Abstract. Urban environments ~~increasingly move to the fore of~~ [are of increasing importance in](#) climate and air quality research due to their central role in the population's health and well-being. Tools to model the local environmental conditions, urban morphology and interaction with the atmospheric boundary layer play an important role for sustainable urban planning and policy-making. uDALES is a high-resolution, building-resolving large-eddy simulation code for urban microclimate and air quality. uDALES solves a surface energy balance for each urban facet and models ~~multi-reflection~~ [multi-reflection](#) shortwave radiation, longwave radiation, heat storage and conductance, as well as turbulent latent and sensible heat fluxes. Vegetated surfaces and their effect on outdoor temperatures and energy demand can be studied. Furthermore a scheme to simulate emissions and transport of ~~aerosols and some~~ [passive and](#) reactive gas species is present. The energy balance has been tested against ~~idealized~~ [idealised](#) cases and the ~~particle dispersion against field measurements~~ [dispersion against](#) [wind-tunnel experiments of the DAPPLE field study](#), yielding satisfying results. uDALES can be used to study the effect of ~~specific new constructions and building measures on the local micro-climate; or to gain new insight about the general new buildings and other changes to the urban landscape on the local flow and microclimate, and to gain fundamental insight into the~~ effect of urban morphology on local climate, ventilation and dispersion. uDALES is available online under GNU General Public License and remains under [active](#) maintenance and development.

15 1 Introduction

With an ever-increasing number of people living in cities (UNFPA, 2012), understanding how the urban morphology influences the transport of momentum, heat, moisture and pollutants is central to designing healthy, sustainable and safe urban environments. Indeed, the large number of tall towers being erected in large cities around the world necessitate elaborate studies on how these affect the safety of pedestrians, since these structures [can](#) channel high-momentum air down to ground level
20 ~~(Bloeken et al., 2016)~~[\(Lawson and Penwarden, 1975; Lawson and Penwarden, 1975; Lawson and Penwarden, 2004; Lawson and Penwarden, 2016\)](#)
Densely populated areas are prone to develop an urban heat island (UHI) effect (increased temperatures relative to the surrounding rural areas partially due to the limited vegetation and water surfaces; Oke, 1982; Rosenzweig et al., 2015). The UHI increases the intensity of heat waves, with a measurable increase in mortality rates (Pyrgou and Santamouris, 2018). Furthermore, the large concentrations of people in urban areas create problems with urban air quality; it is a sobering fact that
25 health quality standards are exceeded in most of the world's largest cities, despite the known adverse effects on human health
~~(World Health Organization, 2016)~~[\(World Health Organization, 2021\)](#).

The increased likelihood of extreme weather events due to climate change ~~(IPCC, 2014)~~[\(Seneviratne et al., 2021\)](#) and the need to transition to a less carbon-hungry society makes our ability to predict the urban climate even more important. Design decisions that are taken now will strongly influence whether we will be able to meet the intentions outlined in the ~~Paris~~
30 ~~agreement (UNFCCC, 2016)~~[COP agreements \(UNFCCC, 2020\)](#). The choice of building materials and city layout has to be reconsidered together with intelligent management of water systems and green spaces. Greening of façades and roofs can mitigate the effects of the UHI ~~effect~~[\(Santamouris, 2014\)](#), specifically, ~~it~~[greening](#) improves thermal comfort and lowers heat stress due to enhanced evapotranspiration from vegetation. Green roofs or walls also lead to lower indoor temperatures and reduce the energy demand for air conditioning (Castleton et al., 2010). Consequently, the augmented installation of green
35 infrastructure is a possible remedy for exceedingly hot cities and the subsequent health problems [\(Bozovic et al., 2017\)](#).

With business-as-usual emission regulation policies, mortalities due to outdoor air quality will continue to rise in the period up to 2050 (Lelieveld et al., 2015). The 'metabolic' consumption of energy and materials within cities results in the presence of a wide range of harmful pollutants in the urban atmosphere (Oke et al., 2017). Long-term improvements in air quality must be driven through reduced emissions, however 1) this process requires large-scale, long-term infrastructural and behavioural
40 change and 2) recent studies indicate the complexity and global variability of source contributions (e.g. the importance of non-combustible emission sources; Lelieveld et al., 2015; Grylls, 2020). Short-term and more flexible solutions are therefore also needed; e.g. temporary limitations on transport (Borge et al., 2018), optimised urban design (Llaguno-Munitxa and Bou-Zeid, 2018) and technical innovations for active removal (Sikkema et al., 2015). Accurate predictions of the emission, dispersion, chemical reaction and removal of pollutant species in the urban atmosphere is integral ~~towards~~[to](#) developing our understanding
45 of and therefore solutions to the global challenge of urban air quality.

Reliable methods to model the interaction between the atmospheric boundary layer and the urban morphology are key to predictions of pedestrian safety, urban microclimate and urban air quality. The urban structure is inherently heterogeneous: roads, residential, commercial and industrial zones segment cities and are interspersed with vegetation and open water. More-

over, the urban fabric, i.e. the material composition and texture of the urban surface, is also subject to great variability. This represents a major challenge to the modelling of urban processes due to their large range of associated spatial and temporal scales.

The complexity of the urban structure and fabric makes computational fluid dynamics (CFD) models a popular modelling choice. Wind engineering models are predominantly based on the Reynolds-averaged Navier-Stokes (RANS) equations, which require turbulence parameterisations for the full range of active scales in the flow field [Bloeken \(2015\)](#) ([Blocken, 2015](#)). This allows for the use of relatively large time-steps, or even steady-state simulations that predict the flow field reasonably well. However, the reliance on turbulence parameterisations requires careful validation and sensitivity analyses [Bloeken \(2015\)](#); ([Blocken, 2015](#)). [Many RANS codes, including commercial CFD packages \(Fluent, ANSYS CFX, COMSOL etc\) and open source alternatives](#). In non-neutral situations, which is the predominant atmospheric state over cities (Barlow, 2014; Kotthaus and Grimmond, 2018), the use of RANS is more problematic due to the influence of buoyancy on the velocity field (Hanjalić and Kenjereš, 2008). ~~Popular codes for RANS are any of the commercial CFD packages (Fluent, ANSYS CFX, COMSOL etc), although there are also open source alternatives (e.g. OpenFoam).~~

However, most CFD models neither contain a representation of energy exchanges at the urban surface nor explicitly treat radiative fluxes. Coupling of stand-alone energy balance models is a possibility (Musy et al., 2015), yet technical difficulties persist and different approaches in model design exist across numerous research groups. The exceptions are urban climatology models based on the Reynolds-averaged Navier-Stokes (RANS) equation that are able to take into account the thermal exchanges in the urban area, e.g. MIMO (Ehrhard et al., 2000), MITRAS ([Schlüenzen et al., 2003](#)) ([Schlüenzen et al., 2003](#); [Salim et al., 2018](#)), ENVI-met (Huttner, 2012) and MUKLIMO3 (Sievers, 2016).

Large-Eddy simulation (LES) tools explicitly resolve the ~~bulk of the turbulent scales in the flow,~~ [large turbulent scales of the flow that control the energy budget](#) and are therefore less reliant on turbulence models than RANS models. ~~As they resolve the bulk of the energy-containing scales in the turbulence, they are.~~ [LES is](#) more computationally demanding than RANS models. However, the continuous increase in computational resources makes LES models the most promising method to provide sufficiently detailed and accurate information on how the interaction of heat, moisture and momentum exchanges ~~affected~~ [affects](#) the local urban microclimate. Examples of LES models capable of dealing with the urban terrain are [PALM-USM \(Maronga et al., 2015; Resler et al., 2017\)](#) and ~~OpenFoam2.~~ [PALM-4U \(Maronga et al., 2020; Maronga et al., 2021\) and OpenFoam2. Indeed PALM-4U has similar goals and many similarities](#)

The aim of this paper is to present a new [open-source](#) large-eddy simulation model for the urban environment, uDALES ([Grylls et al., 2021](#)). This model is an extension of the atmospheric LES model DALES (Heus et al., 2010; Tomas et al., 2015). [uDALES explicitly solves the flow around buildings, includes wet thermodynamics, and solves a full surface energy balance including vegetation](#). It can be used to model both the standard idealised flow cases that are pursued in air quality studies (Caton et al., 2003) and realistic case studies (Grylls et al., 2019). uDALES is capable of solving a surface energy balance in a two-way coupled manner with the ~~LES solver~~ [flow](#) and models the dominant processes that ~~shape~~ [characterise](#) the urban environment, such as radiation, effect of vegetation, energy and momentum fluxes from urban surfaces. [uDALES is set up in a modular fashion that makes it relatively straightforward to add additional modules.](#)

The paper is structured as follows. In section 2 the fundamentals of the model are outlined and the treatment of boundary conditions is detailed with a description of the treatment of the wall-fluid interaction. Furthermore the scheme to simulate emissions, transport and reactions of ~~aerosols~~-passive and reactive gas species is introduced. A new method for simulating the surface energy balances is introduced in section 3 together with the procedures for long- and shortwave radiation. Section 4 is used to validate the new model against an urban measurement campaign for the dispersion of air pollution (DAPPLE), and an urban energy balance model. Furthermore the simulation of vegetated surfaces is showcased. Finally in section 5 the future applications and development of uDALES are ~~summarized~~summarised.

2 Model description

The computational core of uDALES is based on DALES (Heus et al., 2010). A number of features have been added to the original code to

2.1 Governing equations

The governing equations solved in uDALES (~~Heus et al., 2010~~) are within the Boussinesq approximation:

$$\frac{\partial \tilde{u}_i}{\partial x_i} = 0, \quad (1)$$

$$\frac{\partial \tilde{u}_i}{\partial t} = -\frac{\partial \tilde{u}_i \tilde{u}_j}{\partial x_j} - \frac{\partial \pi}{\partial x_i} + \frac{g}{\theta_0} \tilde{\theta}_v \delta_{i3} + F_i - \frac{\partial \tau_{ij}}{\partial x_j}, \quad (2)$$

$$\frac{\partial \tilde{\varphi}}{\partial t} = -\frac{\partial \tilde{u}_j \tilde{\varphi}}{\partial x_j} - \frac{\partial R_{\varphi,j}}{\partial x_j} + S_{\varphi}. \quad (3)$$

Here u_i is the component of the velocity vector along the base vector x_i . ~~Time and time~~ is denoted as t . The modified pressure is $\pi = \frac{\tilde{p}}{\rho_0} + \frac{2}{3}e$, where p is the deviatoric pressure, ρ is the density of air and e is the subfilter-scale turbulence kinetic energy. ~~Denoted by θ_v~~ , θ_v is the liquid water virtual potential temperature, δ_{ij} is the Kronecker delta, F_i represents other forcings and τ is the deviatoric part of the subfilter momentum flux. ~~The variable tensor. The generic scalar~~ φ can represent humidity, temperature, particulates or chemical species. The subfilter-scale scalar fluxes are denoted by R_{φ} and the scalar sources or sinks by S_{φ} . Where ~~multiple indices (i, j)~~ repeated indices appear, summation following ~~Einstein notation~~ the Einstein convention is implied. The tildes denote spatially filtered mean variables. Filtering in uDALES is implicit: the grid itself acts as the low-pass filter.

The buoyancy, which exerts a force in the vertical direction, is given by the liquid water virtual potential temperature approximated following Emanuel (1994):

$$\theta_v = \theta \left(1 - \left(1 - \frac{R_v}{R_d} \right) q_t - \frac{R_v}{R_d} q_l \right), \quad (4)$$

with

$$\underline{\theta} = T\Pi^{-1}, \text{ and } \Pi = \left(\frac{p}{p_0} \right)^{\frac{R_d}{c_d}},$$

where where

$$\theta = T\Pi^{-1}, \text{ and } \Pi = \left(\frac{p}{p_0} \right)^{\frac{R_d}{c_d}}. \quad (5)$$

115 Here, θ is the potential temperature, Π is the Exner function, c_d is the heat capacity of dry air, R_d is the gas constant for dry air and R_v is the gas constant for water vapour. This representation explicitly includes the effect of temperature, water vapour content and water droplets.

The subfilter stresses are modelled as

$$\tau_{ij} = -K_m \left(\frac{\partial \tilde{u}_i}{\partial x_j} + \frac{\partial \tilde{u}_j}{\partial x_i} \right), \quad R_{\varphi,j} = -K_h \frac{\partial \tilde{\varphi}}{\partial x_j}, \quad (6)$$

where K_m represents the eddy viscosity and K_h the eddy diffusivity. The Vreman subgrid-scale model (Vreman, 2004) is used to obtain the eddy viscosity. This model is of similar complexity as the commonly used Smagorinsky model (Smagorinsky, 1963), but it behaves better in near-wall regions. The eddy diffusivity is related to the eddy viscosity via a constant turbulent Prandtl number. **2.2 Method of Solution**

uDALES is based on an a Cartesian Arakawa C-grid (Arakawa and Lamb, 1977). Pressure and scalar variables (φ) are defined at cell centres and the three velocity components (u, v, w) are defined at the west, south and bottom sides of the grid cells respectively. Numerical advection is calculated via Advective fluxes are approximated by a second-order central difference scheme for all prognostic fields except for the pollutant concentrations where a κ -advection scheme (Hundsdoerfer et al., 1995) is used to ensure monotonicity. Time integration is done by a third-order Runge-Kutta scheme, following Wicker and Skamarock (2002). uDALES is written in Fortran and the code is parallelised using MPI. For the parallelisation, the domain is sliced along the y -direction.

Incompressibility is enforced by solving a Poisson equation for pressure (Heus et al., 2010). When using periodic lateral boundary conditions, the Poisson equation can be solved directly via a fast Fourier-based transform (FFT) method in x and y and a tridiagonal matrix inversion per wave mode in the z direction. For these boundary conditions, the grid spacing in x and y is constant, but the grid increments can be non-constant in z . When using inflow-outflow boundary conditions, the y direction remains periodic so can still be solved using FFT, and the $x-z$ planes are solved using cyclic reduction, with a Neumann condition for pressure on the inlet, top, and bottom, and a Dirichlet condition on the outlet (Tomas et al., 2015). In this setting, both x and z directions can be non-uniform.

uDALES is written in Fortran and the code is parallelised using the Message Passing Interface (MPI). uDALES 1.0 employs a one-dimensional parallelisation along the y -direction (Heus et al., 2010). The parallelisation will be upgraded to two dimensions in the next version to further improve scalability.

