, gas-particle interactions, and liquid phase chemistry within particles. Version 9.0 is the first release of MISTRA as an open-source community model. A major review of the code has been performed along with this public version release to improve the user-friendliness and platform-independence of the model. In the past 20 years, MISTRA has been used in over 25 studies to address a wide range of scientific questions. The purpose of this public release is to maximise the benefit of MISTRA to the community by making the model freely available and easier to use and develop. This paper presents a thorough description of the model characteristics and components. We show some examples of simulations reproducing previous studies with MISTRA, finding that version 9.0 is consistent with previous versions.

1 Introduction

1.1 Scientific context and purpose of the model

Atmospheric aerosols are a major component of the Earth climate system. They significantly affect the radiative balance of the atmosphere, through direct (scattering and absorption) and indirect effects (cloud properties modification) (Carslaw et al., 2010; Boucher et al., 2014). However their concentrations, chemical and physical properties are still insufficiently constrained, and the variability associated with their effects is dominant in the uncertainties of climate projections (Bender, 2020). Atmospheric particles also have a fundamental role in the chemistry of the atmosphere, since they offer a large area and volume for (photo)-chemical reactions to occur (Andreae and Crutzen, 1997; Finlayson-Pitts, 2009; George et al., 2015; Simpson et al., 2015; Seinfeld and Pandis, 2016; Kanakidou et al., 2018). Other impacts include the reduction of visibility and health effects of pollution.

Numerical models are essential tools to help understand the relevant processes, and make projections of their evolution in a changing climate (Ervens, 2015). While global three-dimensional (3D) models, and specifically Earth System Models (ESMs) are well suited for climate simulation, the high computing cost of coupled physical-microphysical-chemical processes

modelling limits the space resolution of such models. Currently, a kilometer-scale resolution is already very challenging, thus preventing fully resolved approaches for subgrid scale processes, such as turbulence. Conversely, limited-area and one-dimensional (1D) models can reach sufficiently fine resolution for process-resolving simulations. In turn, the results obtained with such models can be used to develop parameterisations for use in 3D models.

Whatever the model, a crucial step is the validation based on field measurements. Balloon or flight surveys provided valuable data for this purpose, but the number of investigated parameters is necessarily limited, with many uncertainties and unknown values. Another useful tool for atmospheric chemistry and physics understanding is the atmospheric simulation chambers (see for instance <https://www.eurochamp.org>, last accessed 01-July-2021). These platforms enable the simultaneous measurement of a large number of chemical species and associated physical characteristics, in a constrained volume. The resulting datasets are highly valuable to validate models. In turn, numerical models are complementary tools to help understand and interpret measured results.

In this paper, we present the 1D atmospheric chemistry model MISTRA-v9.0, including size-resolved aerosol processes as well as particle-chemistry interaction. MISTRA-v9.0 also includes a box-model configuration, which can be adapted for atmospheric simulation chamber applications. In Sect. 1.2 and 1.3, we give a brief history of the MISTRA model, then an overview on the recent developments presented in this paper. Section 2 gives a thorough description of processes implemented in the model. Section 3 presents practical and technical aspects of MISTRA-v9.0 with the main settings, while a set of example simulations reproducing previous studies settings and configurations is presented in Section 4, to show the consistency of MISTRA-v9.0 with previous results.

1.2 History of MISTRA and reference publications

The MISTRA model was originally designed to study the Microphysics in STRatus clouds, and was written based on a fog model (MIFOG: Bott et al. (1990); Bott and Carmichael (1993); von Glasow and Bott (1999)). Bott et al. (1996) developed the first version of MISTRA, for the simulation of cloud microphysics in the marine boundary layer (MBL). The unique feature of this model is the use of a two-dimensional particle distribution, with one dimension accounting for dry particle radius, and the second dimension for the total particle radius. Based on this first version of MISTRA, Bott (1997) further included typical particle distributions of urban and rural aerosols for the study of MBLs influenced by continental air masses. In this work, the radiative forcing of stratiform clouds was assessed. The radiation code used in MISTRA, called PIFM1, was updated by Loughlin et al. (1997) and the new radiation code, PIFM2, was evaluated. The collision-coalescence process was implemented in MISTRA by Bott (2000, 2001). Bott (1999a) adapted the chemistry module from Bott and Carmichael (1993) in MISTRA, with special emphasis on sulfur chemistry, and studied the retroaction of cloud processing over the microphysics in Bott (1999b). Meanwhile, von Glasow (2000) developed another chemistry module for MISTRA, with special emphasis on halogen chemistry, and presented the results for cloud free (von Glasow et al., 2002a) and cloudy MBLs (von Glasow et al., 2002b). Our paper develops the branch of MISTRA based on von Glasow (2000).

From the early 2000s to the mid 2010s, MISTRA was regularly improved with respect to the chemistry and the gas-particle interactions, and was used in several studies, many of them with a focus on halogen chemistry. A major improvement was the

introduction of a module for aerosol nucleation which improved the iodine chemistry (Pechtl et al., 2006, 2007). The gas-phase chemical mechanism was updated by Sommariva and von Glasow (2012).

Over the years, numerous modelling studies were performed using MISTRA (von Glasow and Crutzen, 2004; Pechtl and von Glasow, 2007; Lawler et al., 2009; Jones et al., 2010; Joyce et al., 2014) including alternative model configurations where the chemistry was computed in a zero-dimension (0D) atmospheric box mode (Buys et al., 2013), and a 0D chamber mode (Buxmann et al., 2015). MISTRA was also adapted to model specific environments such as volcanic plumes (Aiuppa et al., 2007; Bobrowski et al., 2007, 2015) polar conditions (Piot and von Glasow, 2008, 2009; Buys et al., 2013), and was coupled with an ocean model for studies over the Dead Sea (Smoydzin and von Glasow, 2007, 2009). A module for firn chemistry was developed and coupled to MISTRA to specifically address the influence of chemical reactions occurring in the snowpack on the oxidative capacity of the atmosphere in snow covered regions (Thomas et al., 2011, 2012). In this study, we present a selection of a few specific model settings reproducing previous work, to compare the original results with those obtained with MISTRA-v9.0.

1.3 Recent developments and public release

The previous (non-public) version of MISTRA (v7.4.1) included the update of the gas-phase chemical mechanism by Sommariva and von Glasow (2012). A version 8 featuring an alternative chemical bin definition was partly developed but not completed, thus explaining the current version number. More information about past versions of MISTRA can be found in the preface of the manual (https://github.com/Mistra-UEA/Mistra/blob/master/doc/manual_v9.0.pdf). Since 2015, significant efforts have been devoted to release MISTRA as an open-source model, including major technical improvements. The original code, written in Fortran77, has been updated to Fortran90 to ease future maintenance and developments. To improve robustness and portability of the code, intensive controls throughout the code have been performed to track issues, fix bugs, and conform to strict coding rules (Metcalf et al., 2004). This was achieved with the help of the Fortran analyser Forcheck (v14.6, no longer distributed), as well as standard code check options of compilers. Computing efficiency has also been improved by factorising parts of code, and re-indexing arrays to respect column-major order in Fortran (i.e. innermost do-loops should be leftmost indexes). The chemical "Kinetic PreProcessor" (KPP) has been updated to the latest version 2.2.3 (<https://people.cs.vt.edu/~asandu/Software/Kpp/> last accessed 23 June 2021). Overall, several technical developments have been implemented to make the model as user-friendly as possible, and easier to adopt. The model code of MISTRA-v9.0 now has improved readability, documentation, and is available under licence EUPL-v1.1 on <https://github.com/Mistra-UEA>.

2 Scientific description

2.1 Overview of the model components

MISTRA is a one-dimensional model of the MBL. Figure 1 shows schematically the most important processes that are included in the model for a cloudy MBL. The meteorological and microphysical part consists of the boundary layer model MISTRA

described in detail by Bott et al. (1996) and Bott (1997). The most important processes are turbulent mixing, condensation, evaporation and radiative heating. Apart from dynamics and thermodynamics, MISTRA includes a detailed microphysical module that calculates particle growth explicitly and includes feedbacks between radiation and particles. The radiative-transfer parameterisation is a standard two-stream code using 6 spectral bands for visible and 12 bands for infrared radiation (Loughlin et al., 1997). A chemistry module computes the atmospheric chemistry in the gas phase and in the particles. Gas phase chemistry is active in all model layers; aerosol chemistry only in layers where the relative humidity has been greater than the deliquescence humidity and not dropped below the crystallisation humidity (as discussed in Sect. 2.3.3). When a cloud forms, cloud droplet chemistry is also active. Fluxes of sea salt aerosol and gases from the ocean are included. A nucleation module is also included to account for new particles nucleated from the gas phase species.

Figure 1. Schematic depiction of the most important processes included in the one-dimensional boundary layer model MISTRA. The free troposphere and marine boundary layer are denoted as FT and MBL, respectively.

2.2 Meteorology, microphysics and thermodynamics

The model is one-dimensional, thus all variables are taken to be horizontally homogeneous. The set of prognostic variables comprises the horizontal components of the wind speed u and v , the specific humidity q , and the potential temperature θ . The Boussinesq approximation is applied and the air pressure is derived from the large scale hydrostatic equilibrium.

The set of governing equations for these prognostic variables is:

$$\frac{\partial u}{\partial t} = -w \frac{\partial u}{\partial z} + \frac{\partial}{\partial z} \left(K_m \frac{\partial u}{\partial z} \right) + f_c(v - v_g) \quad (1)$$

$$\frac{\partial v}{\partial t} = -w \frac{\partial v}{\partial z} + \frac{\partial}{\partial z} \left(K_m \frac{\partial v}{\partial z} \right) - f_c(u - u_g) \quad (2)$$

$$\frac{\partial q}{\partial t} = -w \frac{\partial q}{\partial z} + \frac{\partial}{\partial z} \left(K_h \frac{\partial q}{\partial z} \right) + \frac{C}{\rho} \quad (3)$$

$$\frac{\partial \theta}{\partial t} = -w \frac{\partial \theta}{\partial z} + \frac{\partial}{\partial z} \left(K_h \frac{\partial \theta}{\partial z} \right) - \left(\frac{p_0}{p} \right)^{\frac{R_a}{c_p}} \frac{1}{c_p \rho} \left(\frac{\partial E_n}{\partial z} + LC \right) \quad (4)$$

105 where f_c is the Coriolis parameter, u_g and v_g are the geostrophic wind components, K_m and K_h are the turbulent exchange coefficients for momentum and heat, L is the latent heat of condensation, C the condensation rate, ρ the air density, p the air pressure, p_0 the air pressure at the surface, R_a the specific gas constant for dry air, c_p the specific heat of dry air at constant pressure, and E_n the net radiative flux density, respectively. The first term on the right of each equation is the large scale subsidence. Strictly, in a one-dimensional framework, the vertical velocity w should be zero everywhere, otherwise this implies

110 a downward mass transport (for $w < 0$) without lateral outflow at the bottom of the 1D model column as would occur in the real atmosphere. Therefore the mass balance is violated if subsidence is included. However, including subsidence is essential for modelling stratiform cloud evolution (e.g. Driedonks and Duynkerke, 1989). In runs where only aerosol chemistry is studied, i.e. in runs without clouds, the vertical velocity is set to zero ($w = 0$) in the model to avoid this problem, while for the cloud runs subsidence is usually included.