2.3 Immersed boundary method

The solid-fluid boundary between the air and the urban form is defined through the immersed boundary method (IBM) and wall functions. The IBM allows for obstacles to be placed inside the fluid domain. It works on the principle that solid boundaries can

be modelled by adapting the body force terms in equations (2) and (3) in the cells that are adjacent to the defined boundaries
145 (Mittal and Iaccarino, 2005). This technique is in contrast to other methods where the computational grid is defined such that
it conforms to the solid-fluid boundary. The advantages of using the IBM are that the grid is relatively simple to generate and
that the **pressure field can be solved directly via a fast Fourier-based transform method** **pressure can still be solved using an**
FFT-based solver which is extremely computationally efficient . The IBM introduced into uDALES by Tomas et al. (2015) is
defined such that the obstacles must conform to the defined Cartesian grid (Pourquie et al., 2009). Boundaries are defined at the
150 cell faces such that the normal component of the velocity can be set to zero (and therefore to ensure that there is no advective
flux through the wall by construction). The subgrid-scale flux terms acting across this plane are also nullified. **This version of**
the IBM is second-order accurate but limits the obstacles modelled in the domain to be rectangular and grid-conforming. **This**
version of the IBM is formally second-order accurate but limits the obstacles modelled in the domain to be cubical. However,
the computational grid can be stretched vertically above the IBM obstacles.

155 2.4 Boundary conditions

2.4.1 Top, bottom and immersed boundaries

Various boundary conditions (BCs) can be selected for top, bottom, lateral and immersed boundaries. The BC for momentum
at the top can be given either as a fixed flux (Neumann type) or fixed value (Dirichlet type), where zero-flux (free slip) is the
most common setting. On the bottom and on the immersed boundaries, a no-slip condition for momentum is imposed via the
160 wall function discussed in section 2.3. **Both** Neumann and Dirichlet boundaries can also be applied for scalar quantities at
the top of the domain. For moisture and temperature, the immersed and bottom boundaries can either be prescribed as a flux
or a boundary value. In the case that **the a** Dirichlet condition is chosen, the **resulting** temperature and moisture fluxes
are obtained from the wall function and optionally a surface energy balance can be solved to update the boundary values
dynamically, as discussed in detail in section 3. For other scalar quantities such as tracers and chemical species, the surface
165 fluxes are prescribed.

2.4.2 Lateral boundaries

The lateral boundary conditions are important in determining the planetary boundary layer flow. The three main set-ups are
shown diagrammatically in Fig. 1. The lateral boundary conditions in the x -direction can be set as periodic or ‘inflow-outflow’
(using either Neumann and Dirichlet conditions). In either case the y -direction remains periodic. The inflow condition can be
170 defined by either

- running a precursor simulation from which outlet planes are used to ‘drive’ a later simulation (see **figure Fig. 1b**); **In**
this case the inlet boundary condition is given by a chosen plane in the precursor simulation. At the outlet, the variables
are updated using a convective boundary condition, i.e. through an advection equation with a constant outflow velocity
given by the vertically-averaged velocity profile.

Figure 1. Diagrammatic view of the lateral boundary conditions available in uDALES. (a) Periodic simulation set-up, (b) driver precursor simulation set-up (composed of a periodic precursor simulation and an inflow-outflow target simulation with inflow-outflow boundaries) and (c) inflow generation set-up (turbulent profiles generated numerically at the inlet and a run-up region in the streamwise direction to allow the flow to develop).

- 175 – following the cell perturbation method (see figure 1c; Kong et al., 2000; Tomas et al., 2015). an inflow generation method. This method currently uses the cell perturbation method (see Fig. 1c; Kong et al., 2000; Tomas et al., 2015), where the mean velocity and the velocity fluctuations at a recycle plane are used to generate the velocity field at the inlet plane, and thereby turbulence develops in a region downstream from the inlet (the run-up region), after which the geometry of interest is placed. The size of the run-up region is variable, and it is planned to add an artificial turbulence generation feature (e.g. Xie and Castro, 2008) in future versions.
- 180

The three main simulation set-ups are shown diagrammatically in figure 1. The lateral boundary conditions are important in determining the planetary boundary layer flow that is modelled in uDALES.

2.5 Wall functions

Nearly all urban surfaces can be considered to be aerodynamically rough. This means that the roughness elements on a surface are much larger than the thickness of the viscous sublayer which is adjacent to every interface between a fluid and a smooth surface. Mean turbulent quantities can thus vary drastically close to walls and processes near the wall cannot be resolved on the grid and therefore need to be modelled. Processes close to vertical walls are qualitatively different from horizontal walls, particularly in the presence of buoyancy (e.g. Hölling and Herwig, 2005). However, vertical walls are commonly treated the same way as horizontal walls, namely the formation of a constant stress layer with logarithmic wind profile is assumed. This is due to the a lack of established alternatives.

185

190

2.5.1 Wall-functions for momentum and temperature

For atmospheric flows wall functions on horizontal surfaces are commonly based on similarity laws determined by **Buckingham** **Buckingham**- Π analysis. Such similarity laws for the surface layer have been known since the fundamental paper of Obukhov (1946) and subsequent work together with A. Monin (Monin and Obukhov, 1954). A wall function for momentum and temperature based on Uno et al. (1995) was introduced into uDALES, in which the eddy fluxes u_*^2 and $\theta_{v*} u_*$ are given by

$$u_*^2 = u^2 \frac{\kappa^2}{\ln(z/z_0)^2} F_m(z, z_0, z_{0h}, Ri_B), \quad (7)$$

$$\theta_{v*} u_* = u \Delta\theta_v \frac{\kappa^2}{Pr \ln(z/z_0)^2} F_h(z, z_0, z_{0h}, Ri_B), \quad (8)$$

where u is the velocity magnitude in the wall adjacent cell, $\Delta\theta_v$ is the temperature difference between the wall and the adjacent cell, z_0 is the momentum roughness length, z_{0h} is the roughness length for heat, κ is the **von Von** Kármán constant and the functions F_m and F_h describe the relationship between the atmospheric temperature and wind profile (Bulk Richardson number, Ri_B) and the corresponding surface fluxes.

Due to the fact that surfaces are generally not dynamically smooth, momentum transfer has a strong dependence on the form drag introduced by the pressure differences across those obstacles. However, for scalar transport no equivalent principle to pressure exists. In fact, it has been shown (Garratt, 1994) that for rough surfaces scalar transport becomes less efficient compared to momentum transport near the wall. We thus adopt the approach of **Uno et al. (1995)** **Uno et al. (1995)** and use a separate roughness length $z_{0h} \leq z_0$ for scalars to approximate the parametric functions F_m and F_h . This one-step iterative approach has been employed in LES studies before (Cai, 2012a, b) and is **very attractive given the fact that the** **attractive since** computational costs are low. The same method is used for vertical walls as well, where z and Ri_B are defined perpendicular to the wall. By doing this, the Richardson number loses its context and one must be careful interpreting its values. For more details see Suter (2019).

To verify the correct implementation of the wall function, results from uDALES are compared **directly to LES results from Cai (2012a)** to results from a different LES model employed by Cai (2012a). The simulation set-up is a flow over a canyon-like cavity. The canyon is **$h = 18$ m high and $l = 18$ m wide** **$H = 18$ m high and $W = 18$ m wide**. The domain size is **24 m \times 40 m \times 90 m** **$L_x=24$ m, $L_y=40$ m, $L_z=90$ m** with $80 \times 40 \times 91$ grid cells. This results in a resolution of **0.3 m \times 1 m \times 0.3 m** **$\Delta_x=0.3$ m, $\Delta_y=1$ m, $\Delta_z=0.3$ m** inside the canyon; and a grid that is stretched in the vertical direction above. The simulation is periodic in x and y (**figure Fig. 1a**) and driven by a constant free-stream velocity $U_F = 2.5$ m s⁻¹. Two cases are examined: 1) the **downstream upstream** wall and roof are heated (T_0+9 K, assisting case) and 2) the **upstream downstream** wall and roof are heated (T_0+9 K, opposing case). In Case 1 the buoyancy flux from the heated **downstream upstream** wall will assist the recirculation forming inside the canyon, while in Case 2 the additional buoyancy will oppose the general flow in the cavity. **In Figure**

In Fig. 2 the mean temperature fields for both cases are compared **and show excellent** to figures reproduced from Cai (2012a) and show good agreement. In the assisting case, the heat is concentrated on the **downstream upstream** canyon edge from where it is efficiently mixed with air aloft. The mean temperature inside the canyon is thus only slightly elevated. In the

opposing case, the downdraft along the heated wall leads to a more complicated flow patterns inside the canyon, effectively reducing the exchange between the canyon and the atmosphere. As a result, more heat is trapped inside the canyon, leading to increased temperatures. The quantitative agreement with Cai (2012a) confirms good qualitative agreement with Cai (2012a) indicates the correct implementation of the wall function for temperature for both horizontal and vertical walls.

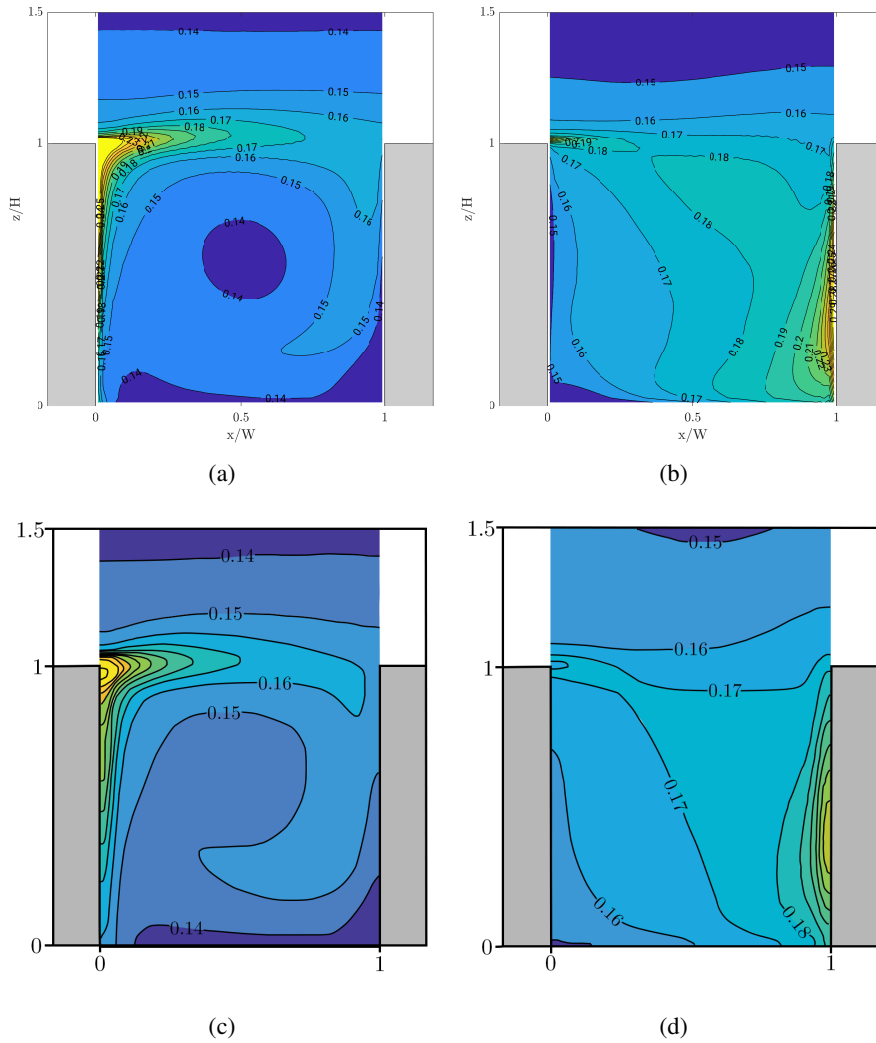

Figure 2. Mean temperature fields (a&b) compared to results reproduced from Cai (2012a, c&d). In all cases, T_0 was subtracted. Left column shows the assisting case, right column the opposing case.

2.5.2 Wall function for moisture

The surface moisture fluxes require additional consideration. In uDALES it is assumed that water is stored in the soil and in
 230 vegetation, where any such surface has a water balance:

$$\frac{dW}{dt} = P - \frac{E_{\star}}{L_v}, \quad (9)$$

where W [kg m^{-2}] is the soil moisture content, P [$\text{kg m}^{-2} \text{s}^{-1}$] is the water supply rate, E is the latent heat flux [W m^{-2}] and L_v [J kg^{-1}] is the latent heat of vaporization. The behaviour of plants under various environmental conditions has
 235 been studied extensively (Moene and van Dam, 2014). However, of major interest are the exchanges of momentum, heat and
 water between the surface and the atmosphere. Apart from water availability in the top soil, the evaporation from vegetation is
 determined mainly by the solar radiation reaching the leaves. The phase change from liquid water into water vapour in the air
 requires large amounts of energy, generally provided by the radiation. Furthermore, the pores in the leaves, stomata, are open
 during the daytime to allow the exchange of gases used in photosynthesis, facilitating transpiration. Tall vegetation like trees
 also provide shade for lower surfaces. While trees are indeed a very interesting topic in the research area of the urban climate,
 240 trees and tall vegetation are not considered here.