115 Turbulence is treated with the level 2.5 model of Mellor and Yamada (1982) with the modifications described in Bott et al. (1996) and Bott (1997). The turbulent exchange coefficients K_m and K_h are calculated via stability functions $S_{m/h}$ and $G_{m/h}$, where the subscript m stands for shear and h for buoyancy production. The prognostic equation for the turbulence kinetic energy (TKE) e is:

$$\frac{\partial e}{\partial t} = -w \frac{\partial e}{\partial z} + \frac{\partial}{\partial z} \left(K_e \frac{\partial e}{\partial z} \right) + \frac{(2e)^{3/2}}{l} \left(S_m G_m + S_h G_h - \frac{1}{16.6} \right) \quad (5)$$

120 assuming a constant dissipation ratio (last term on the right). For more details and an explanation of the calculation of the mixing length l , the exchange coefficient K_e for the TKE, and the functions $S_{m/h}$ and $G_{m/h}$ see Mellor and Yamada (1982), Bott et al. (1996), and Bott (1997).

The microphysics is treated using a joint two-dimensional particle size distribution function $f(a, r)$ where a is the dry aerosol radius the particles would have if no water is present in the particles, and r is the total particle radius. The two-dimensional

125 particle grid is divided into 70 logarithmically equidistant spaced dry aerosol classes. The minimum aerosol radius is generally set to 0.005 μm and the maximum radius 15 μm . Choosing these values allows to account for all accumulation mode particles and most of the coarse particles. The minimum and maximum, as well as the number of bins for both dimensions of the particle spectrum are adjustable. Each of the 70 dry aerosol classes is associated with 70 total particle radius classes, ranging from the

Figure 2. The two-dimensional particle spectrum as function of the dry aerosol radius a and the total particle radius r . Added are the chemical bins. I: sulfate aerosol bin, II: sea salt aerosol bin, III: sulfate cloud droplet bin, IV: sea salt droplet bin. For simplicity a 35 by 35 bin grid is plotted, in the model 70 x 70 bins are used.

actual dry aerosol radius up to 60 μm (150 μm in cloud runs). See Figure 2 for a depiction of 2D particle grid. The prognostic
 130 equation for $f(a, r)$ is:

$$\frac{\partial f(a, r)}{\partial t} = -w \frac{\partial f(a, r)}{\partial z} + \frac{\partial}{\partial z} \left(K_h \rho \frac{\partial f(a, r)}{\partial z} \right) - \frac{\partial}{\partial z} \left(w_t f(a, r) \right) - \frac{\partial}{\partial r} \left(\dot{r} f(a, r) \right) \quad (6)$$

Again, subsidence is the first term on the right, followed by turbulent mixing, particle sedimentation (w_t is the sedimentation velocity) and changes in f due to particle growth ($\dot{r} = dr/dt$). The 2D particle spectrum is initialised with distribution depending on the type of aerosol chosen (see Bott, 1997, and ref. therein). Currently, particle distributions are provided for
 135 typical marine, rural and urban air masses. Other distributions are available for specific studies, such as a polar distribution (see for instance Buys et al., 2013, and the corresponding example simulation). Particles are initialised with a water coating according to the equilibrium radius of the dry nucleus at the ambient relative humidity. During the integration, particle growth is calculated explicitly for each bin of the 2D particle spectrum using the growth equation after Davies (1985) Bott et al. (see also 1996):

$$140 \quad r \frac{dr}{dt} = \frac{1}{C_1} \left[C_2 \left(\frac{S_\infty}{S_r} - 1 \right) - \frac{F_d(a, r) - m_w(a, r) c_w dT/dt}{4\pi r} \right] \quad (7)$$

with the ambient supersaturation S_∞ and the supersaturation at the droplet's surface S_r according to the Köhler equation:

$$S_r = \exp \left[\frac{A}{r} - \frac{Ba^3}{r^3 - a^3} \right]. \quad (8)$$

where factors A and B account for the Kelvin effect and the solute effect, respectively.

The change in particle radius is not determined by changes in water vapour saturation alone, but also by the net radiative flux at the particle's surface $F_d(a, r)$, that leads to temperature changes and therefore to condensation or evaporation. The constants C_1 and C_2 in equation (7) are:

$$C_1 = \rho_w L + \frac{\rho_w C_2}{D'_v S_r \rho_s} \quad C_2 = k' T \left[\frac{L}{R_v T} - 1 \right]^{-1}, \quad (9)$$

$m_w(a, r)$ is the liquid water mass of the particle, c_w and ρ_w are the specific heat and density of water, ρ_s is the saturation vapour density and R_v the specific gas constant for water vapour. The thermal conductivity k' of moist air and the diffusivity of water vapour D'_v have been corrected for gas kinetic effects following Pruppacher and Klett (1997) (their equations 13.20 and 13.14, respectively). For the accommodation coefficient of water (condensation coefficient), a value of $\alpha_c = 0.036$ is used (see table 5.4 in Pruppacher and Klett (1997) for a compilation of measured α_c values; in table 13.1 they use $\alpha_c = 0.036$ as “best estimate”).

The condensation rate C in equation (4) is determined diagnostically from the particle growth equation (7). Collision-coalescence processes are not included in the model because this leads to difficulties when redistributing the chemical species in the particles. A version of MISTRA including collision-coalescence without considering chemistry does exist (Bott, 2000), and this limitation of MISTRA-v9.0 is discussed in Sect. 4.1.2.

For the calculation of the radiative fluxes, a δ -two stream approach is used (PIFM2 Zdunkowski et al., 1982; Loughlin et al., 1997). The radiative fluxes are used for calculating heating rates and the effect of radiation on particle growth. The radiation field is calculated with the aerosol/cloud particle data from the microphysical part of the model, so feedbacks between radiation and particle growth are fully implemented. The calculation of photolysis frequencies is described in Sect. 2.3.5.

2.3 Chemistry

The multiphase chemistry module comprises chemical reactions in the gas phase as well as in aerosol and cloud particles. Transfer between gas and aqueous phase and surface reactions on particles are also included. The reaction set was based on that of Sander and Crutzen (1996) plus some organic reactions from Lurmann et al. (1986). It has been updated and expanded by von Glasow and Crutzen (2004) to include a better description of the oxidation of DMS. Iodine chemistry was significantly improved by Pechtl et al. (2006, 2007). Further updates to the chemical mechanism were done by Sommariva and von Glasow (2012). The current mechanism is provided in the model manual (tables in Appendix D). In the following, the term aqueous phase is used as generic term for sub-cloud aerosol, interstitial aerosol (i.e. non-activated aerosol particles in cloudy layers), and cloud particles.

2.3.1 Gas phase and uptake

The prognostic equation for the concentration of a gas phase chemical species c_g (in mol m^{-3}) including subsidence, turbulent exchange, deposition on the ocean surface, chemical production and destruction, emission and exchange with the aqueous phases is:

$$\frac{\partial c_g}{\partial t} = -w \frac{\partial c_g}{\partial z} + \frac{\partial}{\partial z} \left(K_h \rho \frac{\partial c_g}{\partial z} \right) - D + P - S c_g + E - \sum_{i=1}^{n_{kc}} \left[\overline{k_{t,i}} \left(w_{l,i} c_g - \frac{c_{a,i}}{K_h^{cc}} \right) \right]. \quad (10)$$

Again subsidence is the first term on the right and is included only in runs with clouds, otherwise $w = 0$. P and S are chemical production and loss terms, respectively, H_s^{cc} is the dimensionless Henry constant obtained by $H_s^{cc} = H_s^{cp} RT$, where H_s^{cp} is in $\text{mol m}^{-3} \text{Pa}^{-1}$, $w_{l,i}$ is the dimensionless liquid water content (V_{aq}/V_{air}) of bin i (see explanation in Sect. 2.3.2). The emission E as well as dry deposition D are effective only in the lowermost model layer. The calculation of the dry deposition velocity v_g^{dry} , that is needed for the determination of D , is explained at the end of this section. Note that both E and D are not inserted as fluxes in equation 10. Instead, the actual fluxes have to be divided by the thickness of the lowermost model layer to yield D and E . The last term in equation (10) describes the transport from the gas phase into the aqueous phases according to the formulation by Schwartz (1986) (see also Sander, 1999), n_{kc} is the number of aqueous classes as explained below. For a single particle, the mass transfer coefficient k_t is defined as:

$$k_t = \left(\frac{r^2}{3D_g} + \frac{4r}{3\bar{v}\alpha} \right)^{-1} \quad (11)$$

with the particle radius r , the mean molecular speed $\bar{v} = \sqrt{8RT/(M\pi)}$ (M is the molar mass), the accommodation coefficient α , and the gas phase diffusion coefficient D_g . D_g is approximated using the mean free path length λ as $D_g = \lambda \bar{v}/3$ (e.g. Gombosi (1994), p. 125).

Chameides (1984) points out that the time needed to establish equilibrium between the gas and aqueous phase differs greatly for individual species and that soluble species never reach equilibrium in cloud droplets, emphasizing the importance of describing phase transfer in the kinetic form that is used here. Audrieff et al. (1998) and Chaumerliac et al. (2000) point out that for reactive species like H_2O_2 , the use of the Henry equilibrium assumption instead of the detailed description of mass transfer in the kinetic form that is used here would lead to significant errors in cloud droplet concentrations.