A wall function for moisture fluxes from vegetated surfaces was newly developed for uDALES. The moisture flux from roof
 and wall facets can be described identically to the heat flux (Eq. (8)). However, it is not obvious what the moisture difference
 Δq between the wall and the atmosphere is, because water is usually not available directly on the surface and therefore one
 cannot assume that the air close to the surface is saturated with water vapour. Furthermore, open water surfaces are as of yet
 245 uncommon on buildings and most of the flux will thus stem from vegetation or soil of green roofs/walls. Plants lose water
 by opening their stomata, but also through their outermost layer, the cuticle. A large number of processes are involved in the
 transport of water in soil and plants. Indeed, the nature of the ground influences the roots and their water uptake; plants have
 varying metabolisms depending on age, size, season etc. . Modelling these processes is seldomly done in detail in atmospheric
 models. We thus utilise a modified Jarvis-Stewart (JS) approach (Jarvis, 1976; Stewart, 1988). This approach adds additional
 250 resistance to the transport of moisture from vegetation and soil to the atmosphere. The added resistance is based on empirical
 functions depending on plant and environmental parameters. The resistances for the plant canopy (r_c [s m^{-1}]) and for the soil
 (r_s [s m^{-1}]) can be expressed as:

$$r_c = \min\left(r_{\max}, \frac{r_{c,\min}}{D} f_1(K) f_2(W_G) f_3(T_s)\right), \quad (10)$$

$$r_s = \min(r_{\max}, r_{s,\min} f_2(W_G)), \quad (11)$$

255 where D [$\text{m}^2 \text{m}^{-2}$] is the leaf area index, the term f_1 is a function of net shortwave radiation K [W m^{-2}], f_2 depends on soil
 moisture content W_G [kg m^{-2} -³] and f_3 on the wall temperature T_s [K]. Following Van den Hurk et al. (2000) for f_1 and

Figure 3. Diagram of the resistances encountered in a simplified soil-plant-atmosphere system.

f_2 and Moene and van Dam (2014) for f_3 , these are given by:

$$f_1^{-1} = \min\left(1, \frac{c_1 K + 0.05}{0.81(c_1 K + 1)}\right), \quad (12)$$

$$f_2^{-1} = \min\left(1, \max\left(0.001, \frac{W_G/d - W_{\text{wilt}}}{W_{\text{fc}} - W_{\text{wilt}}}, \frac{W_G - W_{\text{wilt}}}{W_{\text{fc}} - W_{\text{wilt}}}\right)\right), \quad (13)$$

$$260 \quad f_3^{-1} = \max(0.001, (1 - c_2(c_3 - T_s)^2)), \quad (14)$$

$$h_{\text{rel}} = \max\left(0, \min\left(1, \frac{1}{2}\left[1 - \cos\left(\pi \frac{W_G}{W_{\text{fc}}}\right)\right]\right)\right), \quad (15)$$

where $c_1 = 0.004 \text{ m}^2 \text{ W}^{-1}$, $c_2 = 0.0016 \text{ K}^{-2}$, $c_3 = 298 \text{ K}$, d **m is the thickness of the soil layer**, $W_{\text{wilt}} [\text{kg m}^{-3}]$ is the soil moisture at the wilting point, $W_{\text{fc}} [\text{kg m}^{-3}]$ is the soil moisture at field capacity and $h_{\text{rel}} [-]$ is the relative humidity above soil following Noilhan and Planton (1989). The moisture flux from roof and wall facets is then expressed as

$$265 \quad q_* u_* = \frac{q_a - q_{\text{sat}}(T_s)}{\frac{1}{u C_h} + r_c} + \frac{q_a - q_{\text{sat}}(T_s) h_{\text{rel}}}{\frac{1}{u C_h} + r_s}, \quad (16)$$

with the units $[\text{kg kg}^{-1} \text{ m s}^{-1}]$. The heat transfer coefficient $C_h = \frac{\kappa^2}{Pr \ln(z/z_{0h})^2} F_h(z, z_0, z_{0h}, Ri_B)$ is obtained from the standard wall function (Eq. (8)) where the vegetation is considered with appropriate roughness lengths. To determine the saturation specific humidity $q_{\text{sat}} [\text{kg kg}^{-1}]$ we use **empiric empirical** formulas from Bolton (1980) and Murphy and Koop (2005) that are accurate within normal temperature ranges encountered in cities.

270 2.6 Emissions and chemistry

A key application of urban LES models is the study of urban air pollution. This entails modelling the life cycle (emission, dispersion, chemical reaction and removal) of pollutants within the LES domain at the relevant (microclimate) scales. The high-resolution, time-resolving nature of uDALES makes it able to accurately resolve the transport of passive scalar fields within

the turbulent urban flow field. The capability to model both idealised (point and line sources with initial Gaussian distributions) and realistic emissions (via networks of volumetric point sources) has been introduced into uDALES. The chemistry of the null cycle has also been added to capture the reactions between nitrogen oxides (NO_x) and ozone (O₃; Grylls et al., 2019).

Idealised emission sources are integral for fundamental studies of urban pollution dispersion (e.g. line sources within infinite canyons; Caton et al., 2003). Point sources are used to represent passive scalar releases in the validation of uDALES in section 4.1. Realistic traffic emissions are obtained by coupling the LES model with a traffic microsimulation and emissions model within the preprocessing routine. By rasterising the resulting pollutant emissions to the grid used in uDALES, traffic emissions can be read into the LES model and simulated via a network of pollutant sources at the lowest level of the domain. Grylls et al. (2019) used the traffic microsimulation model VISSIM (PTV AG, 2017) and an instantaneous, general regression emissions model (Luc Int Panis, 2006) to use uDALES to study pollution dispersion over a case study region in London, UK.

Chemical reactions occurring at a similar timescale to the dispersion of pollutants within the urban canopy layer (UCL) significantly alter the spatial and temporal evolution of the affected pollutant species. This phenomena is particularly important in accurately capturing Nitrogen Dioxide, NO₂, and Ozone, O₃, concentrations. By time-resolving the relevant reactions within urban LES, a greater understanding can be gained of these harmful air pollutants and on the effect of these reactions on e.g. pedestrian-level exposure. The chemistry of the null cycle, which has no net chemical effect (meaning that NO_x and O_x are conserved), follows

The photodissociation R1 has the rate constant J_{NO_2} , and reactions R2 and R3 the first order rate constants k_2 and k_3 , respectively. The chemical processes of the null cycle have been added into uDALES using reactions rates from Wallace and Hobbs (2006). The relatively high reactivity of the Oxygen radical, O[•], permits a simplification of the null cycle leading to the following prognostic relationships (Zhong et al., 2017):

$$\epsilon_{NO} = J_{NO_2} [NO_2] - k_3 [NO] [O_3], \quad (17)$$

$$\epsilon_{NO_2} = -J_{NO_2} [NO_2] + k_3 [NO] [O_3], \quad (18)$$

$$\epsilon_{O_3} = J_{NO_2} [NO_2] - k_3 [NO] [O_3], \quad (19)$$

where ϵ is an additional source term on the right-hand-side of [equation 3 Eq. \(3\)](#) for reactive pollutant fields. The chemistry is implemented following a split fully implicit time-integration scheme. A validation of the chemical scheme can be found in Grylls et al. (2019).

3 Surface energy balance

Any attempt to understand the urban microclimate must start with an analysis of its surface energy balances (SEB; Oke et al., 2017). Urban areas exchange energy in various forms (Erell et al., 2011), such as incoming and outgoing longwave (L^\downarrow , L^\uparrow) and shortwave radiative fluxes (K^\downarrow , K^\uparrow), the turbulent sensible heat flux (H), the turbulent latent heat flux (E), ground heat flux (G) and the heat storage per unit time (dQ/dt , often denoted ΔQ). These fluxes have to balance and the SEB is expressed as

$$\frac{dQ}{dt} = (L^\downarrow - L^\uparrow) + (K^\downarrow - K^\uparrow) - (H + E + G) + O, \quad (20)$$

where all the terms have unit W m^{-2} .

Several possible approaches for studying urban climate have been used, ranging from observation to numerical simulations. In this context, the physical processes determining the SEB and their complex interactions must be taken into account the urban climate can be found in the literature, e.g. (Mirzaei and Haghighat, 2010; Mirzaei, 2015; Moonen et al., 2012; Arnfield, 2003; Rizwan et al., 2008; Grimmond, 2007; Barlow, 2014).

A common approach is the use of standalone urban energy balance (UEB) models. UEBs are based on the concept that total energy in the urban boundary layer, the lowest few hundred meters of the atmosphere, has to be conserved. UEBs are widely used as surface schemes in numerical weather prediction and regional atmospheric models, such as the Town Energy Budget (Masson, 2000, TEB) used by the French national weather service (Météo-France) or the Joint UK Land Environment Simulator (Best et al., 2011; Clark et al., 2011, JULES) by the UK Met Office. They are computationally inexpensive and include many physical processes, but are still very simplified representations a very simplified representation of the urban environment making them computationally inexpensive. The building geometry is often only represented in an averaged sense, and no single building can be studied. Furthermore, the transport in the air is parameterised. Other UEBs include variations of TUF (Krayenhoff and Voogt, 2007; Yaghoobian and Kleissl, 2012), SUEWS (Järvi et al., 2011), RayMan (Matzarakis et al., 2010) and the SOLWEIG model (Lindberg et al., 2008), Grimmond et al. (2010) provides. Grimmond et al. (2010) provide an overview and comparison of UEB models. We introduced the concept of a

The surface energy balance into uDALES, where every bottom and immersed boundary has in uDALES is implemented per facet, with each facet having its own material properties and all the energy fluxes from. All fluxes from Eq. (20) and (9) are modelled. The surface properties W_G and T_s can vary in time and are spatially heterogeneous. Often Eq. (20) is considered for a large area, averaging out many local features: e.g. in urban energy balance models the horizontal scales are usually $10^2 - 10^4$ m (Grimmond et al., 2010). The time-resolutions is correspondingly coarse. The much higher resolution of uDALES allows to consider permit the consideration of individual surfaces, where all the terms of Eq. (20) become rather intricate. The turbulent sensible and latent heat fluxes change with every wind gust while the internal wall temperatures are much less sensitive and vary on much larger time scales. Furthermore, the radiation terms depend strongly on the orientation of the surface, shading and the field of view. For example, if a large portion of the field of view of a surface comprises of other surfaces it likely receives only little direct sunlight, since it is often shaded. However, it is likely to receive a large amount of longwave radiation from its surroundings as building walls are generally warmer than the sky. Due to the large spatial and

temporal variability in surface temperatures, especially in heterogeneous terrain, it is important to consider the surface energy balance carefully to achieve more realistic urban representation in LES models. To account for these effects, every surface in uDALES is divided into several smaller facets. The energy budget , including radiation, has to be evaluated for each facet.

340 3.1 Urban facets

uDALES accepts grid-conforming immersed boundaries (see section 2.3), i.e. cuboids , and for the calculation of the surface energy balance it is necessary that each side of those blocks (i.e. each facet) is either entirely internal or external. Accepting these restraints simultaneously leads to a finer representation of the surface. Most topographic elements, like buildings, are sliced into smaller blocks. An example is shown in Figure 4. Suspended and overhanging structures are currently not supported.
345 or blocks. These blocks therefore always span an integer number, generally more than one, of LES grid-cells in each dimension. Suspended and overhanging structures are currently not supported. To represent more complex geometries, such blocks of potentially different sizes can also touch as seen in Fig. 4. For the calculation of the surface energy balance, however, it is necessary that each face (side) of a block is either entirely internal or external. For this reason, touching blocks often need to be sliced into smaller blocks. These restraints simultaneously lead to a finer representation of the surface. However, due
350 to the grid-conformity of blocks this refinement can never go below LES resolution. After all blocks have been subdivided if necessary, the outside faces are termed *facets*.

Facets represent all types of surfaces present in the urban landscape, such as roofs, walls, roads and green roofs. Every facet is thus also assigned properties accordingly, needed for the wall function and energy balance calculation . These are the momentum roughness length z_0 [m], the heat roughness length z_{0h} [m], the shortwave albedo α [-] and the longwave emissivity
355 ϵ [-]. Furthermore, every facet consists of multiple layers each with properties: thickness d [m], density ρ [kg m^{-3}], specific heat capacity c_p [$\text{J kg}^{-1} \text{K}^{-1}$] and thermal conductivity λ [$\text{W m}^{-1} \text{K}^{-1}$]. The last three terms can be combined to form the thermal diffusivity $\kappa = \lambda / (\rho c_p)$ [$\text{m}^2 \text{s}^{-1}$].

Additional facets have to be introduced to populate the voids between building blocks (i.e. roads, parks, etc.). The floor facets immediately adjoining a building are given the same length as the corresponding wall facets and a width of one grid cell. The
360 rest of the floor is then filled with rectangles, restrained by a maximum side length. Alternatively, if the nature and configuration of the floor is known in more detail the facets can be created accordingly and be specified using the facet properties.

Following Krayenhoff and Voogt (2007) we add a wall along the domain edge of a height equal to the median building height in the domain. This wall is used to approximate the effect of the surrounding built environment on radiation, that cannot be captured within the model domain. These bounding wall facets are solely used for radiative calculations and do not appear
365 in the LES simulation and have thus have no direct effect on air flow. An example of urban facets, including roads and bounding walls, can be seen in Figure Fig. 11a.

3.2 View factors

To calculate the radiative exchanges between two facets, their geometric relation to one another has to be determined and the radiative processes need to be described. To achieve this, there are commonly two alternative approaches pursued in complex

Figure 4. A building consisting of two blocks A and B. Block B will be divided into four smaller blocks, so all faces are either entirely on the in- or outside of the building.

370 urban topography: 1) ray tracing and Monte Carlo simulation; and 2) radiosity approach with configuration factors. For very complex or curved surfaces radiative exchange is commonly determined by tracing randomized rays of a Monte Carlo simulation with considerable computational effort. This approach becomes more and more feasible with increasing computational power and specialised GPU computing platforms. A big advantage of this approach is its potential to also handle specular reflections. Ray tracing models have for example been used to study urban photovoltaic energy potential
 375 (Erdélyi et al., 2014) and urban climate and meteorology (Krayenhoff et al., 2014; Girard et al., 2017).