Ambient particle populations are never monodisperse, i.e. one has to account for particle with different radii. The mean transfer coefficient $\overline{k_t}$ for a particle population is given by the integral:

$$\overline{k_t} = \frac{4\pi}{3w_l} \int_{\lg r_{\min}}^{\lg r_{\max}} \left(\frac{r^2}{3D_g} + \frac{4r}{3\bar{v}\alpha} \right)^{-1} r^3 \frac{\partial N}{\partial \lg r} d \lg r, \quad (12)$$

where the size distribution function $\partial N/\partial \lg r$ depends on the type of aerosol chosen.

2.3.2 Aqueous phase

Aqueous chemistry is calculated in four bins (see Figure 2): deliquescent aerosol particles with a dry radius less than 0.5 μm are included in the “sulfate aerosol” bin #1, whereas deliquescent particles with a dry aerosol radius greater than 0.5 μm are in the “sea salt aerosol” bin #2. Although the composition of the particles changes over time, the terms “sulfate” and “sea salt” aerosol are used to describe the origin of the particles. The particles get internally mixed by exchange with the gas phase but, as mentioned earlier, not by particle collisions. Depending on the type of aerosol relevant to the study, various initial compositions of the aerosol bins may be chosen.

When the total particle radius exceeds the dry particle radius by a factor of 10, i.e. when the total particle volume is 1000 times greater than the dry aerosol volume, the particle and its associated chemical species are moved to the corresponding sea salt or sulfate-derived cloud particle class (#3 and #4, respectively). This threshold roughly coincides with the critical radius derived from the Köhler equation (see Eq. 8). Conversely, when particles shrink, they are redistributed from the droplet to the aerosol bins.

Therefore in a cloud-free layer there are two ($n_{kc} = 2$) aqueous chemistry bins (sulfate and sea salt aerosol) and in a cloudy layer two cloud droplet (sulfate and sea salt derived) and two interstitial aerosol (sulfate and sea salt) bins, giving a total of four ($n_{kc} = 4$) aqueous chemistry bins. In each of these bins the following prognostic equation is solved for each chemical species $c_{a,i}$ (in mol m^{-3}), where the index i stands for the i -th aqueous bin:

$$\frac{\partial c_{a,i}}{\partial t} = -w \frac{\partial c_{a,i}}{\partial z} + \frac{\partial}{\partial z} \left(K_h \rho \frac{\partial c_{a,i}}{\partial z} \right) - D + P - L c_{a,i} + E + P_{pc} + \overline{k_{t,i}} \left(w_{l,i} c_g - \frac{c_{a,i}}{K_h^{cc}} \right) \quad (13)$$

The individual terms have similar meanings as in equation (10). The calculation of the sedimentation velocity $v_{a,i}^{\text{dry}}$, that is needed for the calculation of the dry deposition D , is explained at the end of this section. The additional term P_{pc} accounts for the transport of chemical species from the aerosol to the cloud droplet regimes and vice versa when droplets are formed or when they evaporate, i.e. when particles move along the Köhler curve and get activated or unactivated. If only phase transfer is considered, equation (13) reduces in steady state conditions ($\partial c_{a,i} / \partial t = 0$) to the Henry equilibrium $c_{a,i} = w_{l,i} c_g K_h^{cc}$.

The concentration of H^+ ions is calculated like any other species, i.e. no further assumptions are made. The charge balance is satisfied implicitly.

2.3.3 Hysteresis of particle activation

Cloud-processing, i.e. the change of aerosol mass due to uptake of gases, is included based on the model of Bott (1999b).

It has been observed in many laboratory experiments that soluble aerosol remains in a highly concentrated metastable aqueous state when they are dried below their deliquescence humidity. Only when they reach the crystallisation humidity they can be regarded as “dry”. This effect is called the hysteresis effect. For NaCl the crystallisation point is about 45 % relative humidity (Shaw and Rood (1990), Tang (1997), Pruppacher and Klett (1997), and Lee and Hsu (2000)).

The crystallisation humidity for many mixed aerosol particles containing sulfate or nitrate is below 40 % relative humidity (Seinfeld and Pandis (1998) and references therein), implying that aerosol particles that already had been involved in cloud cycles will also be in an aqueous metastable state. Therefore most soluble aerosol particles will be present in the atmosphere as metastable aqueous particles below their deliquescence humidity. If the humidity drops below the crystallisation humidity, these particles can only reactivate when the deliquescence humidity is reached.

2.3.4 Accounting for the chemical activity

Aerosol particles are usually highly concentrated solutions. Laboratory measurements show that NaCl molalities can be in excess of 10 mol/kg (Tang, 1997) implying high ionic strengths. Therefore, it is necessary to account for deviations from ideal behaviour by including activity coefficients. The Pitzer formalism (Pitzer, 1991) is used to calculate the activity coefficients for the actual composition of each aqueous size bin. The implementation by Luo (Luo et al. (1995) and pers. comm. 1999) is used in MISTRA. It computes the activity of 7 main ions (H^+ , NH_4^+ , Na^+ , HSO_4^- , SO_4^{2-} , NO_3^- , and Cl^-). The activities of 15 other ions are scaled on the previous ones based on the results from Liang and Jacobson (1999) and Chameides and Stelson (1992).

2.3.5 Photolysis

Here an overview of the calculation of the photolysis rates is given, for a detailed description see the model manual, Chapter 5. Photolysis is calculated online using the method of Landgraf and Crutzen (1998). The photolysis rate (or photo dissociation coefficient) J_X for a gas X can be calculated from the spectral actinic flux $F(\lambda)$ via the integral:

$$J_X = \int_I \sigma_X(\lambda) \phi_X(\lambda) F(\lambda) d\lambda \quad (14)$$

where λ is the wavelength, σ_X the absorption cross section, ϕ_X the quantum yield and I the photochemically active spectral interval. If the integral in equation (14) were approximated with a sum, the number of wavelength intervals needed for an accurate approximation of the integral would be in the order of 100, which would lead to excessive computing times. Landgraf and Crutzen (1998) suggested a method using only 8 spectral intervals approximating (14) by:

$$J_X \approx \sum_{i=1}^8 J_{i,X}^a \delta_i \quad (15)$$

where $J_{i,X}^a$ is the photolysis rate for a purely absorbing atmosphere. The factor δ_i :

$$\delta_i = \frac{F(\lambda_i)}{F^a(\lambda_i)} \quad (16)$$

describes the effect of scattering by air molecules, aerosol and cloud particles. $F^a(\lambda_i)$ is the actinic flux of a purely absorbing atmosphere. The factor δ_i is calculated online for one wavelength for each interval, while the $J_{i,X}^a$ are pre-calculated with a fine spectral resolution and are approximated during runtime from lookup tables or by using polynomials. The advantage of

this procedure is that the fine absorption structures that are present in σ_X and ϕ_X are considered and only Rayleigh and cloud scattering, included in $F(\lambda_i)$, are treated with a coarse spectral resolution, which is justified.

For the calculation of the actinic fluxes, a four stream radiation code is used in addition to the two stream radiation code used for the determination of the net radiative flux density E_n , because different spectral resolutions and accuracies are needed for these different purposes. Based on the findings of Ruggaber et al. (1997), photolysis rates inside aqueous particles are increased by a factor of two to account for the actinic flux enhancement inside the particles due to multiple scattering.

2.3.6 Emission and deposition

The emission of gases is accounted for in the model, either with constant emission fluxes (for instance, for DMS and NH_3 emitted from the sea surface), or with scenarios of emission variable in time (see for instance the example run based on the study of Joyce et al. (2014)).

Sea salt particles are emitted by bursting bubbles at the sea surface (e.g. Woodcock et al. (1953), Pruppacher and Klett (1997)). The parameterisations of Monahan et al. (1986) and Smith et al. (1993a) are implemented to estimates the flux of particles. The former is advised for small to moderate wind speeds, while the latter has to be used for high wind speeds.

The dry deposition velocity for gases v_g^{dry} at the sea surface is calculated using the resistance model described by Wesely (1989):

$$v_g^{\text{dry}} = \frac{1}{r_a + r_b + r_c}. \quad (17)$$

The aerodynamic resistance r_a is calculated using:

$$r_a = \frac{1}{\kappa u_*} \left[\ln \left(\frac{z}{z_0} \right) + \Phi_s(z, L_{\text{MO}}) \right], \quad (18)$$

with the friction velocity u_* , the von Kármán constant $\kappa = 0.4$, and the stability function Φ_s which depends on the Monin-Obukhov length L_{MO} , the roughness length z_0 and a reference height z . The quasi-laminar layer resistance r_b is parameterised for gases as:

$$r_b = \frac{5Sc^{2/3}}{u_*}. \quad (19)$$

The Schmidt number Sc can be written as $Sc = \nu/D_g$ with the kinematic viscosity of air ν and the gas diffusion coefficient D_g as in Eq. 11. The surface resistance r_c is calculated using the formula by Seinfeld and Pandis (1998) (their equation (19.30)):

$$r_c = \frac{2.54 \times 10^4}{H^* T u_*}, \quad (20)$$

with the effective Henry constant H^* .

The dry deposition velocity of particles $v_{a,i}^{\text{dry}}$ is calculated after Seinfeld and Pandis (1998):

$$v_{a,i}^{\text{dry}} = \begin{cases} \frac{1}{r_a + r_b + r_a r_b w_t} + w_t & \text{lowest model layer} \\ w_t & \text{rest of model domain.} \end{cases} \quad (21)$$

where the quasi-laminar resistance r_b is parameterised for particles as:

$$r_b = \frac{1}{u_* (Sc^{-2/3} + 10^{-3/St})}. \quad (22)$$

The Stokes number St can be written as $St = w_t u_*^2 / (g\nu)$. The particle sedimentation velocity w_t is calculated in the microphysical module assuming Stokes flow and taking into account the Cunningham slip flow correction for particles with $r < 10\mu\text{m}$ and after Beard for larger particles (see Pruppacher and Klett (1997)).

3 Technical description

3.1 Namelist settings

3.1.1 General configuration switches

Table 1 presents the switches available to define the model configuration.

3.1.2 Initialisation and run settings

Initial atmospheric conditions are set in the namelist with the parameters presented in Table 2. Note that default values are set for all of them, however they should be systematically redefined by the user to match the simulated atmosphere. Standard settings (timing and geography, run duration) are straightforward and are not detailed hereafter. In addition to these, surface settings are detailed in Table 3.