However, for planar surfaces, as are present in this study, the radiosity approach is generally faster (Walker et al., 2010). In this approach it is assumed that the radiosity across a facet is uniform. This allows the separation of the geometric relation between two facets from the radiative process itself (Howell et al., 2010). View factors (configuration factors) describe this geometric relation. The radiosity approach has been used to study the urban climate (e.g. Aoyagi and Takahashi, 2012; Resler
 380 et al., 2017). The approach currently employed in uDALES follows Rao and Sastri (1996). It has to be noted at this point that several conventional assumptions were made regarding the radiation and radiative properties of all of the facets (e.g. Krayenhoff et al., 2014; Howell et al., 2010), namely: 1) no wavelength dependency, except the separation into short- and longwave; 2) facets are “grey” in the longwave regime, i.e. absorptivity = emissivity; 3) facets are isothermal; 4) reflections are diffuse; 5) emitted radiation is diffuse; and 6) the radiosity (leaving radiant flux) is uniform across the facet.

385 For calculating both longwave and shortwave radiation, view factors are used. The view factor $\psi_{i,j}$ is defined as the ratio of radiation leaving the surface of facet i hitting surface of facet j , divided by the total amount of radiation leaving facet i . View factors thus take values between 0 and 1 and $\sum_{j \in q} \psi_{i,j} = 1$, where q is the set of all facets that can be seen by i (including the sky). All view factors $\psi_{i,j}$ between any two facets i and j have to be calculated. This makes the number of calculations needed $\mathcal{O}(n^2)$.

390 Several numerical methods exist to calculate view factors between surfaces, since in most cases the analytical solution to the problem is not known. The fact that view factors only depend on the geometry allows one to calculate all $\psi_{i,j}$ *a priori* and store the resulting matrix as an input to the LES model. Numerical integration was used to obtain the view factors in this study. Considerable computational savings can be achieved by replacing the integration over two areas by integration over two surface boundaries. The view factor can then be expressed as (Siegel and Howell, 2001)

$$395 \quad \psi_{i,j} = \frac{1}{2\pi A_i} \oint_{C_i} \oint_{C_j} [\ln(S) dx_j dx_i + \ln(S) dy_j dy_i + \ln(S) dz_j dz_i], \quad (21)$$

where S is the distance between two infinitesimal line segments along the contours of the facets (C_i, C_j). The numerical integration of $\ln(S)$ is done using 6th order Gauss-Legendre quadrature, which is effective and accurate for straight-edged contours (Rao and Sastri, 1996). The evaluation of **equation Eq. (21)** is impossible in the case that the two contours share a common edge, because $S = 0$. Ambirajan and Venkateshan (1993) provide an exact analytical solution for the contribution
400 from the element on the common edge of the two surfaces to the overall view factor:

$$\Delta\psi_{i,j} = \frac{L_c^2}{2\pi} \left(\frac{3}{2} - \ln(L_c) \right), \quad (22)$$

where L_c is the length of the common edge. Since all facets are straight-edged, the only error in this approach lies in the approximation of $\ln(S)$ within the elemental intervals of the integration. High order quadratures thus ensure accurate numerical results.

405 View factors can be calculated using **equations Eq. (21) and (22)** as long as both facets can see each other entirely. Three important exceptions can be identified: 1) The facets cannot see each other at all, given their position and orientation; 2) a facet intersects the plane defined by the other facet; 3) the view is (partly) blocked by **another surface an obstacle**. The first case occurs frequently; **e.g. E.g.** any west facing facet cannot possibly see any other west facing facet or any facet that is **located** entirely to the east. This relationship is reciprocal. The second problem can be circumvented by cropping the intersecting facet
410 along the intersection line. The view factors can then be calculated using the now smaller facet and the result remains accurate. There is no straightforward solution to the third problem, assessing if the view between two facets is blocked. Depending on how the facets are arranged and the geometry of the object blocking their view, determining a precise view factor can be difficult. To avoid computationally expensive solutions **such as Monte Carlo simulations** we determine a percentage p_b that the facets can see of each other and multiply ψ with that percentage. To obtain p_b we define five points, the four corners and
415 the centre, on every facet and determine if they can see the corresponding point on the other facet. The weight of the centre is 50% and the weight of each corner 12.5%.

The sky view factor ($\psi_{\text{sky},i}$) denotes the fraction of radiation leaving i that enters the sky vault and does not impinge on any other facet. It is the residual view factor after summing over all facets: $\psi_{\text{sky},i} = 1 - \sum_{j=1}^p \psi_{i,j}$, where p is the total number of facets. The sky view factor is also used to determine how much diffusive radiation from the sky any facet receives. For **the a**
420 validation of the view factor calculations see Suter (2019).

3.3 Shortwave radiation budget

Assuming no transmission of radiation through the surface, the net shortwave radiation K (W m^{-2}) on a facet i is defined as

$$K_i = K_i^\downarrow - K_i^\uparrow, \quad (23)$$

where the reflected shortwave radiation (K^\uparrow) can be expressed as

$$425 \quad K_i^\uparrow = \alpha_i K_i^\downarrow. \quad (24)$$

The incoming shortwave radiation (K_i^\downarrow) can be divided into three parts (Oke et al., 2017): direct solar radiation (S_i), diffuse radiation from the sky (D_i) and diffusely reflected radiation from other facets (R_i):

$$K_i^\downarrow = S_i + D_i + R_i. \quad (25)$$

430 It is important to consider all three components. Many of the urban facets can be completely shaded, thus $S_i = 0$, but potentially receive diffuse radiation from the sky or reflected radiation from other facets.

The direct solar radiation on a facet is defined as (Wu, 1995)

$$S_i = I \cos(\nu - \varphi_i) \cos(\chi_i) f_{e,i}. \quad (26)$$

435 The solar irradiance (I) is a model input and can be a constant or follow a diurnal cycle; it is assumed that all effects of atmospheric turbidity and clouds are included. The effect of geometry is captured by the sunlit fraction of the facet $f_{e,i}$, the two cosines account for the orientation of the facet in relation to the sun. The angle ν is the solar zenith and φ_i the slope angle of the facet (i.e. $\varphi_i = 0$ for a horizontal facet and $\varphi_i = \pi/2$ for a vertical facet). The angle χ_i is constructed in the following way

$$\chi_i = \begin{cases} \pi/2 & \text{if surface faces away from sun,} \\ 0 & \text{if the surface is horizontal,} \\ |\Omega_h - \Omega_i| & \text{otherwise.} \end{cases} \quad (27)$$

440 **Where Here,** Ω_h is the solar azimuth and Ω_i is the azimuth of facet i . Like the solar irradiance, the solar zenith and azimuth angles are also model inputs. Solar angles for all coordinates, dates and times can be readily obtained from online sources such as the ‘‘Solar Position Calculator’’ from the National Oceanic and Atmospheric Administration (NOAA, 2018).

445 The facet azimuth angles are also used to determine whether the facet is shaded or not. If $|\Omega_h - \Omega_i|$ is larger than $\pi/2$, the facet is not oriented towards the sun and is thus self-shaded. If the facet i is not self-shaded the sun might still be blocked by another facet j . Therefore, the path between every non-self-shaded facet and the sun is calculated and checked if it intersects with any other facet. The same principle as for view factors is used and the sunlit status is calculated for the four corners and

the centre of the facet, where the centre contributes 50% and each corner 12.5% to the total sunlit fraction $f_{e,i}$.

The diffuse radiation (D_i) is caused by light scattering in the sky and is given by

$$450 \quad D_i = \psi_{\text{sky},i} D_{\text{sky}}, \quad (28)$$

where D_{sky} , the total diffuse sky radiation, is a model input. The sky view factor $\psi_{\text{sky},i}$, is dependent on the urban geometry and has to be calculated for every facet. In [equation Eq. \(28\)](#) we ignore the directionality of D_{sky} , which is in reality anisotropic (Morris, 1969), [and can thus which allows us to](#) use $\psi_{\text{sky},i}$ directly to calculate the fraction of diffuse sky radiation impinging on i .

455

Shortwave radiation reflected by the environment has to be considered as well. All reflections are currently assumed to be perfectly diffusive (Lambertian), i.e. the amount of reflected light on a given surface is distributed equally in all directions. This is necessary to utilise view factors but does, by definition, not allow specular reflections. The amount of reflected light arriving at facet i is thus given by

$$460 \quad R_i = \sum_{j=1}^p \psi_{j,i} K_j^\uparrow, \quad (29)$$

where $\psi_{j,i}$ is the view factor between facet j and i and p is the total number of facets.

The calculation of the short wave contribution is implemented into uDALES through [a iteration an iterative](#) algorithm. First, view factors for all facet pairs (i,j) are calculated and stored. The direct solar and diffuse sky radiation give an initial approximation for the shortwave budget of every facet. To account for multiple reflections, the calculation of K_i^\uparrow (Eq. (24)-(29))
465 has to be iterated for all facets using the following scheme:

– first reflection ($n = 0$)

1. calculate initial $K_{i,0}^\downarrow = S_i + D_i$ using (26), (28)

2. calculate initial $K_{i,0}^\uparrow$ using (24)

470 3. calculate $R_{i,0}$ using (29)

4. recalculate $K_{i,1}^\downarrow = K_{i,0}^\downarrow + R_{i,0}$

– iterate following steps for $n = 1, 2, \dots$, until all changes are below a desired threshold ϵ_k :

1. only the additional reflected radiation from the previous iteration is considered for further reflections, i.e. $K_{i,n}^\uparrow = \alpha_i R_{i,n-1}$

475 2. recalculate $R_{i,n}$ based on the updated K_n^\uparrow

3. update $K_{i,n+1}^\downarrow = K_{i,n}^\downarrow + R_{i,n}$

4. calculate convergence criterion: $\max_i \left((K_{i,n+1}^\downarrow - K_{i,n}^\downarrow) / K_{i,n}^\downarrow \right) \leq \epsilon_k$

Once the algorithm has converged, K^\downarrow and also K^\uparrow (via (24)) are known for all facets. This algorithm converges quickly, usually within 10 iterations for <1% error, since albedos are generally low resulting in a large fraction of the radiation being absorbed and additional parts being lost towards the sky with every cycle.

3.4 Longwave radiation

The net longwave radiation L consists of four components.

$$\underline{L_i = \varsigma_{L,i} (\psi_{\text{sky},i} L_{\text{sky}}^\downarrow + L_{\text{env},i}^\downarrow + L_{R,i}) - L_i^\uparrow} \quad [\text{Wm}^{-2}],$$

where $\varsigma_{L,i}$ is the longwave absorptivity and $L_{\text{env},i}^\downarrow$ is the incoming longwave radiation from other facets. Since $\varsigma_{L,i}$ is

$$485 \quad L_i = \epsilon_i (\psi_{\text{sky},i} L_{\text{sky}}^\downarrow + L_{\text{env},i}^\downarrow + L_{R,i}) - L_i^\uparrow \quad [\text{Wm}^{-2}], \quad (30)$$

where ϵ_i is the longwave emissivity and $L_{\text{env},i}^\downarrow$ is the incoming longwave radiation from other facets. Since ϵ_i is generally close to unity for normal building materials, no reflections are considered for longwave radiation and the incoming reflected radiation $L_{R,i} = 0$. The incoming longwave radiation from the sky ($L_{\text{sky}}^\downarrow$) is given as a model input. L_i^\uparrow is the outgoing longwave radiation depending on the surface temperature $T_{s,i}$ according to the Stefan-Boltzmann law $L_i^\uparrow = \sigma \epsilon_i T_{s,i}^4$ with the Stefan-Boltzmann constant $\sigma \approx 5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$ and ϵ_i is the emissivity of facet i . The incoming longwave radiation from the other facets is given by:

$$490 \quad L_{\text{env},i}^\downarrow = \sigma \sum_{j=1}^p \psi_{j,i} \epsilon_j T_{s,j}^4 \quad [\text{Wm}^{-2}], \quad (31)$$

where p again is the total number of facets, $\psi_{j,i}$ is the view factor between facet j and i , ϵ_j is the emissivity of facet j and $T_{s,j}$ is the surface temperature of facet j . The calculation of the longwave contribution does thus not require explicit iteration.

495 3.5 Surface energy budget of ground, wall and roof facets.

To calculate the temperature evolution of every facet, we assume that every wall and roof consists of K layers of building material (see Fig. 5). The temperature at the interface of layer $k \in \{1, \dots, K-1\}$ and $k+1$ is defined as T_k . Furthermore, let T_K be the indoor temperature of the facet and $T_s = T_0 = T(z=0)$ be the outdoor surface temperature used for calculating radiation and convective heat fluxes. Here, $T_s = T(\xi=0) = T_0$ is the outside surface temperature used for calculating radiation and convective heat fluxes and ξ is the facet coordinate pointing inwards from the surface. Furthermore, $T(\xi=d) = T_K$ is the indoor temperature of the facet, where d is the total facet thickness. At every instant, T_0 is given determined by the balance of energy fluxes at the surface:

$$\underline{-G_i(T_0) = K_i + L_i(T_0) + H_i(T_0)} \underline{-G_i(T_0) = 0}. \quad (32)$$

Figure 5. Grid layout used to model conductive heat flux.

The net radiation on the right-hand side of the equation above is terms K_i and L_i are given by the radiation calculations discussed in the previous section, and G_i is the ground heat flux (positive if heat transfers into the facet). The values of H (positive if from facet to atmosphere) are the time mean fluxes provided by the wall function, K . The net short-wave radiation K_i only depends on the position of the sun, and the incoming longwave radiation $\varsigma_{L,i}(\psi_{\text{sky},i}L_{\text{sky}}^\downarrow + L_{\text{env},i}^\downarrow)$ $L_i^\downarrow = \varsigma_{L,i}(\psi_{\text{sky},i}L_{\text{sky}}^\downarrow + L_{\text{env},i}^\downarrow)$ can be calculated from the other facets temperatures facets' surface temperatures. The two remaining unknown terms are L_i^\uparrow and the ground heat flux G_i .

A defining aspect of this problem is that the boundary condition at the surface, which drives the energy exchange with the wall, is strongly non-linear, under the assumption that the ground heat flux (G_i) is purely conductive, i. e. $G_i = \lambda \frac{\partial T}{\partial z} \Big|_0$, which can be written as: . Under the assumption that the ground heat flux (G_i) is purely conductive, i.e. $G_i = -\lambda \frac{\partial T}{\partial \xi} \Big|_0$, the boundary condition (32) can be written as:

$$\lambda \frac{\partial T}{\partial z} \frac{\partial T}{\partial \xi} \Big|_0 = \epsilon \sigma T_0^4 + r, \text{ where } r = -(K + L^\downarrow + H), \quad (33)$$

where $r = -(K + L^\downarrow - H)$ and λ is the thermal conductivity in $\text{W m}^{-1} \text{K}^{-1}$ and z is pointing into the layer. This boundary condition . We omit the subscript i in Eq. (33) and the description of the facet-internal processes in the rest of this section.