3.1.3 Special runs setting

When a specific run requires multiple adjustments in various parts of the code that were not already including namelist options, a single general switch might be used instead of defining several new namelist entries for each parameterisation that require special settings. An example of such global switch for special configuration is given with the `lpJoyce14bc` switch, used to activate all relevant parts of code to reproduce the base case of Joyce et al. (2014) study (particle distribution and composition, gas and particle emission scenario, special formulation of accommodation coefficient for N_2O_5 , and of gas dry deposition, etc.). Similarly, switches `lpBuys13_0D` and `lpBuxmann15alph` are used to reproduce all relevant settings of the studies of Buys et al. (2013, 0D case) and Buxmann et al. (2015, alpha case), respectively.

Table 1. General configuration switches in MISTRA-v9.0

Switch name	Description
rst	defines if the model is restarted (true) or not (false, default setting).
mic	this switch is used to turn on (true, default setting) or off (false) the 2D microphysical distribution
chem	this switch is used to turn on (true, default setting) or off (false) the whole chemistry module. If turned off, only the physics and microphysics is activated.
halo	activate (default setting, true) or unactivate (false) the chemical reactions involving halogen species (Cl, Br, and I)
iod	activate (default setting, true) or unactivate (false) the chemical reactions involving iodine species
nuc	activate (true) or unactivate (false, default setting) the nucleation module.
Napari	activate (true, default setting) or unactivate (false) the ternary $\text{H}_2\text{SO}_4\text{-H}_2\text{O-NH}_3$ nucleation
Lovejoy	activate (true, default setting) or unactivate (false) the OIO homogeneous nucleation
ifeed	nucleation feedback over background particles (0=no feedback, default setting; 1=with feedback, 2=partial feedback for microphysics only, see Chapter 4 of the manual for a complete description of the nucleation module).
box	use the box version (0D: true) or the whole 1D version (false, default setting) of the chemistry module.
BL_box	define whether the box represents a single layer extracted from the 1D model ($\text{BL_box} = \text{false}$, default setting) or an average of the whole boundary layer ($\text{BL_box} = \text{true}$).
nlevbox	index of the designated layer if $\text{BL_box} = \text{false}$
z_box	height of the boundary layer represented by the box if $\text{BL_box} = \text{true}$
chamber	use the chamber version (true) or the whole 1D version (false, default setting) of the chemistry module.
binout	request binary output files (true) or not (false, default setting).
netcdf	request netCDF output files (true, default setting) or not (false).

3.2 How to run MISTRA

3.2.1 Get the code

- 310 The model is provided on GitHub on the following repository: <https://github.com/Mistra-UEA/Mistra>. It is released under the European Union Public Licence (EUPL) v1.1, which permits free commercial and private use and unrestricted distribution, but requires that future developments of MISTRA are shared under the same licence. The version of KPP adapted for MISTRA is provided along with the distribution, and is released under its own licence.

3.2.2 System requirements and installation

- 315 A Fortran compiler is mandatory to compile the model code. During the recent development stages, MISTRA has been regularly compiled using either GNU Fortran (gfortran) or Intel Fortran (ifort). New users are advised to choose one of those compilers.

Table 2. Namelist settings for model initialisation of MISTRA-v9.0

Parameter name	Unit	Description
detamin	m	constant vertical grid spacing for the lowest 100 prognostic layers (default = 10 m).
etaw1	m	height of the highest prognostic layer (50 layers with exponentially increasing thickness on top of the 100 layers with constant height). Default is 2000 m.
rnw0	μm	minimum dry particle radius in the 2D particle spectrum.
rnw1	μm	maximum dry particle radius in the 2D particle spectrum.
rw0	μm	minimum total particle radius in the 2D particle spectrum.
rw1	μm	maximum total particle radius in the 2D particle spectrum.
iaertyp	–	aerosol distribution: 1 for urban aerosol, 2 for rural aerosol, 3 for marine aerosol (default setting).
rp0	Pa	pressure at ground/sea level.
zinv	m	inversion height. It must be lower than the highest prognostic layer.
dtinv	K	temperature jump at inversion level.
ug	m s^{-1}	geostrophic wind speed in x direction.
vg	m s^{-1}	geostrophic wind speed in y direction.
nuvProfOpt	–	option for vertical profile of geostrophic wind speed components. By default, the same values are applied to the whole atmospheric column, apart from the 4 lowest layers where wind components are reduced to 75 %, 50 %, 25 %, and 0 % at ground/sea level. Alternatively, using <code>nuvProfOpt</code> , other specific profiles can be defined. Currently, only one alternative profile for geostrophic wind components is proposed: if <code>nuvProfOpt=3</code> is selected, the geostrophic wind is constant above the inversion level, and linearly decreases in the whole MBL to reach zero at ground/sea level.
wmin	m s^{-1}	minimum subsidence speed (default is 0 m s^{-1}).
wmax	m s^{-1}	maximum (in negative values) subsidence speed.
nwProfOpt	–	profile option for subsidence. See appendix 1 for a description.
xm1w	kg kg^{-1}	moisture content in the MBL
xm1i	kg kg^{-1}	moisture content in the FT (i.e. above inversion level).
rhMaxBL	1	maximum relative humidity (default=1) in the MBL (additional constrain to <code>xm1w</code> parameter).
rhMaxFT	1	maximum relative humidity in the FT (additional constrain to <code>xm1i</code> parameter).
cGasListFile		names of user gas files for non radical species.
cRadListFile		names of user gas files for radical species.
scaleO3_m	D.U.	ozone column, to scale the photolysis rates computed. It has no effect on the radiation calculation.

The implementation of KPP output files into MISTRA is done with bash and csh scripts, thus any change in the chemical mechanism will require these shells.

Plotting scripts provided as example are written for ferret and NCL (NCL), but neither are necessary to run the model.

320 Only KPP needs to be installed on the user system and the instructions to do so are in the readme file of the KPP distribution

Table 3. Namelist settings for surface initialisation and parameterisation in MISTRA-v9.0

Parameter name	Unit	Description
<code>isurf</code>		sets the type of surface, 0 for ocean or snow (default setting), 1 for layered soil.
<code>tw</code>	K	initial surface temperature.
<code>ltwcst</code>		constant (true, default setting) or time-varying (false) surface temperature.
<code>ntwopt</code>		scenario number for time varying surface temperature (if <code>ltwcst</code> = true).
<code>jpAlbedoOpt</code>		surface albedo option ^a : 0 for ocean surface (default setting: albedo = 0.05), 1 for snow surface (albedo = 0.8).
<code>z0</code>	m	roughness length at the surface.
<code>lpmona</code>		aerosol source after Monahan et al. 1986 (small to moderate wind speed)
<code>lpsmith</code>		aerosol source after Smith et al. (1993b) (high wind speed)

^a Currently, constant albedo is used over the 6 solar wavelength bands. Alternative choice with varying albedo could be implemented with this namelist option.

package. Preprocessed files using the current chemical mechanism are provided in the distribution, so the installation of KPP can be skipped until the user needs to modify the chemical mechanism.

3.2.3 Prepare the chemical mechanism files

This section can be skipped if no change is applied to the current chemistry mechanism. All files related to the chemical mechanism are contained in the subdirectory `./src/mech`. The chemical mechanism, written with the formalism of KPP, is contained in two main files: `master_gas.eqn` for gas phase reactions, and `master_aqueous.eqn` for the liquid phase mechanism. For convenience, all necessary steps to prepare the equation files for KPP, run KPP, and adapt the resulting output from KPP for MISTRA have been set up in a Makefile, so that the user simply has to run `make` in the `./src/mech` directory to proceed. The resulting files are copied to the main source directory.

3.2.4 Compile the model

In `./src`, after ensuring that the Makefile refers to the correct Fortran compiler, and links to the appropriate netCDF libraries, compile the model running `make`. The resulting executable file is `mistra`.

3.2.5 Set a namelist and initial chemical species concentration

As presented in details in Sect. 3.1, the namelist file allows the user to configure the model, by setting the main options and initialisation values. Several namelists are provided in the distribution and can be used as starting points to define new ones corresponding to the user requirements. The set of initial concentration, and emission of gas phase species can be set in a tab-

separated table, whose name has to be specified in the namelist. If no file is specified, the `./src/mech/gas_species.csv` file is used by default.

3.2.6 Set a param file and run

340 The param file allows the user to specify the namelist to use for the run, and to define the paths to the input, output and mechanism directories. For most cases, these directories will be the default ones (`./input`, `./output`, and `./src/mech`), and only the namelist name should be specified. Several param files are provided as example. This script is in charge of creating the subdirectory for output (which will be named the same as the param file name), and launch the model.

4 Consistency with previous versions

345 In this section, we present a series of example runs that have been performed to evaluate the model. All the examples provided here reproduce the settings of previous studies carried out with previous versions of MISTRA. For that purpose, several namelists have been introduced to hold all relevant parameters in order to reproduce the same simulation scenarios as in the original publications. These namelists, as well as the scripts used to produce the plots presented here, are available in the MISTRA repository.

350 4.1 Meteorology and microphysics

4.1.1 Comparison with 1996 version: LWC, TKE and 2D spectrum

The first example focuses on the physical and microphysical aspects of the model. For this purpose, the chemistry is switched off. The initialisation settings are identical to those of the original paper from Bott et al. (1996), and are provided in the namelist BTZ96. Some model changes have been maintained for this comparison, even if this leads to differences to the original version.

355 For instance, the number of bins in the 2D particle spectrum is set to 70×70 in MISTRA-v9.0 while it was of 40×50 in the version of Bott et al. (1996). However, we adjusted the minimum and maximum particle radius values so that the resolution is nearly identical in both versions.

This simulation reproduces conditions over the North Sea, for 3 simulated days (2 are shown, the first one is used as model spin up) centered on the 22 July. The radiative code used by Bott et al. (1996) has been updated from PIFM1 to PIFM2 by
 360 Loughlin et al. (1997), and the simulation settings were the same in both papers. For this reason, we compare figures from the study of Loughlin et al. (1997) with the current output of MISTRA.

Both Fig. 3 and Fig. 4 show very similar model output between the 1996 version of MISTRA and the current version. The runs are similar, qualitatively and quantitatively (the maximum LWC is 6 % higher, the maximum TKE is 2.5 % higher in MISTRA-v9.0 than in the 1996 version), without changing the findings and conclusions of the original study.

365 Bott et al. (1996) also shown the distribution of particles in the 2D grid, and we used the same graph format in Fig. 5. Qualitatively, the two simulations are similar. MISTRA-v9.0 exhibits more particle growth for the smallest dry radius bins;

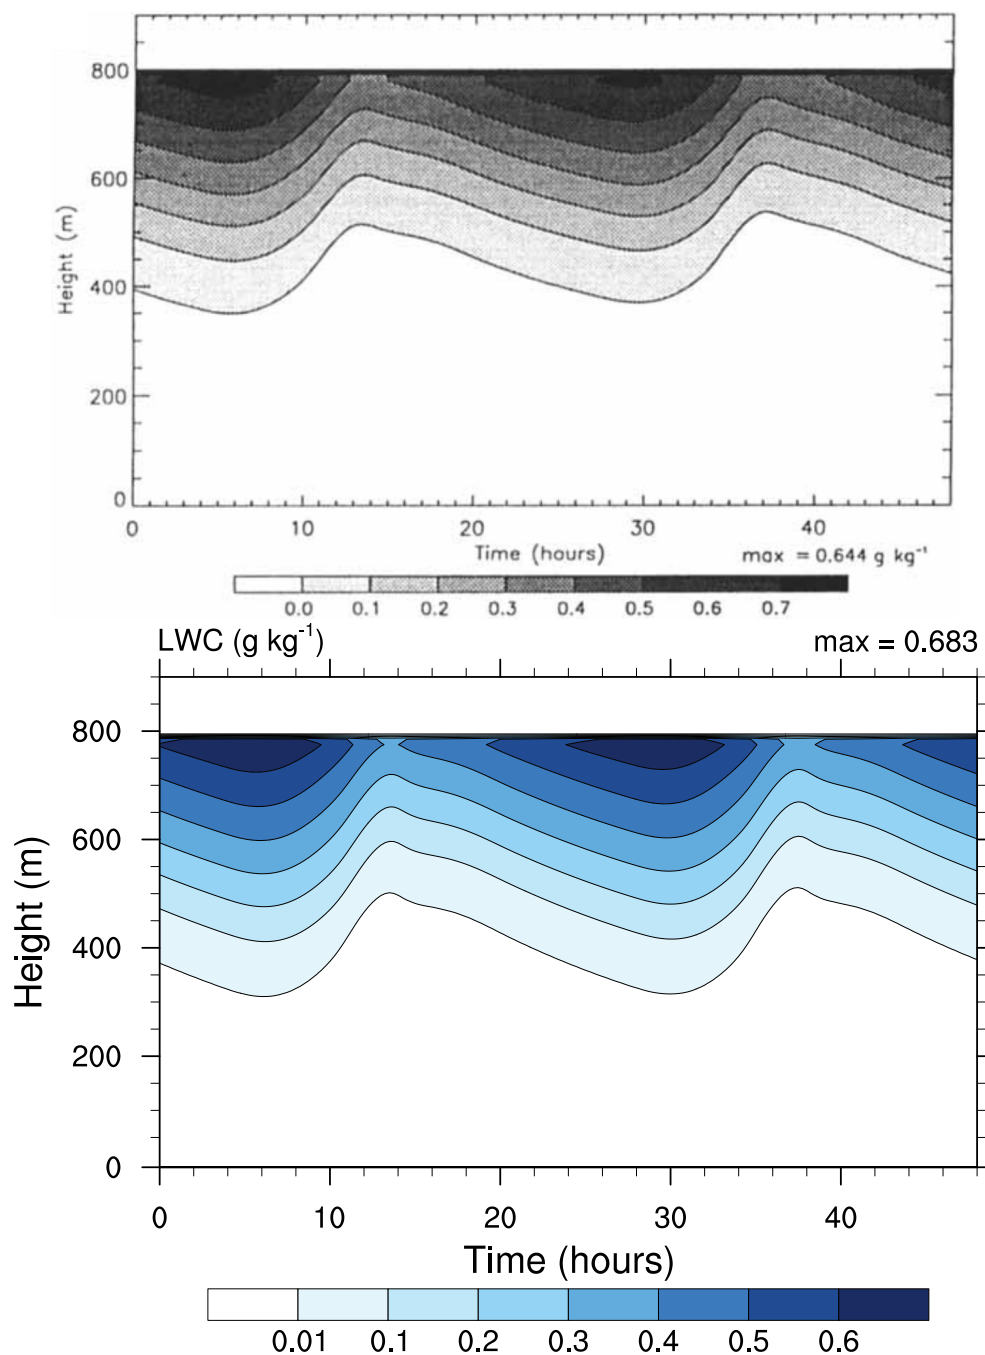

Figure 3. Contour plot of cloud water content (in g kg^{-1}) as a function of height and simulation time. Top: study from Loughlin et al. (1997, Fig. 1a). Bottom: MISTRA-v9.0. For both, the simulation settings are identical to those in Bott et al. (1996). Top panel reproduced with permission from Loughlin et al. (1997, Fig. 1a). Copyright (1997) by John Wiley and Sons.

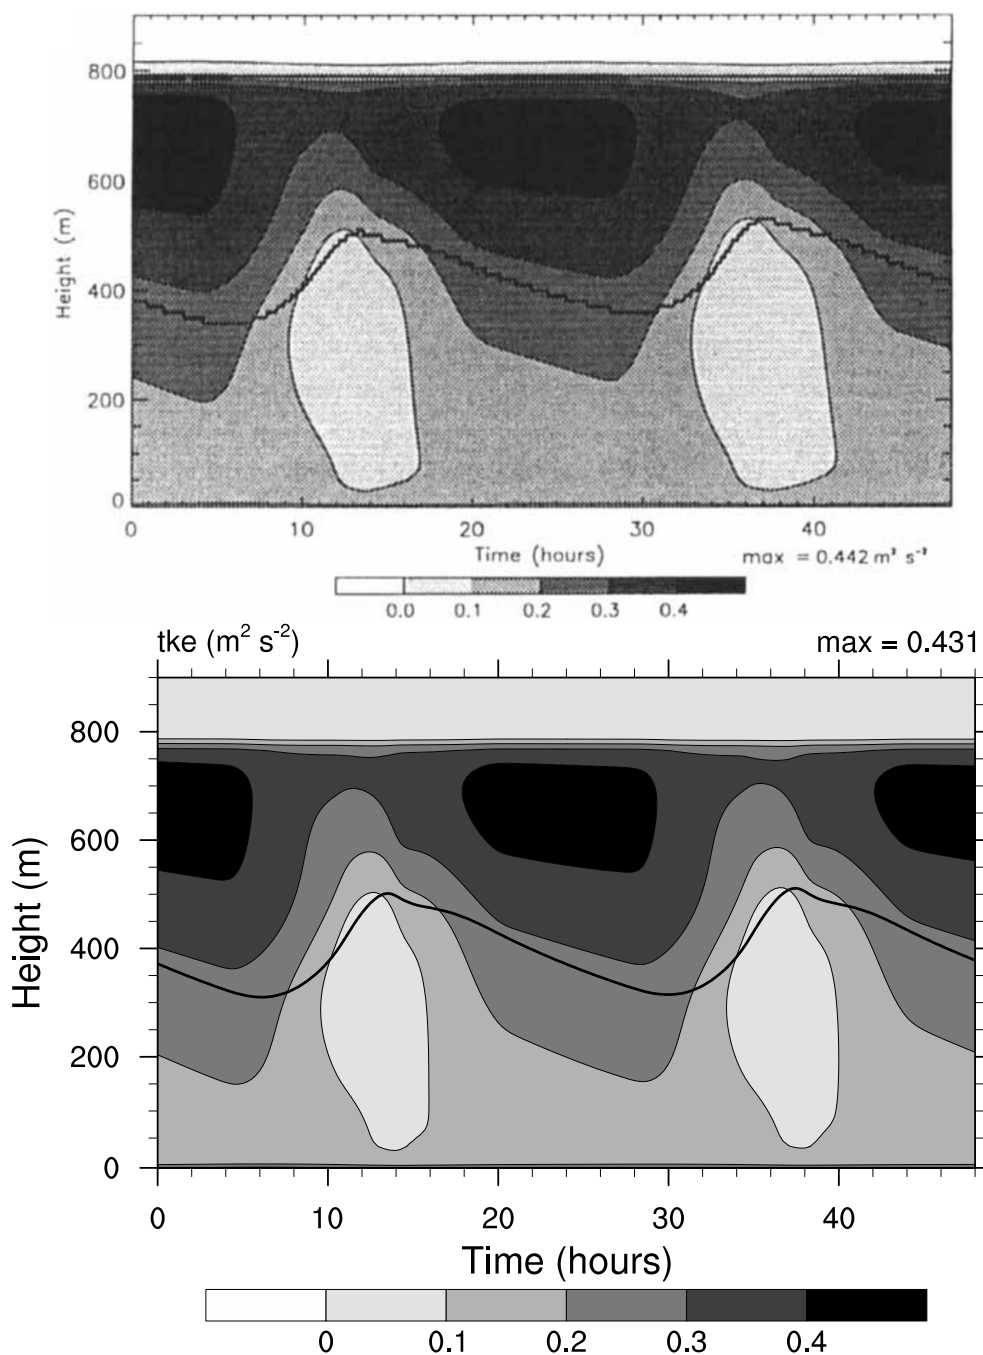

Figure 4. Contour plot of turbulent kinetic energy (in $\text{m}^2 \text{s}^{-2}$ as a function of height and simulation time. The thick line shows the bottom of cloud, defined as LWC dropping below 0.01 g kg^{-1} . Top: study from Loughlin et al. (1997, Fig. 4a). Bottom: MISTRA-v9.0. For both, the simulation settings are identical to those in Bott et al. (1996). Top panel reproduced with permission from Loughlin et al. (1997, Fig. 4a). Copyright (1997) by John Wiley and Sons.