Equation (33) requires information about both the temperature and its gradient at the boundary, and it would thus be very useful to have a numerical method for which these both are available at the same location without approximation. To achieve this, the variables are distributed in pairs of the temperature T_k and its gradient $T' = \frac{\partial T_k}{\partial z} \Big|_k$ $T' = \frac{\partial T}{\partial \xi} \Big|_k$ on the cell edges, implying that there are $2(K + 1)$ unknowns if the wall is discretised into K layers. This grid layout is not conventional, but is closely related to Hermitian interpolation (Peyret and Taylor, 2012) and has been used successfully to predict non-hydrostatic free-surface flow (Van Reeuwijk, 2002).

A solution will be constructed using a set of piecewise continuous quadratic polynomials, which will turn out to be splines. Consider a second order polynomial

$$T(z\xi) = a + bz\xi + cz\xi^2, \quad (34)$$

valid over the interval $z_k < z < z_{k+1}$. Defining $T(z_k) = T_k$, $T(z_{k+1}) = T_{k+1}$, $T'(z_k) = T'_k$ and $T'(z_{k+1}) = T'_{k+1}$ $\xi_k < \xi < \xi_{k+1}$. Defining $T(\xi_k) = T_k$, $T(\xi_{k+1}) = T_{k+1}$, $T'(\xi_k) = T'_k$ and $T'(\xi_{k+1}) = T'_{k+1}$, it is straightforward to demonstrate that

the quadratic is consistent with the following relation between the temperatures and its derivatives

$$\frac{1}{2}(T'_k + T'_{k+1}) = \frac{T_{k+1} - T_k}{d_{k+1}}, \quad (35)$$

530 where $d_{k+1} = z_{k+1} - z_k$ $d_{k+1} = \xi_{k+1} - \xi_k$. The coefficients a, b, c are determined by requiring that $T(z_k) = T_k$, $T(z_{k+1}) = T_{k+1}$ and $T'(z_k) = T'_k$ $T(\xi_k) = T_k$, $T(\xi_{k+1}) = T_{k+1}$ and $T'(\xi_k) = T'_k$, with result

$$T(\underline{z}\xi) = \frac{(z - z_k)(z_{k+1} - z)}{2d_{k+1}} \frac{(\xi - \xi_k)(\xi_{k+1} - \xi)}{2d_{k+1}} (T'_k - T'_{k+1}) + \frac{z_{k+1} - z}{d_{k+1}} \frac{\xi_{k+1} - \xi}{d_{k+1}} T_k + \frac{z - z_k}{d_{k+1}} \frac{\xi - \xi_k}{d_{k+1}} T_{k+1}. \quad (36)$$

Here, (35) was used to make the representation symmetrical in the arguments. By evaluating the temperature and its gradient at z_k and z_{k+1} ξ_k and ξ_{k+1} it becomes clear that (36) indeed satisfies the requirements of a spline, as a set of these functions
535 produces a curve which is continuous in both the temperature and the gradient of the temperature. An important property of (36) is that the mean temperature in the layer is given by

$$\frac{1}{d_{k+1}} \int_{z_k}^{z_{k+1}} \int_{\xi_k}^{\xi_{k+1}} T(\underline{z}\xi) dz d\xi = \frac{1}{2}(T_k + T_{k+1}) + \frac{d_{k+1}}{12}(T'_k - T'_{k+1}). \quad (37)$$

The temperature evolution inside the wall is described by an unsteady heat equation of the form

$$\frac{\partial T}{\partial t} = \frac{\partial}{\partial z} \frac{\partial}{\partial \xi} \left(\varkappa \frac{\partial T}{\partial z} \frac{\partial T}{\partial \xi} \right), \quad (38)$$

540 where \varkappa is the thermal diffusivity in $\text{m}^2 \text{s}^{-1}$. Integrating this equation over the interval $z_k < z < z_{k+1}$ $\xi_k < \xi < \xi_{k+1}$ and substituting (37) results in the relation

$$\frac{d}{dt} \left(\frac{d_{k+1}}{2}(T_k + T_{k+1}) + \frac{d_{k+1}^2}{12}(T'_k - T'_{k+1}) \right) = \varkappa(\underline{z}\xi_{k+1})T'_{k+1} - \varkappa(\underline{z}\xi_k)T'_k. \quad (39)$$

Equations (35) and (39) provide $2K$ equations. The final two equations are provided by the boundary conditions. The boundary condition at $z = 0$ is the right-hand side of the surface energy balance equation 33 $\xi = 0$ is of Robin-type and is given by Eq.
545 (33), where the outgoing longwave radiation is expressed in the form $L_i^\uparrow = (\epsilon_i \sigma T_0^3) T_0$ $L^\uparrow = (\epsilon \sigma T_0^3) T_0$. At the building interior a constant temperature $T_K = T_B$, $dT_K/dt = 0$ Dirichlet boundary condition of constant temperature $T_K = T_B$ is imposed.

In matrix form, the system of equations for K layers is given by

$$A\mathbf{T}' = \mathbf{b} + B\mathbf{T}, \quad (40)$$

$$550 \quad C \frac{d}{dt} \mathbf{T} + D \frac{d}{dt} \mathbf{T}' = E\mathbf{T}'. \quad (41)$$

The matrix A is determined by the left hand side and and matrix B by the right hand side of Eq. (35). The vector \mathbf{b} contains the sum of the surface energy fluxes (without the ground heat flux and outgoing longwave radiation, i.e. $-(K_i + \varsigma_{L,i}(\psi_{\text{sky},i} L_{\text{sky},i}^\downarrow + L_{\text{env},i}^\downarrow) + H_i)/\lambda_1 - (K + \varsigma_L(\psi_{\text{sky}} L_{\text{sky}}^\downarrow + L_{\text{env}}^\downarrow) - H)/\lambda_1$). Matrices C, D and E stem from Eq. (39) (see Suter (2019) for more details) (see Suter, 2019, for more details). After rearranging and substitution of (40) into (41) we obtain

$$555 \quad (C + DA^{-1}B) \frac{d\mathbf{T}}{dt} = EA^{-1}B\mathbf{T} + EA^{-1}\mathbf{b}, \quad (42)$$

where $^{-1}$ indicates matrix inversion. Note that it has been assumed here that \mathbf{b} does not depend on time for simplicity. Time integration is done with a fully implicit backward Euler **step scheme**. The matrices involved in this scheme are of the size $(k+1)^2$ and matrix inversion can become expensive for walls with a large number of layers, especially considering that the calculation has to be performed for each facet individually. The pre-calculation of A^{-1} is possible if all facets have the same number of layers and one remaining matrix division is required for the time integration. **The surface energy balance has been validated in** [A full validation of the scheme can be found in Suter \(2019\)](#).

3.6 Surface energy and water budget of vegetated surfaces

The surface energy budget of vegetated surfaces **closely** follows the description in section 3.5 **very closely**. Since no tall vegetation is **currently being considered**, we represented vegetated surfaces as normal **considered here**, vegetated surfaces can be represented by facets. The facet properties can be chosen accordingly, e.g. green roofs are often thicker than conventional roofs and vegetation albedo differs from building materials. To represent the additional roughness introduced by vegetation z_0 and z_{0h} can be adapted. **Additional to the terms in Eq. the** [In order to model a vegetated surface](#), a latent heat flux E is **being introduced:** [added to](#) (32):

$$K_i + L_i(T_0) \underline{+} \underline{-} H_i(T_0) \underline{+} \underline{E} \underline{-} \underline{G}_i(T_0) \underline{+} \underline{G} \underline{-} \underline{E}_i(T_0) = 0. \quad (43)$$

The values of E (**positive if from the facet to the atmosphere**) are the time mean fluxes provided by the wall function for moisture **and are based on** (see next section) and use the surface properties from the previous time-step.

The soil moisture content **is then updated according to the water balance of facets:** $W_{G,i}$ [kg m^{-2}] changes as water evaporates according to Eq. (9). The soil moisture budget is discretised using an explicit Euler method which, after ensuring that $W_{G,i} \geq 0$, results in

$$W_{G,i}^{n+1} = \max\left(0, W_{G,i}^n + \left(\underline{P}_i \underline{-} \frac{E_i}{L_v}\right) \Delta t_E\right), \quad (44)$$

where L_v is the latent heat of vaporization P_i [$\text{kg m}^{-2} \text{s}^{-1}$] is a water supply rate, Δt_E is the time interval between two energy balance time-steps. We assume that all soil moisture is in the outermost layer of thickness $d_{1,i}$. Furthermore the terms for plant canopy resistances, soil resistance and relative humidity at soil level used in the wall function for moisture (2.5.2) are adjusted based on the new values of the green roof temperature, soil moisture and radiation.

3.7 Integration into LES

A schematic of the **implementation and the order of several model routines are shown in Figure** [computation order of the most relevant model routines in uDALES is shown in Fig. 6](#). Every time-step (except the initial one) starts with applying the conditions at the lateral boundaries, e.g. periodicity. Then the effects of wet thermodynamics, such as temperature changes due to evaporating and condensing water, are considered. In the advection step, quantities are transported according to the resolved velocity field. The transport due to the non-resolved **sub-grid processes is modelled directly after.** [Followed](#) **subgrid**

processes is calculated next, followed by additional forcings such as the Coriolis effect. Finally, the top and bottom boundary conditions are applied and the immersed boundary method ensures that there is no wind and transport into buildings. At this point the momentum, temperature and moisture fluxes from the wall functions are calculated for all surfaces based on their surfaces properties. The fluxes are then added to the prognostic equations (2) & (3) before time integration is done and a new time-step starts. The calculation of the energy and water budget is not done at every LES time-step (t^n to t^{n+1}), since the time scales associated with the walls are generally much larger than the atmospheric ones. The routines to update the energy balance are thus only invoked after several Δt . In every iteration of the main routines the wall fluxes are thus accumulated. Furthermore the walls may extend across processor boundaries. All processors know about the facet properties and calculate the local wall fluxes according to the state of the local fluid cells. For the facet energy balance the processor average has to be determined. If between two energy balance time-steps (at t_E , with intervals $\Delta t_E > \Delta t$. The sensible and latent heat fluxes, which are calculated every LES time-step, are integrated over the facets and over the time increment Δt_E to ensure their accurate representation in the surface energy balance calculations. Since facets can extend across multiple processes, each process calculates the local wall fluxes. If the time increment Δt_E takes q LES time-increments (Δt), and the facet area (A) is split across l processors (A_k), the mean latent and sensible heat fluxes during that time period can be calculated as on facet i are given by

$$E_i = \frac{1}{A \Delta t_E} \sum_{o=1}^p \sum_{p=1}^q \sum_{k=1}^l A_k E_{i-o}^{op} \Delta t_{-}^{op}, \quad (45)$$

$$H_i = \frac{1}{A \Delta t_E} \sum_{o=1}^p \sum_{p=1}^q \sum_{k=1}^l A_k H_{i-o}^{op} \Delta t_{-}^{op}. \quad (46)$$

At every

At every energy balance time step t_E , the longwave and shortwave budgets are updated, and the water budget is calculated according to Eq. (44) using the values obtained from Eq. (45) & (46). The new facet temperatures are calculated following Eq. (42) and subsequently the facet properties are updated accordingly. These facet average fluxes and the calculation of the energy balance is done on a single processor; for this purpose the information is gathered via MPI and the updated facet properties are redistributed afterwards. The calculation of the energy balance is done on a single processor. The information about the facet fluxes is gathered via MPI and the updated facet properties are redistributed afterwards. The accumulation of the wall fluxes is calculated at every LES time-step. However the execution and communication time is negligible compared to the fluid dynamics calculations, which becomes obvious when comparing the number of facets ($\mathcal{O}(10^4)$) to the number of fluid cells ($\mathcal{O}(10^8)$).

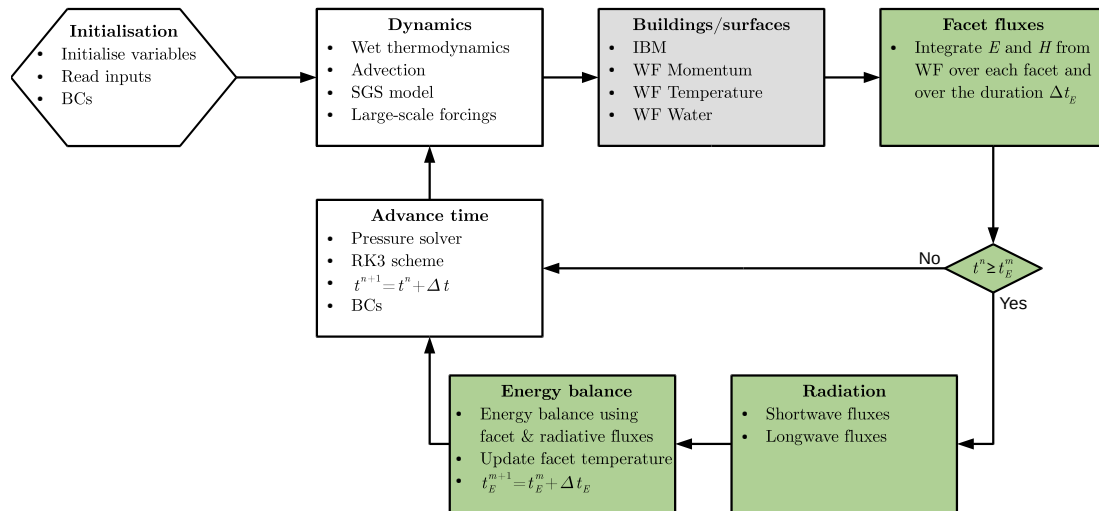

Figure 6. Schematic of the main routines in uDALES, unshaded . Unshaded boxes refer to DALES core routines (see Heus et al. (2010)) (see Heus et al., 2010) . The grey box indicates the routines that are used when considering buildings. The green boxes refer to the energy balance routines

4 Test cases

615 4.1 Validation using DAPPLE windtunnel wind-tunnel experiments

The dynamic core of uDALES(DALES) , DALES, has been validated extensively and used as part of several atmospheric intercomparison studies (Heus et al., 2010). The adapted version of the code with the IBM implemented has been validated against both wind and water tunnel data for idealised geometries (Tomas et al., 2016; Tomas, 2016). A further validation of uDALES is presented for its application to realistic urban morphologies and passive scalar dispersion under neutral dynamic
620 conditions using wind-tunnel data from the Dispersion of Air Pollution and its Penetration into the Local Environment (DAPPLE) project.