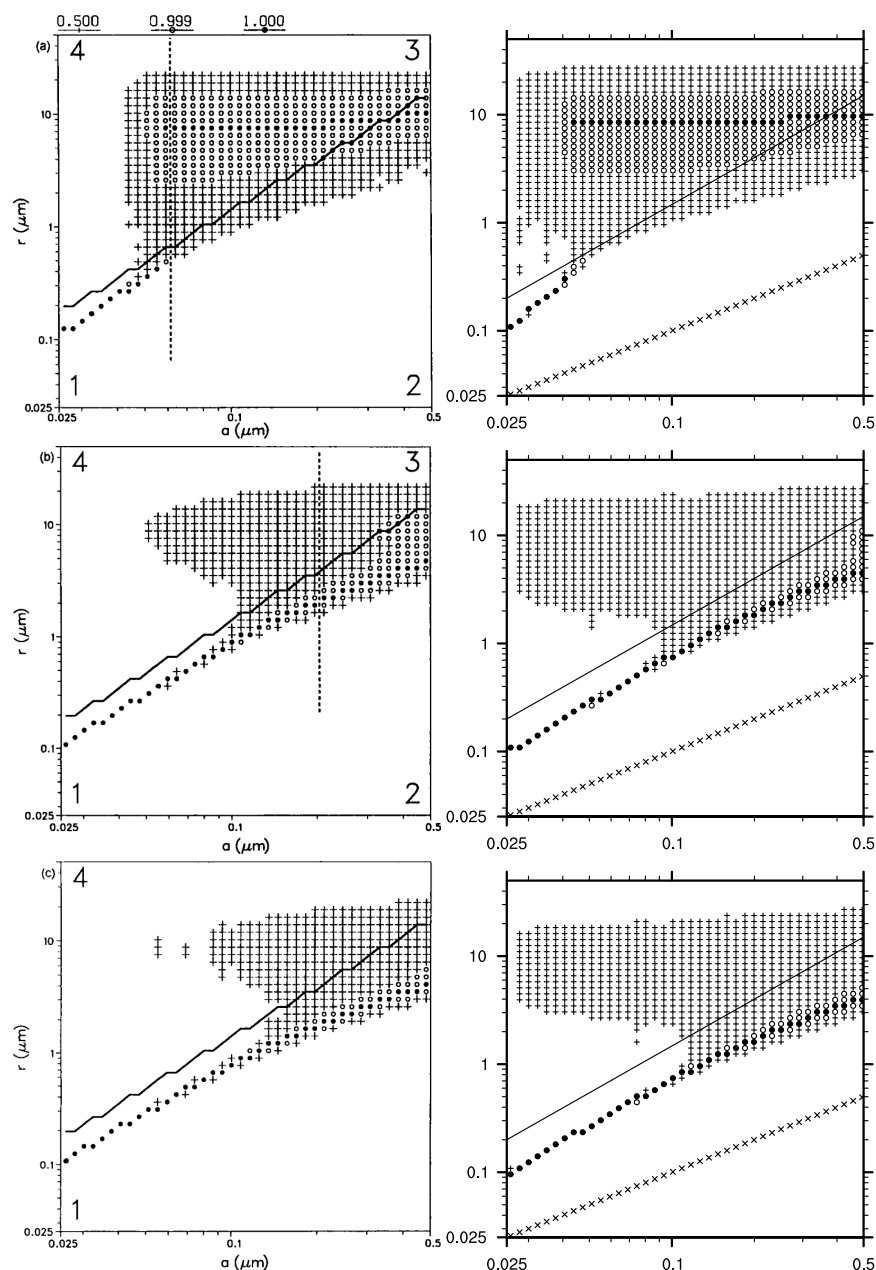

Figure 5. Distribution of particles in the 2D particle grid and at different heights in the cloud. This graph is built identical to Bott et al. (1996, Fig. 12): for each dry radius class (on x-axis), the total radius containing the maximum number of particles is marked with a filled circle; total radii containing 50 % to 99 % of the maximum are marked with open circles, and total radii containing 1 % to 50 % of the maximum are marked with plus signs. The 1:1 values (i.e. where total radius equal to dry radius) are represented with cross signs. The full line shows the activation radius as accounted for in MISTRA. From top to bottom row is top (785 m), middle (605 m), and bottom (555 m) of the cloud. Left column: version of 1996, panels are from Bott et al. (1996, Fig. 12). Right column: MISTRA-v9.0 Left column reproduced with permission from Bott et al. (1996, Fig. 12). Copyright (1996) by John Wiley and Sons.

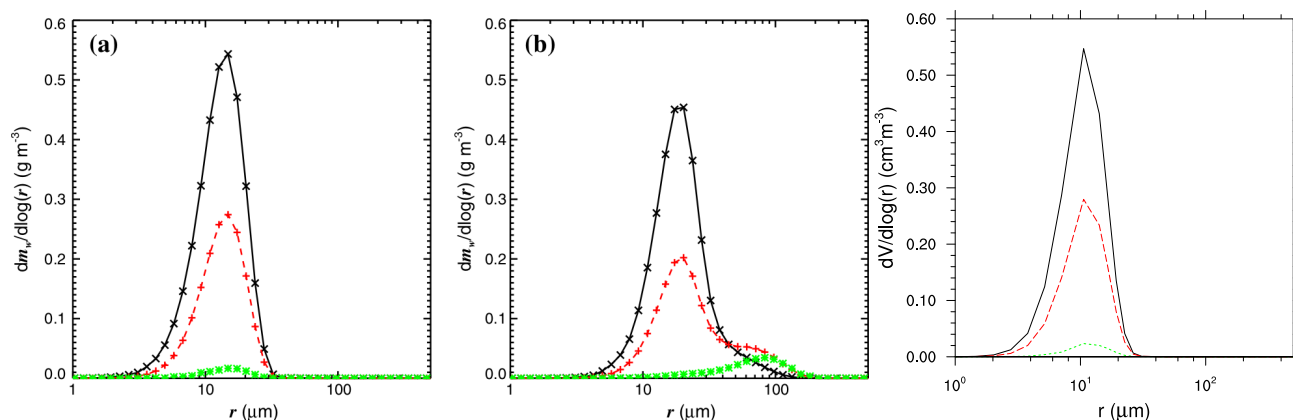

Figure 6. One dimensional distribution of particle mass as a function of radius. Left: no-chem-MISTRA without collision coalescence. Center: no-chem-MISTRA with collision-coalescence. Right: MISTRA-v9.0. Each panel shows the distribution in the top (black line), middle (red line), and bottom of cloud (green line). The left and central panels are from Bott (2020, Fig. 2, published under CC BY 4.0 licence). The simulation settings were taken from Bott (2020).

however, this happens only for a minority of the particles ('plus' signs in Fig. 5 denotes bins where particle concentration is less than half the maximum particle concentration, for each dry radius class). As stated previously, the 1996 version of MISTRA used by Bott et al. (1996) included the first version of the radiative code PIFM1, now updated to PIFM2. The differences between both radiation schemes are likely the reason for this slightly different particle distributions observed for small dry particle radius. This figure also highlights the microphysics properties and dynamics of particle within the cloud, with the activation of particles occurring when the supersaturation (not shown) is high enough, which is the case in the upper part of the cloud. Conversely, in the middle and bottom parts of the cloud most of the particles are found below the critical radius, even if some particles grow to above their respective critical radius, since the supersaturation is not high enough.

4.1.2 Impact of neglecting coalescence

As pointed out in the general presentation of the model (Sect.2.2), the collision-coalescence process is not accounted for in MISTRA-v9.0, which is a limitation of the model. The collision-coalescence process was implemented in a version of MISTRA without chemistry (Bott, 2000), hereafter referred to as MISTRA-coal-nochem for brevity. In a recent study, Bott (2020) used MISTRA-coal-nochem and compared the results with and without activating this process (Fig. 6). He showed that accounting for the collision-coalescence process leads to significant differences in the particle distribution, with a bimodal spectrum with particles larger than 40 μm when collision-coalescence is activated (Fig. 6b) Conversely, when particles grow solely by diffusional uptake of water vapour, their size distribution remain in the 2 to 30 μm range (Fig. 6b). We defined a namelist, named Bott2020, reproducing the same settings as in Bott (2020) to perform a further evaluation of MISTRA-v9.0 against MISTRA-coal-nochem. The resulting one-dimensional particle distribution is presented in Fig. 6c, and shows similar results as compared to MISTRA-coal-nochem.

Figure 7. Contour plot of humidity, potential temperature and temperature in the run based on Joyce et al. (2014). Left panel: original study (Figure published under CC BY 3.0 licence). Right panel: MISTRA-v9.0.

Despite the important differences in particle distribution when collision-coalescence process is included, this limitation in MISTRA-v9.0 is expected to have insignificant effect for simulations without clouds (non-activated particles only). Conversely, cloudy runs should be restricted to conditions where collision-coalescence is less important, i.e. cases where no or little drizzle formation would be expected. According to Duynkerke (1998), drizzle formation starts to be important when the cloud depth is greater than 300 m. Future development plans with MISTRA-v9.0 include a re-evaluation of the feasibility of including the collision-coalescence process along with chemistry.

4.2 Chemistry in 1D simulations

A namelist reproducing the settings of the study by Joyce et al. (2014) is provided as `namelist.Joyce14bc`. In this study, MISTRA was used to simulate an urban pollution plume from Fairbanks, Alaska. The model was thus used in an alternative configuration, with surface covered by snow (with the relevant physical properties). An emission scenario of NO_x was defined, and the evolution of gas and aqueous phase species was evaluated. In such configuration, the meteorological parameters have a strong influence over the stability of the atmosphere, thus in turn over the vertical exchange of chemical species. In Fig. 7, key meteorological variables are presented for both the original study and the new runs obtained with MISTRA-v9.0. As expected, there is excellent agreement between both versions, which shows that the recent code developments did not alter the model with regards to the plotted variables.

Figures. 8 and 9 show the comparison of gas and particle phase chemical species, between the original study of Joyce et al. (2014) and MISTRA-v9.0. Again, the plotted variables agree very well between both versions, with nearly identical results. In

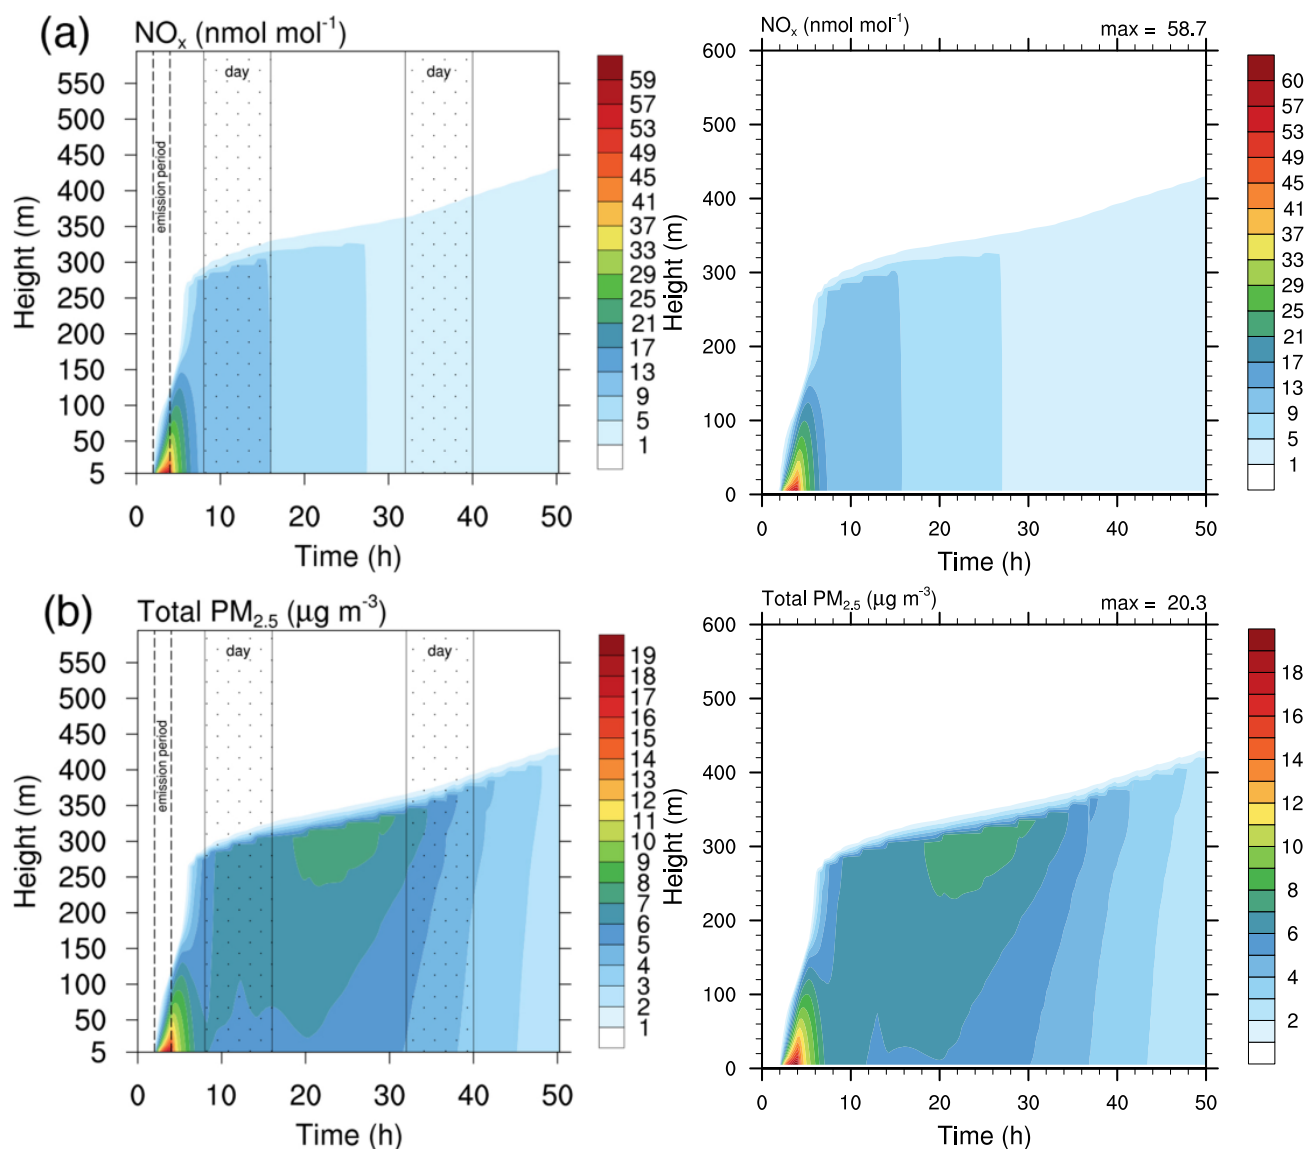

Figure 8. Contour plot of NO_x and $\text{PM}_{2.5}$ in the run based on Joyce et al. (2014) study. Left panel: original study (Figure published under CC BY 3.0 licence). Right panel: MISTRA-v9.0. Scales are identical for both.

Fig. 9, the only exception is ammonium (NH_4^+ , bottom right panel on each side) whose maximum concentration is decreased by 60 % in MISTRA-v9.0. The reason of this change was investigated, and we found that in the original run, the initialisation of a variable in the routine computing the gas-particle exchange rates was missing. This is now corrected in MISTRA-v9.0, and explains the differences for NH_4^+ .

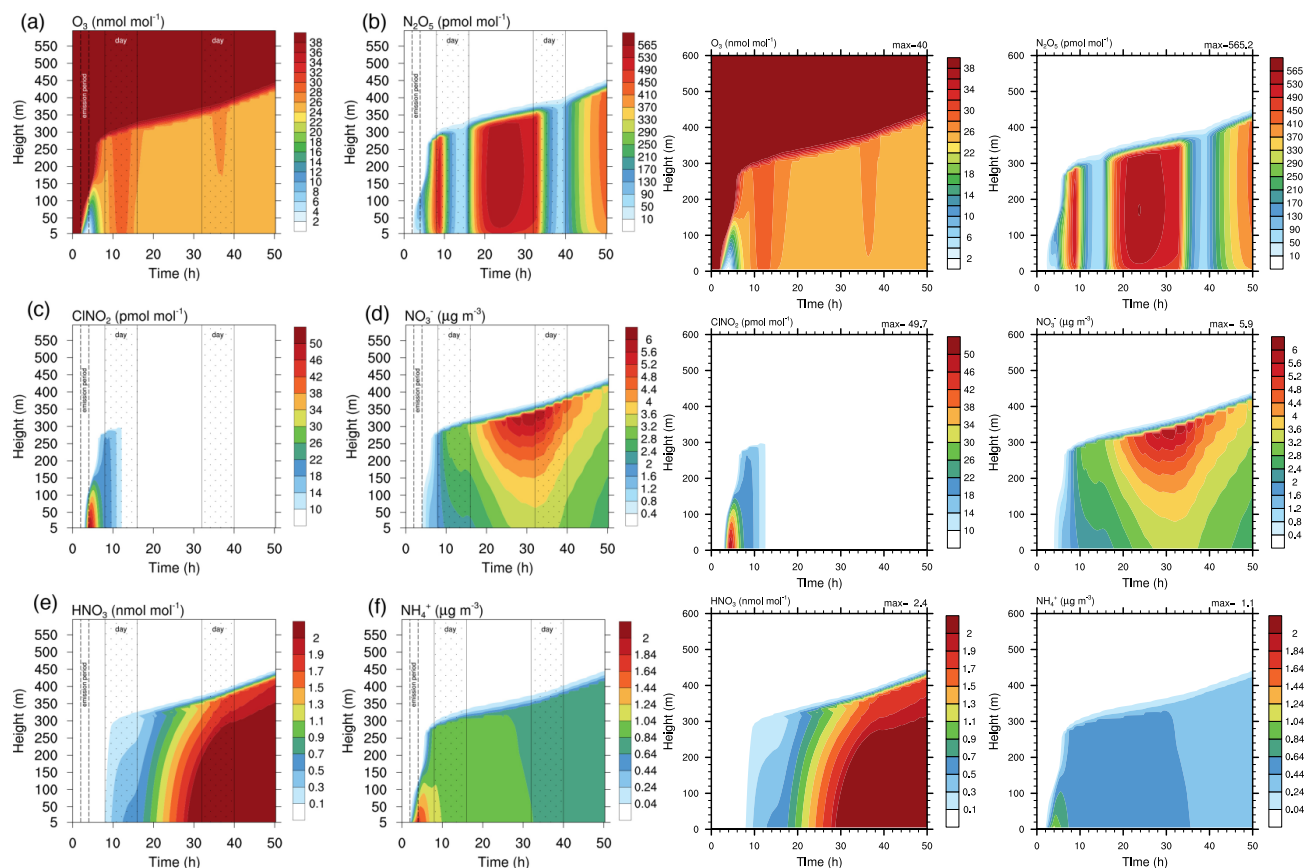

Figure 9. Contour plot of height versus time for 4 gases and 2 aqueous phase species in the run based on Joyce et al. (2014). Left side: original study (Figure published under CC BY 3.0 licence). Right side: MISTRA-v9.0. Scales are identical, except NH_4^+ where the scale for MISTRA-v9.0 is half that of the original paper.

4.3 Box and chamber model configurations

We present two additional configurations of MISTRA-v9.0, as an atmospheric box (0D) model (Buys et al., 2013), and in chamber configuration following the study of Buxmann et al. (2015). In both cases, we set namelists (namelist.Buys13_0D and namelist.Buxmann15_alpha, respectively) with the same settings as in the original publications.

Figures 10 and 11 compare model output between each model version, and show that minor differences exist but are very limited, and the results agree well qualitatively. This comes as a further demonstration of the good consistency of MISTRA-v9.0 with previous results.