DAPPLE was a large, multi-disciplinary study of both urban meteorology and pollution dispersion that consisted of field measurements, wind tunnel wind-tunnel modelling and computational simulations (Arnold et al., 2004). The case study area was the region surrounding the junction of Marylebone Road and Gloucester Place in Central London, United Kingdom. Wind
625 tunnel experiments Marylebone Road is a wide street with several lanes in each direction, aligned with building blocks of different sizes and heights. At the intersection with Gloucester Place, a street of approximately half the width of Marylebone Road, is an in total 53-m high building on top of a wider, three-storey (11 m) base, and opposite a building with an in total 49-m tall spire. The streets in the proximity of the junction are arranged in an irregular grid-based layout.

Wind-tunnel experiments with passive scalar releases were conducted over the case study region as part of this project
630 (alongside passive scalar releases in the field; Carpentieri et al., 2009, 2012). The wind tunnel model the DAPPLE project (Carpentieri et al., 2009; Carpentieri and Robins, 2010; Carpentieri et al., 2012). The wind-tunnel model of the study area was

set-up with a radius of about 500 m and at a 200:1 scale, the freestream velocity was 2.5 m s^{-1} , the wind direction was south-westerly and a turbulent neutral boundary layer was developed upstream of the urban geometry using Irwin spires and 2-D roughness elements. The experiment contained three-dimensional velocity measurements over the Gloucester Place/Marylebone Road intersection area using Laser Doppler anemometry (LDA; Carpentieri et al., 2009). Vertical velocity profiles were measured for several points in the intersection with an averaging time of 3 min. Pollution dispersion experiments were performed by releasing a tracer gas from different locations upstream of the street intersection and measuring its concentration using a fast response flame ionisation detector (FFID; Carpentieri and Robins, 2010; Carpentieri et al., 2012). Xie and Castro (2009) conducted an LES study that reproduced these the wind-tunnel results data with good agreement.

640 4.1.1 Simulation set-up

The main A uDALES simulation is set up to reproduce the DAPPLE wind-tunnel experiments, namely vertical profiles of mean (time-averaged) velocities, root-mean-square (rms) velocities, and Reynolds shear stresses, along with a horizontal profile of mean and root-mean-square scalar concentrations. The target simulation uses inflow-outflow boundary conditions in the streamwise direction and is driven through a precursor (driver) simulation. by a precursor simulation. Analysis of the subgrid-scale fluxes indicated that a 2 m resolution is sufficient to resolve the majority of the energetic turbulent scales with subgrid fluxes not exceeding 4.5 %, except in cells adjacent to the ground surface. Details of the two simulations are provided in Table 1. A diagrammatic view of the modelled urban morphology is shown in figure 7, reproducing the model used in the wind tunnel experiment at full scale. The markers and the axis x_r in figure 7 indicate the location of scalar point sources and measuring positions. The Figure 7 shows a diagrammatic view of the modelled urban morphology, which reproduces the model used in the wind-tunnel experiment at full scale. The mean building height of the DAPPLE morphology, h_m , is 22 m. The figure indicates the locations P_1 – P_9 for comparison with the measured vertical velocity profiles (circles in Fig. 7), scalar release locations (triangles in Fig. 7), and the horizontal axis x_s aligned with Marylebone Road along which the scalar concentrations are compared. The case study morphology is rotated such that the south-westerly incoming wind direction is aligned with the x_D -axis. The mean building height, h_m , is 22 m and the reference velocity, u_{ref} , is 2.5 m s^{-1} . precursor simulation x -direction. Additional blocks are added in the upstream area of the domain outside the study area to emulate the effects of generic buildings or roughness elements in the wind-tunnel (cf. Xie and Castro, 2009)

The use of a precursor simulation allows for the incoming boundary layer to be defined independently of the main target simulation (which can be particularly useful when reproducing wind tunnel wind-tunnel experiments or studying transitional flows). The driver precursor simulation is set up to reproduce the boundary layer boundary-layer dynamics obtained upwind of the wind tunnel wind-tunnel morphology in the experiment of Cheng and Robins (2004) with a freestream velocity $u_{ref} = 2.5 \text{ m s}^{-1}$. A staggered cubic array was used in the driver precursor simulation, with a mean block height of 4m 4 m . The height and packing density (0.25) was obtained from the mean velocity profile using the relationship defined by Macdonald et al. (1998). Figure 8 compares the mean horizontally-averaged mean velocity and turbulent statistics produced in the driver precursor simulation against the incoming profiles from the wind tunnel wind-tunnel . A good agreement is shown indicating that the inlet to the main target simulation closely matches that of the wind tunnel data.

Table 1. Simulation set-up details for **driver precursor** and **main target** simulations used in the uDALES validation. Boundary conditions (BC) defined for the x - and y -directions.

		Simulation	
		Driver Precursor simulation	Main Target simulation
Grid size	Grid points (x,y,z)	200×400×100	450×400×100
	Cell size [m]	2×2×2	2×2×2
	Domain size [m]	400×800×200	900×800×200
	x momentum BCs BC	Periodic	Inflow-outflow
	y momentum BCs BC	Periodic	Periodic
	x scalars BCs BC	-	Inflow-Outflow
	y scalar BCs BC	-	Inflow-Outflow
	Flow forcing	$F_x = 0.000125 \cdot 1.25 \times 10^{-4} \text{ m s}^{-2}$	Inlet from driver precursor sim.
	Run-up time [s]	50,400 25,200	-
	Main run time [s]	50,400	44,000
	Averaging period [s]	-	25,200 22,000

The **driver** wind-tunnel data. The root-mean-square error between the normalised wind-tunnel velocity profile and simulation velocities at corresponding heights is 0.04. The **precursor** simulation had to be run-up to reach a statistical steady state prior to obtaining converged statistics (run-up times and averaging periods given in Table 1). The simulations were run on the UK national supercomputer ARCHER using 100 cores. The precursor simulation took 18 hours and the target simulation 48 hours wall time.

4.1.2 Results

Mean and turbulent flow and scalar statistics obtained in uDALES are compared to those of the **wind tunnel** wind-tunnel experiments. Figure 9 compares the mean and turbulent (**Reynolds stress**) vertical profiles obtained at position **R** P_1 (note all variables are rotated for alignment with the axes x and y ; refer to **Figure** Fig. 7). Position **R** P_1 is situated within a large intersection and directly downwind of an elevated spire. The simulation illustrates a good agreement between all three mean velocity profiles. The **higher second** order statistics are also shown to generally provide a good agreement, with the most significant discrepancy shown to be the relatively larger peaks in the Reynolds stress profiles at $z = 2h_m$. These peaks are related to the wake of the upwind spire. Capturing the form of this spire is challenging due to its oblique angle upon the Cartesian grid (refer to **Figure 7** Fig. 7b) and as such both its frontal area and vertical form may lead to the relatively larger fluxes over this region(the dimensions of the spire also had to be approximated due to a lack of available data). . Similar agreement was obtained over the 8 other positions within the modelled domains(the red crosses in Figure 7) .

Table 2 displays validation metrics of the uDALES simulation with DAPPLE wind-tunnel measurements for the mean velocity magnitude at measurement positions P_1 – P_9 , including the root-mean-square error (RMSE), fractional biases (FB),

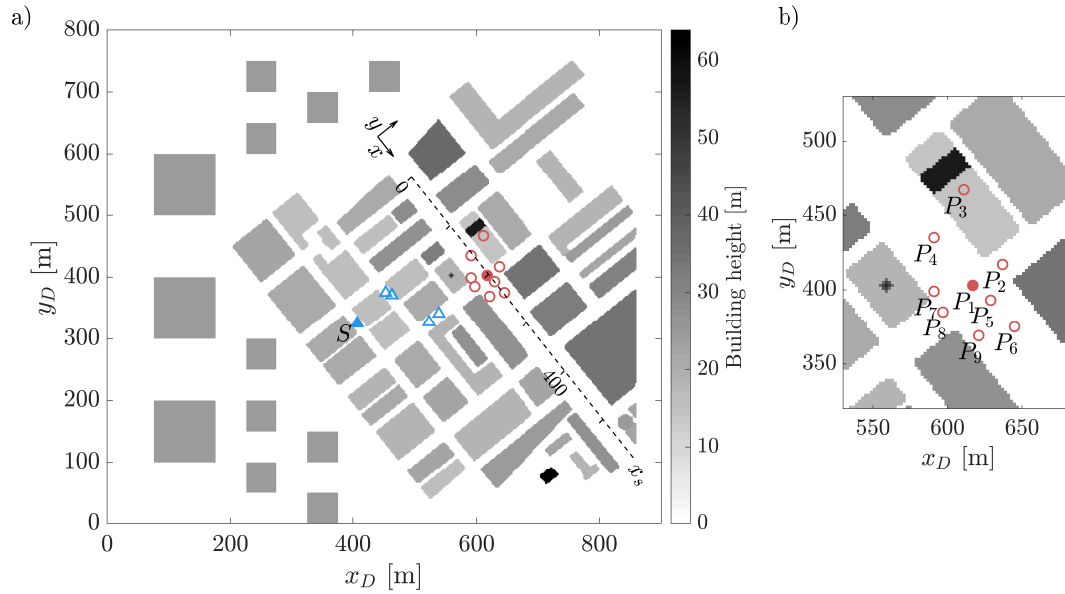

Figure 7. Diagrammatic view of the urban morphology used in the main simulation. The positions of the measuring points around the main intersection are denoted by red crosses (point R used in this validation) and the position of the scalar releases are denoted by blue triangles (release point S discussed here). An additional horizontal axis, x_r , is used to plot a profile of the spanwise pollutant concentration along the Marylebone Road. The axes x and y are aligned with the Marylebone Road and used in the results section. Diagrammatic view of the (a) urban morphology in the DAPPLE simulation and (b) detailed view on the main intersection of Marylebone Road and Gloucester Place with positions of velocity profile measurements P_1 – P_9 (circles) around the intersection and positions of the upstream scalar releases (triangles). Velocity measurements at point P_1 (filled circle) and spanwise pollutant concentration along Marylebone Road (along the horizontal axis x_s) from scalar release at point S (filled triangle) are shown in Fig. 9 and Fig. 10. Additional axes x and y are aligned with Marylebone Road.

Table 2. Validation metrics of uDALES simulation with DAPPLE wind-tunnel measurements for mean velocity magnitude at positions P_1 – P_9 and for mean scalar concentration along axis x_s : the root-mean-square error (RMSE), fractional bias (FB), and factor of two (FAC2).

	P_1	P_2	P_3	P_4	P_5	P_6	P_7	P_8	P_9	x_s
RMSE [-]	0.06	0.06	0.15	0.11	0.06	0.09	0.14	0.09	0.14	0.04
FB [-]	-0.17	-0.05	0.12	-0.02	-0.04	-0.03	-0.47	-0.18	-0.08	0.11
FAC2 [-]	1	1	0.77	1	0.94	0.94	0.65	0.94	0.88	0.67

and factor of two (FAC2) (COST Action 732, 2007). The root-mean-square errors range from 0.06 to 0.15. The fractional biases are typically slightly below zero, indicating that the simulation had a small tendency to under-predict the velocities. The FAC2 measures the fraction of predictions that lie within factor of two of the observations, which was generally high, and for some locations all predictions (simulation velocities) are within a factor two of the experiment data (i.e., FAC2 = 1).

685

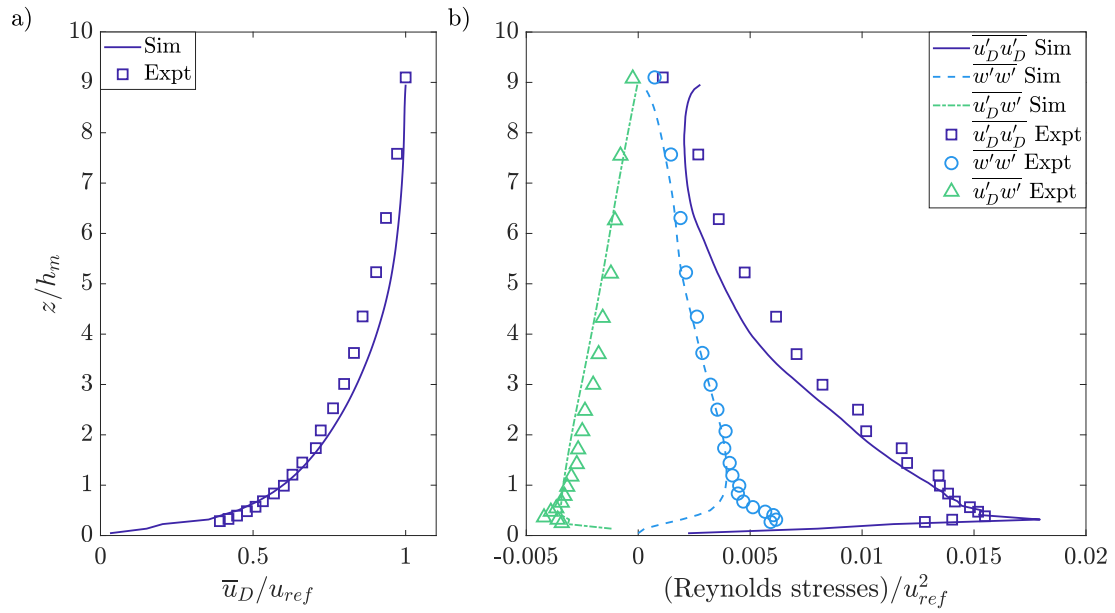

Figure 8. (a) Mean horizontally averaged (a) mean velocity and (b) turbulent Reynolds stress profiles of the precursor simulation and the boundary layer developed before the urban area in the wind tunnel wind-tunnel experiments of the DAPPLE project. Note the use of subscript D to denote alignment with the axes x_D and y_D (see Figure Fig. 7). The data for these profiles was averaged for 3600 s.

Validating the model against a point source release of a passive scalar acts to validate the integrative effects of the modelled flow field (both within and above the UCL) and the treatment of scalars in the model (in particular the κ -advection scheme).

690 Comparison of the (a) normalised scalar concentrations φ and (b) root-mean-square concentrations of the wind tunnel experiments of DAPPLE and simulation along the axis x_r for a point source scalar release at position S.

Figure 10 displays the normalised mean pollutant concentration and variance along the axis x_r (as defined in Figure 7). Marylebone Road (the axis x_s) from a point source scalar release at position S (see Fig. 7), normalised with the reference wind speed u_{ref} , reference height h_m , and scalar source flux q_φ (Carpentieri and Robins, 2010). The simulation is shown to provide a very close agreement to the results obtained in the wind tunnel wind-tunnel experiment both in terms of the mean concentration and the normalised root mean square concentration. Validation metrics for the mean concentration along the axis x_s are shown in Table 2. This finding validates the application of uDALES to model pollution dispersion within realistic urban morphologies.

4.2 Verification of surface energy balance

700 To study the behaviour of the surface energy balance in uDALES a simple case has been set up devised. The boundary conditions are periodic in x and y and a zero-flux boundary is imposed at the top. The geometry layout is shown in Figure 11 and the Fig. 11a. The scenario parameters are listed in table Table 3.

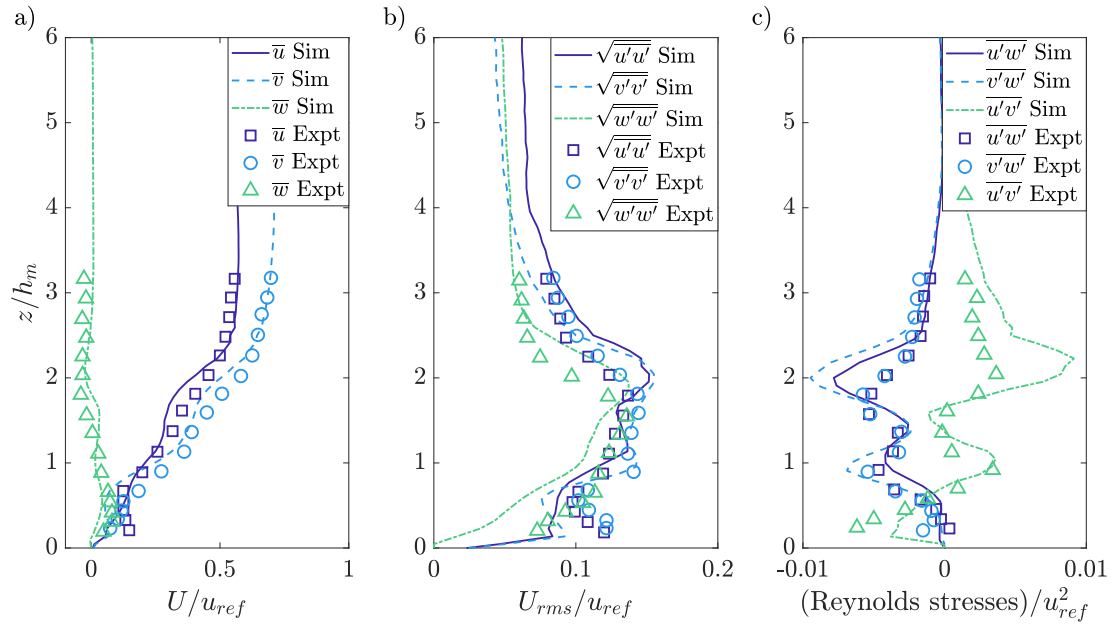

Figure 9. Vertical profiles of the **mean velocities** (a), **root-mean-square mean velocities**, (b) **root-mean-square velocities** and **Reynolds stresses** (c) **Reynolds stresses** at position **R** P_1 (see Fig. 7). Plotted against the **wind tunnel** wind-tunnel experiment results of the DAPPLE project.

Figure 10. Comparison of the normalized (a) mean scalar concentrations $\bar{\varphi}$ and (b) root-mean-square concentrations $\sqrt{\varphi' \varphi'}$ of the wind-tunnel experiments of DAPPLE and simulation along the axis x_s for a point source scalar release at position **S** (see Fig. 7).

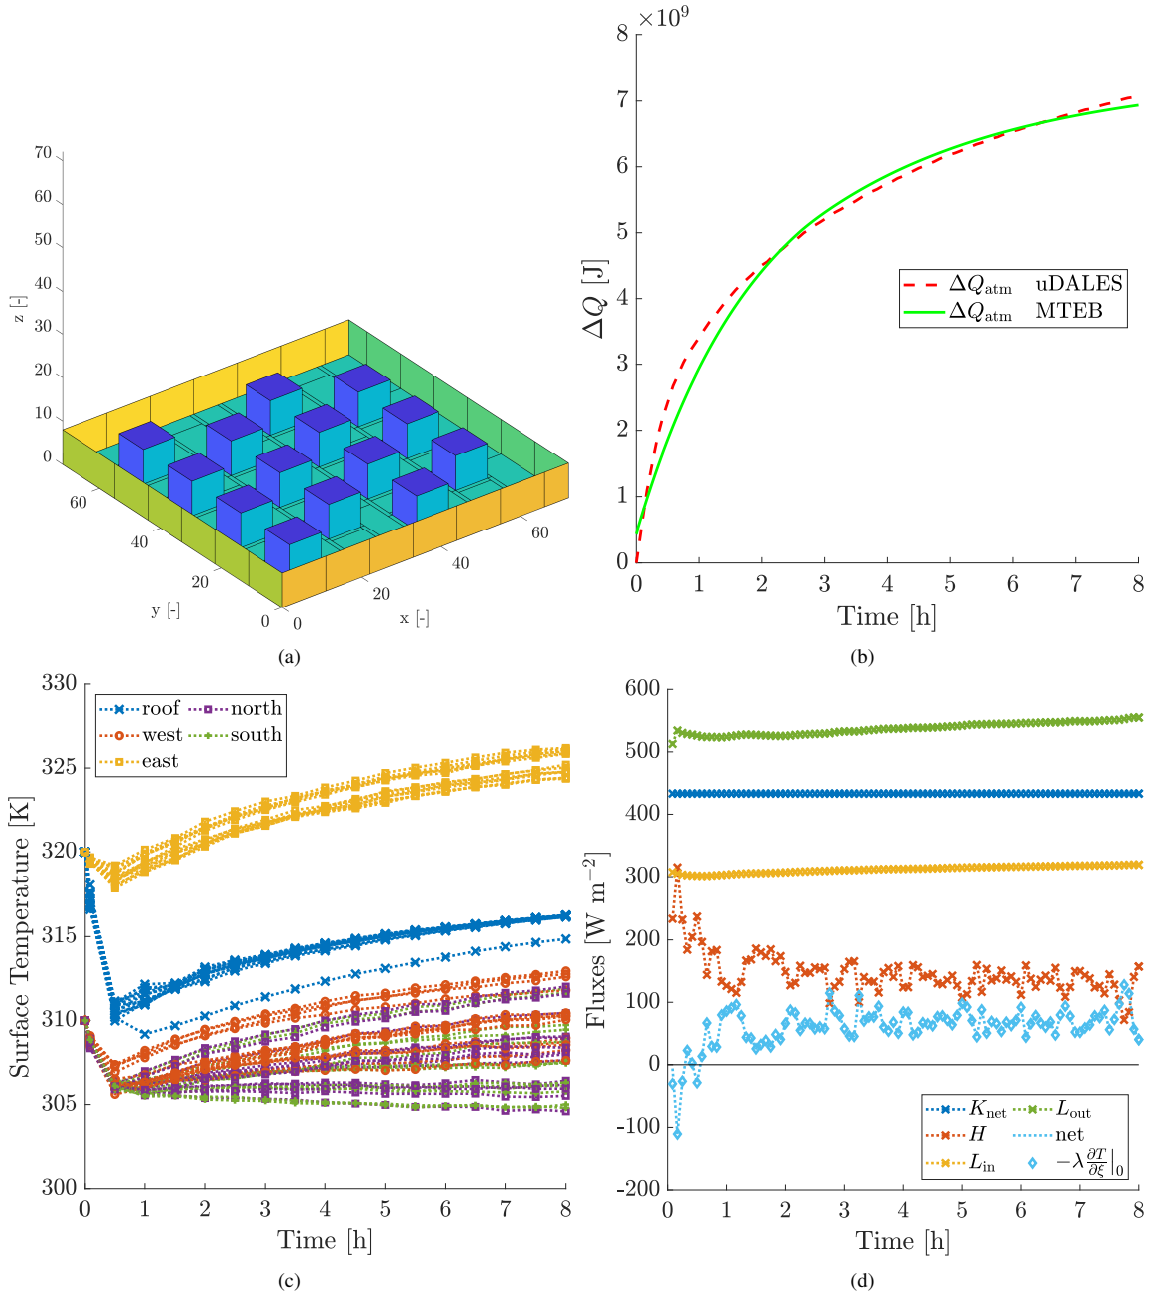

Figure 11. (a) Geometry of the surface energy balance test case. (b) Comparison between uDALES and MTEB of the total energy change of the air over time. (c) Temperature evolution of all building facets. (d) Energy fluxes of a single floor facet.

Table 3. Scenario parameters of the surface energy balance test case .

Property	Value	Property	Value
Domain size [m]	$72 \times 72 \times 72\text{m}$	Facet emissivity	0.85
Solar elevation zenith (Z) [$^\circ$]	45° 45	Nr. of wall layers	3
Solar azimuth (Ω_h) [$^\circ$]	90° , E 90	Wall thickness [m]	$3 \times 0.1\text{m}$
I Direct normal solar radiation (I) [W m^{-2}]	750W m^{-2}	Road thickness [m]	$3 \times 0.33\text{m}$
Diffuse sky radiation (D_{sky}) [W m^{-2}]	100W m^{-2}	Freestream velocity U (U) [m s^{-1}]	2m s^{-1}
$L_{\text{sky}}^\downarrow$ Sky longwave radiation ($L_{\text{sky}}^\downarrow$) [W m^{-2}]	200W m^{-2}	Building temp. temperature (T_B) [K]	301K
Facet albedo	0.5	Initial air temp. temperature [K]	300K

The focus here lies in is on the interaction of LES, wall function and surface energy balance. The sensible heat flux H is calculated by the wall function at every LES time-step ($O(1s)$) and the heat is added/removed from the fluid. This flux is integrated between energy balance time-steps by using Eq. (46) with $\Delta t_E = 300$ s. For the boundary conditions chosen, the temperature change of the fluid has to equal the total energy flux from the surface.

Figure 11c shows the temperature evolution of all facets. It is evident that the temperatures will largely be influenced by the solar radiation, accordingly east-facing facets are the warmest. Furthermore, one of the roof facets was given green roof properties, resulting in lower surface temperatures and it clearly stands apart from the other roofs.

Figure 11d shows the surface fluxes of a single road facet. Net shortwave radiation K is unchanged throughout the simulation and L only varies slightly since most facets don't experience a large surface temperature change. The sensible heat flux H shows fluctuations due to the turbulent nature of the flow. Figure 11d also demonstrates that the net flux ($K + L + H$ $K + L - H$) matches the ground heat flux ($\lambda \frac{\partial T_0}{\partial z} - \lambda \frac{\partial T}{\partial \xi} \Big|_0$) predicted by the energy balance, verifying that the energy balance is correctly linked to the wall functions.

The case presented in this section is very idealised and is thus well suited to also be studied with the urban energy balance model MTEB (Suter et al., 2017). Most of the parameters can be carried over directly. Solar/radiation properties, air temperature and surface properties are identical to table 3. To obtain the idealised canyon geometry in MTEB we can consider the total area covered by buildings and roads. This results in a building width $b = 72 \cdot (14 \cdot 8^2)/(72^2) = 12.44$ m, canyon width $l = 72 - 12.44 = 59.56$ m and a building height $h = 8$ m. Indeed, the geometries have been chosen to allow close correspondence between the two-dimensional MTEB and the three-dimensional uDALES. MTEB represents the urban canopy as a canyon, with the canyon orientation eliminated by integrating relevant equations horizontally over 360° . Most of the parameters can be carried over directly. Solar/radiation properties, air temperature and surface properties are identical to Table 3. To obtain the idealised canyon geometry in MTEB it was attempted to maintain the same morphology parameters. Considering the area covered with buildings results in a building width $b = 72\text{m} \cdot 14 \cdot (8\text{m})^2/(72\text{m})^2 = 12.44$ m. The canyon width is then given by $l = 72\text{m} - 12.44\text{m} = 59.56$ m and the building height remains $h = 8$ m. The initial surface temperatures in MTEB were chosen to be the mean of the corresponding facets in uDALES. The energy balance of the entire domain is determined by the

balance of the net shortwave and net longwave at the top. The effective albedo of the topography can be calculated in uDALES since the absorbed shortwave of all facets and the incoming shortwave at the top is known. Whereas all Although the facets have an albedo of 0.5 the resulting effective albedo is ≈ 0.35 due to radiation trapping. In MTEB the resulting effective albedo is 0.37 and thus which is in good agreement. The net longwave radiation on the other hand evolves during the simulations since the surface temperatures change. Figure 11b shows the total energy in the system over time for both the uDALES and MTEB runs. The canyon in MTEB does not have a heat capacity, this which leads to an initial jump of energy in the system at the start of the simulation. Over time the two curves agree well. Since the two models are completely independent this is a good indication that the surface scheme in uDALES produces plausible results.