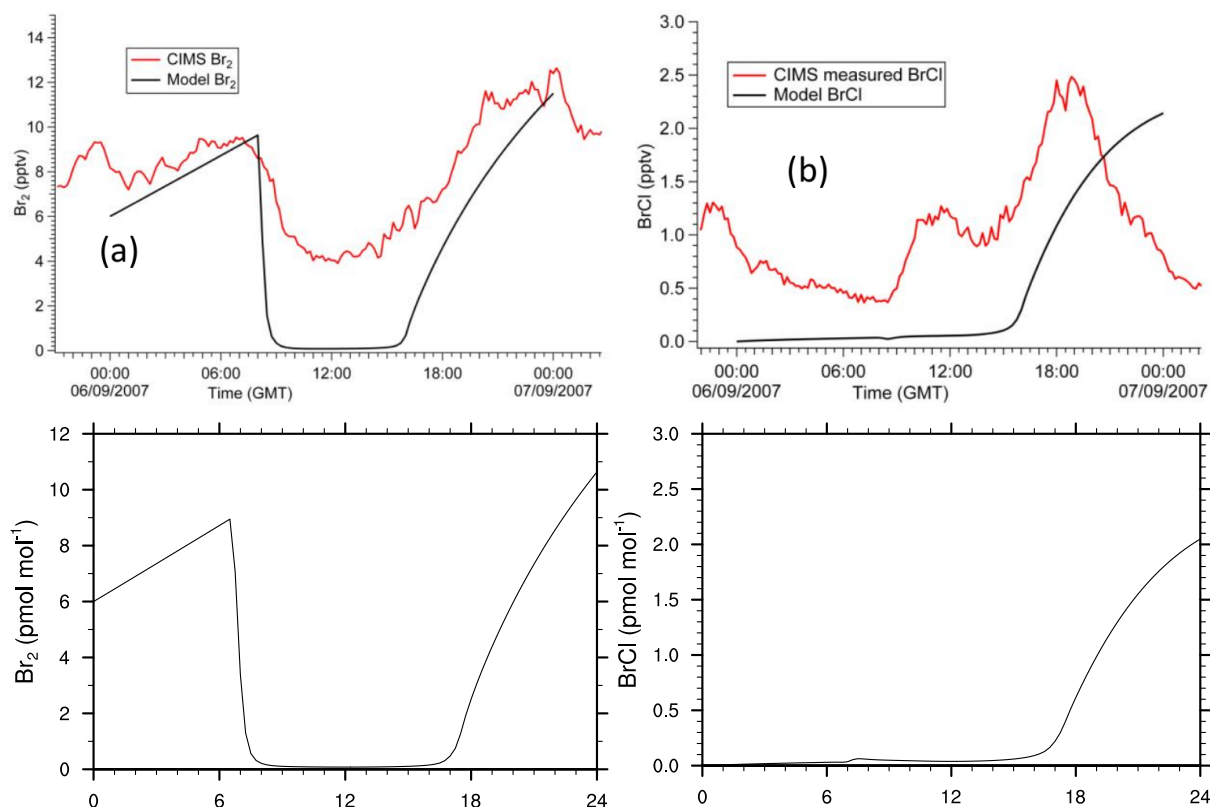

Figure 10. Gas phase concentration of Br_2 and BrCl in a box model run based on the settings of Buys et al. (2013). Top row: original study (Figure 3 published under CC BY 3.0 licence). Bottom row: MISTRA-v9.0. Scales are identical.

5 Conclusions

415 We have presented the current version of the 1D atmospheric chemistry model MISTRA-v9.0, released for the first time as an open-source, community model. We compared current output of a range of test cases against previous studies with identical settings. Results obtained with MISTRA-v9.0 are consistent with the previous results even after 20 years of development. MISTRA-v9.0 is a powerful tool for atmospheric chemistry research purposes, now easier to use, and free to use under EUPL-v1.1 licence. Community input and development is welcome for MISTRA-v9.0.

420 **Code availability.** The code of the MISTRA-v9.0 model, the code of KPP-v2.2.3 tuned for MISTRA (referred to as v2.2.4), the additional example namelists and param files, and all NCL scripts developed to produce the Figures in this article are available on <https://github.com/Mistra-UEA/Mistra>. The archives of code releases are also available on Zenodo: <https://doi.org/10.5281/zenodo.5110025> and <https://doi.org/10.5281/zenodo.5109913> for MISTRA-v9.0 and KPP-v2.2.4, respectively.

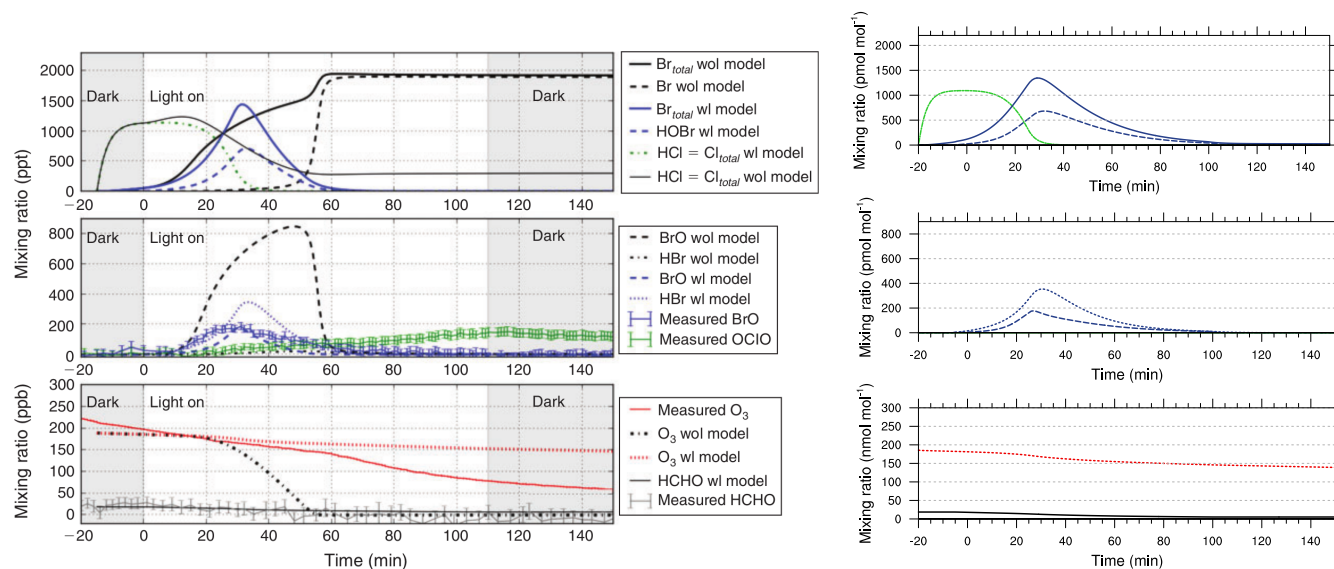

Figure 11. Gas phase concentration in a chamber model run based on the study of Buxmann et al. (2015) (alpha wl sensitivity experiment). Left side: original study. Right side: MISTRA-v9.0 with identical settings. Scales are identical. Left panel reproduced with permission from Buxmann et al. (2015, Fig. 5). Copyright (2015) by CSIRO Publishing.

Appendix A: List of symbols

a	dry particle radius
A, B	Kelvin effect, solute effect factors in the Köhler equation
$c_{a,i}$	aqueous phase concentration in bin i
c_g	gas phase concentration
c_p	specific heat of dry air at constant pressure
c_w	specific heat of water
C	condensation rate
C_1, C_2	constants of Eq. (7)
D	dry deposition term
D'_v	diffusivity of water vapour
D_g	gas phase diffusion coefficient
e	turbulence kinetic energy (TKE)
E	emission of chemical species
E_n	net radiative flux density
$f(a, r)$	aerosol or droplet particle number concentration
f_c	Coriolis parameter
$F_d(a, r)$	net radiative flux at the particle's surface
G_h, G_m	stability functions for buoyancy and shear production (see also S_h, S_m)
H_s^{cc}	dimensionless Henry constant
J_X	photolysis rate
k'	thermal conductivity of moist air
k_t	mass transfer coefficient
K_h, K_m, K_e	turbulent exchange coefficient for heat, momentum, and turbulence kinetic energy
l	mixing length
L	latent heat of condensation
L_{MO}	Monin-Obukhov length
m_w	liquid water mass of the particle
p, p_0	pressure, pressure at ground level
P	chemical production term
q	specific humidity
r	total (i.e. humidified) particle radius
\dot{r}	particle growth
r_a	aerodynamic resistance

r_b	quasi-laminar resistance
r_c	surface resistance
R	gas constant
R_a	specific gas constant for dry air
R_v	specific gas constant for water vapour
S_h, S_m	stability functions for buoyancy and shear production (see also G_h, G_m)
S	chemical loss term, or sink
Sc	Schmidt number
S_r	supersaturation at the droplet's surface
S_∞	ambient supersaturation
t	time
T	temperature
u, v	west–east and north–south horizontal wind component
u_g, v_g	west–east and north–south horizontal geostrophic wind component
u_*	friction velocity
\bar{v}	mean molecular speed
v_g^{dry}	dry deposition velocity
w	subsidence, i.e. vertical wind component
$w_{l,i}$	dimensionless liquid water content ($V_{\text{aq}}/V_{\text{air}}$) of bin i
w_t	sedimentation or terminal velocity
z	vertical coordinate, positive upwards
z_0	roughness length
α	accommodation (or condensation) coefficient
α_c	accommodation (or condensation) coefficient of water
Θ	potential temperature
κ	von Kármán constant
λ	mean free path length
ν	kinematic viscosity of air
ρ	air density
ρ_s	saturation water vapour density
ρ_w	water density
σ_X	absorption cross section of species X
ϕ_X	quantum yield of species X
Φ_s	stability function for aerodynamic resistance calculation

425

Appendix B: List of abbreviations

ESM	Earth System Model
EUPL	European Union Public Licence
FT	free troposphere
KPP	the Kinetic PreProcessor
MBL	marine boundary layer
TKE	turbulence kinetic energy

Appendix C: Subsidence profiles

Three subsidence profiles are currently implemented in MISTRA-v9.0.

- 430
- Option 1 follows the hyperbolic expression of Bott et al. (1996, Eq. (5)).
 - Option 2 linearly decreases from w_{\min} at ground level to w_{\max} at height = $etaw1$.
 - Option 3 linearly decreases from w_{\min} at ground level to w_{\max} at height = z_{inv} .

Figure C1. Vertical profiles of subsidence, computed for $w_{\min} = 0 \text{ cm s}^{-1}$, $w_{\max} = -0.5 \text{ cm s}^{-1}$, and $z_{inv} = 700 \text{ m}$.

Author contributions. JB updated the model code and performed model runs. MT performed additional model runs. JK led the project. AB provided help with the model. JB wrote the first draft of the paper. All co-authors commented and provided significant inputs to subsequent
435 revisions. The technical description of the model (Sect. 2) was mostly written by RvG and adapted for the current publication.

Competing interests. The authors declare that they have no conflict of interest.