735 4.3 East Side Eastside demo

To highlight the capabilities of the model developed in this dissertation, this chapter uDALES, this section discusses the effect of the installation of a green roof on a single building has on the local microclimate. The test area is the Imperial College campus in South Kensington, London. The green roof was installed on the “Eastside ” building. The meteorological conditions were those of 21st June 2017, Eastside building, with the motivation being that green roofs tend to be cooler than conventional roofs and can therefore improve outdoor thermal comfort on warmer days. uDALES was used to study how the flow, humidity, temperatures, and the hottest day in Heathrow, London in 2017. Air temperatures reached 35 surface energy balance are influenced by the presence of a green roof in comparison to a conventional roof.

The simulation domain consists the Imperial College campus, including Eastside, as well as several other surrounding buildings. The geometry was constructed using a surface elevation map raster at 1 m resolution, obtained from GIS data. In this process, the map was rotated to broadly align with the streets and the building heights in the simulation were set to the average of the mean and maximum heights in the GIS data. The resulting geometry is shown in Fig. 12, with the area shown in the later 3D plots highlighted in red.

The meteorological conditions were based on the 21st of June 2017, the hottest day in London that year. The wind was approximately easterly, so the flow is from the right of Fig. 12. The direct normal solar radiation (I) and diffuse sky radiation D_{sky} were determined following ASHRAE (American Society of Heating Refrigerating and Air-Conditioning Engineers Inc., 2011). Specifically, $I = A \exp(-B/\cos(Z))$, where Z is the solar zenith, and $D_{\text{sky}} = CI$, with $A = 1088 \text{ Wm}^{-2}$, $B = 0.205$, $C = 0.134$. The sky longwave was given by Swinbank’s model: $L_{\text{sky}} = 5.31 \times 10^{-13} \times T_{\text{air}}^6$, where T_{air} is the air temperature (Swinbank, 1963). The conventional facet properties are taken from (Bohnenstengel et al., 2011), and the green roof properties are taken from (Oke et al., 2017). The energy balance parameters and facet properties are presented in Tables 4 and 5, respectively.

The horizontal domain size is 960 m \times 480 m with a resolution of 2.5 m in each dimension. Vertically the grid was 2.5 m within the canopy and gradually stretched above to a total height of 768 m, resulting in 384 \times 192 \times 192 grid points. The simulation (10 h) was run on 16 CPUs on a single workstation for ≈ 125 hours. The lateral boundary conditions were periodic and 7 hours of neutral conditions were simulated to allow the development of turbulence in the domain. The facets were initialised with outside temperatures corresponding to their radiative equilibrium and a linear internal temperature profile. The

radiative equilibrium temperatures are generally too hot and for applied studies of the urban environment it is important to consider these initial conditions carefully. It was assumed that unlimited water for evaporation was available in the soil. The atmosphere was set to a uniform temperature of 300K. The spin-up was then continued for an additional hour to allow the development of thermal effects and convection. After 8 hours two simulations with and without green roof on “Eastside” were run for an additional hour and then compared. Inflow-outflow boundary conditions were used, employing a precursor simulation to generate the inflow. The precursor simulation geometry consists of staggered cubes with a side length of 30 m (approximately equal to the mean building height in the target simulation) and a spacing of 10 m. This gives $\lambda_p = \lambda_f = 0.5625$, which is reasonable for Central London (Sützl et al., 2021a). The precursor was run for 9 hours and the outlet plane is written to file every 0.5 s starting from 1 hour, thus generating 8 hours of inflow data for the target simulation. The domain-averaged velocity was kept constant at $U = 4 \text{ m s}^{-1}$. The details for the simulations are shown in Table 4. The simulations were run on ARCHER2 using 96 cores, and took about 18 hours of wall time.

It is to be noted that due to the nature of the simulations differences in velocities and scalar quantities can be caused by a number of effects and not just the direct presence of the green roof. The slight perturbation of the initial and boundary conditions can lead to substantial differences after some time and due to the strongly coupled nature of the system complex flow patterns can emerge and turbulent structures can persist for a prolonged period. Furthermore transient processes are present, driven by

(a) Morphology of South Kensington Campus and surroundings divided into building blocks and overlaid over aerial image. (b)

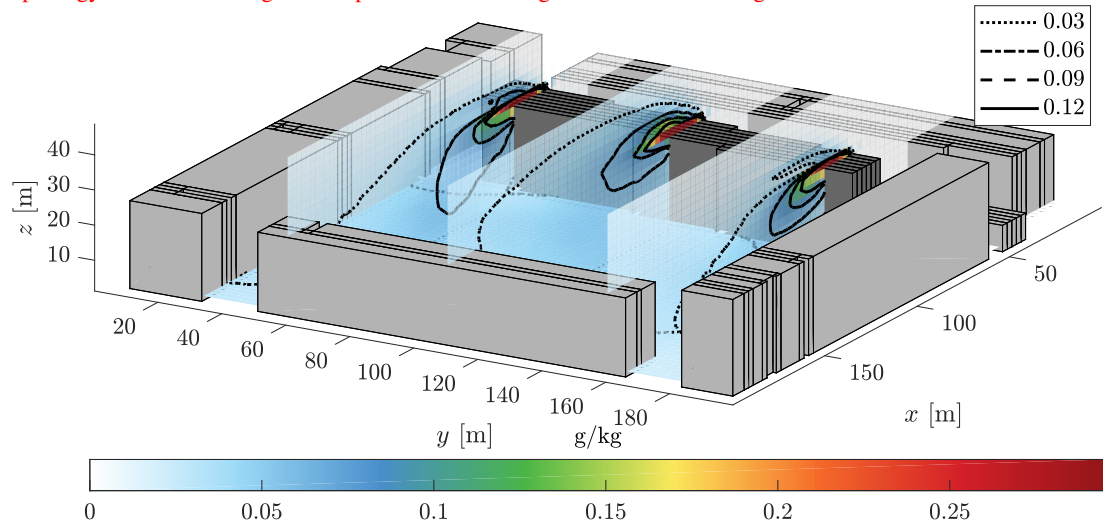

Figure 13. Three vertical and one horizontal slices through difference between final one-hour means of simulations with (q_{GR}) and without green roof(q). “ Eastside ” building coloured in darker grey.

the slow warming of the entire domain. The mean quantities of the simulations will consequently evolve over time and ideally ensembles runs would be studied for statistics.

While cooler roof temperatures can be significant for indoor climate, most of the outdoor activities take place on street level. LES is ideal to study how the air from above the roofs is transported and mixed throughout the atmosphere.

780 **Figure ??b** Figure 13 shows the difference between final one-hour means of the specific humidity field from a simulation for simulations with and without the green roof. We can observe clear downward mixing. The green roof is a source of humidity, as expected. Clear downward mixing can be observed in the building wake. Since there is no other humidity source in the domain, the humidity difference can be attributed entirely to the presence of the green roof. On street level a mean increase in specific humidity of $0.01 \text{ g kg}^{-1} - 0.1 \text{ g kg}^{-1}$ can be observed. This corresponds to a an almost insignificant
 785 difference in relative humidity, since at 30°C 301 K a relative humidity change of 1% equals a specific humidity change of $\approx 0.3 \text{ g kg}^{-1}$.

Facet temperatures at the end of the simulation are visualised in Figure 14a. Figure 14 shows the facet temperatures at the end of the simulation with the green roof. Temperature maxima of up to 340 K occur in west and south facing walls exposed to the sun, with temperatures up to 335 K or 62°C . North and East facing facets on the other hand whereas north- and east-facing facets are close to the air temperature of $\approx 303 \text{ K}$ (not visible). While roofs are exposed to a large shortwave forcing, the sensible heat flux is usually larger than for vertical surfaces due to the higher tangential wind velocities, leading to somewhat cooler surfaces. air temperature. The green roof stands clearly apart from other roofs; the temperature remains also very close to the air temperature even though it is directly exposed to the sun. The resulting latent heat flux from soil and vegetation leads to a surface temperature reduction of $\approx 10 \text{ K}$, with a reduction of over 20 K relative to the surrounding conventional
 790

Figure 14. a) “ Eastside ” building and its surrounding with building . Building facets are coloured based on their final surface temperature. Floors are not colored for clarity, grey surfaces are building internal. View from direction of the sun. (b) Internal Final internal roof temperature profiles for simulations with and without green roof on the “ Eastside ” building. The roof coordinate is initial temperatures were 301 K throughout the reverse of the depth z defined in Fig 5. It points from the roof interior to the outside .

795 roofs . This can also be seen when comparing in Fig. 14, which compares the internal temperature profiles of a simulation with and without green roof in Figure 14b profile of the Eastside roof in each case . The temperature profiles between the four eleven resolved points were reconstructed following Eq. 36. From Figure 14b it is also evident that the initial temperatures of the roofs were chosen too high and the roof has been cooling down over time highlighting the importance of accurate initial conditions. Yet, this is nearly impossible to avoid since the internal temperature profiles are usually not known and depend on
 800 past environmental conditions due to their long associated timescale. (36). Clearly, the conventional roof has absorbed much more heat in the duration of the simulation than the green roof as is evident from the much higher temperatures throughout the roof.

Figure 15 shows the temperature evolution and surface energy fluxes of the “Eastside” heat fluxes of a single facet located on the Eastside roof for both cases. The surface temperatures of both the conventional and green roof decrease start at 301
 805 K and increase over the course of the simulation. The temperature reduction is largely driven by the latent heat flux (E) and by the sensible heat flux (H) for the green and the conventional roof, respectively. For the green roof the radiative fluxes on the facet surface almost balance. Net Since the incoming flow is almost identical for the conventional and green roof cases, the differences are caused mainly by the differences in facet properties. The net shortwave radiation (K_{net}) and the incoming longwave radiation (L_{in}) act to heat the surface. K_{net} does not change during the simulation , since the solar position

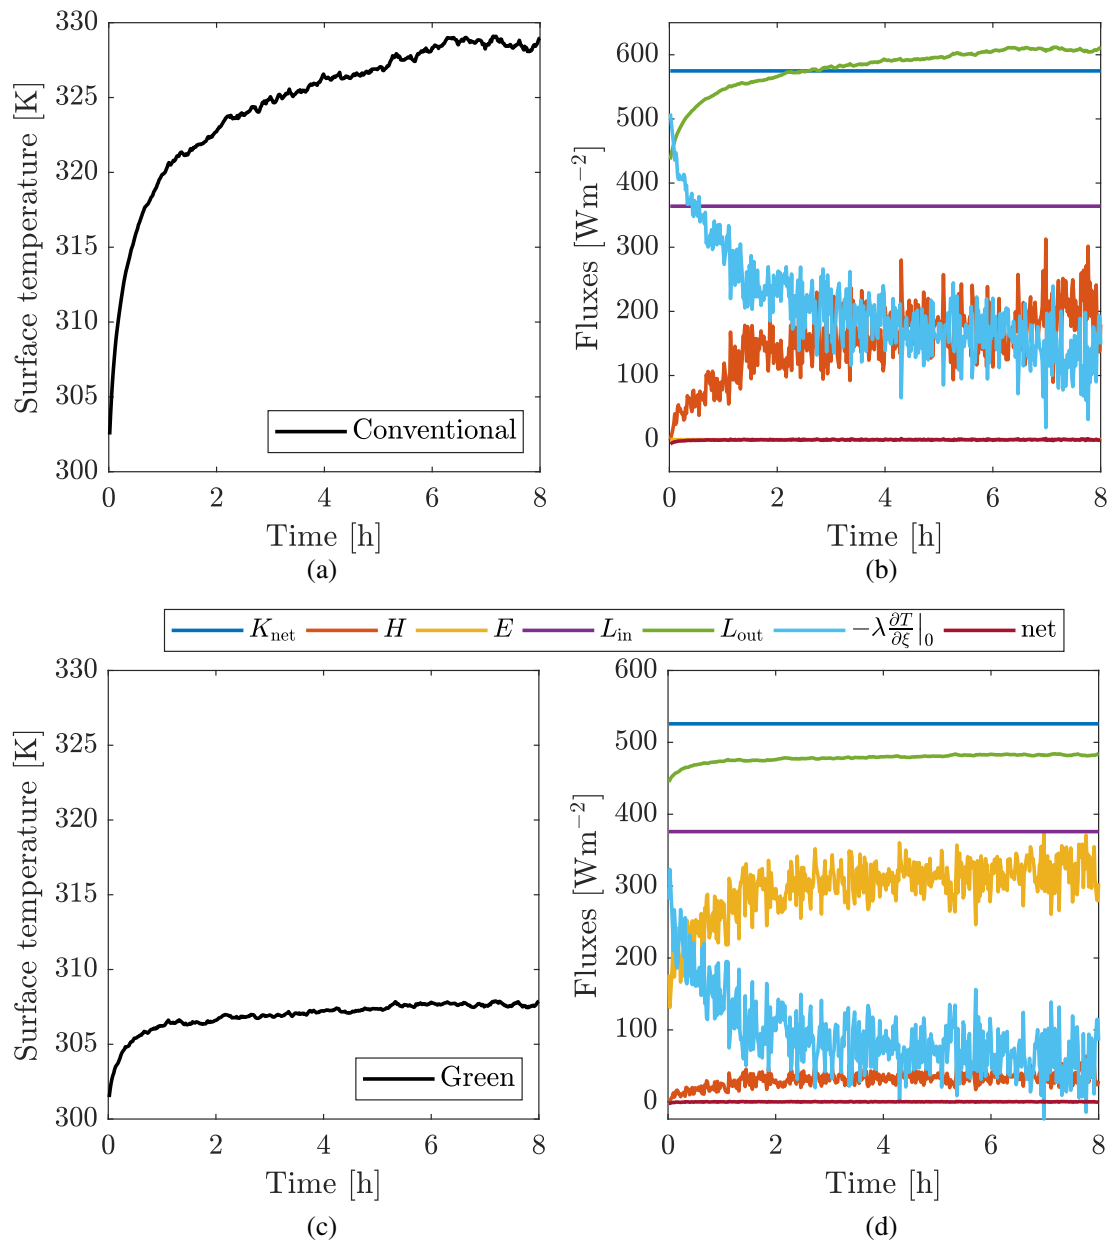

Figure 15. (a) Temperature evolution of a conventional roof facet and the corresponding surface energy fluxes (b). (c) Temperature evolution of a green roof facet and the corresponding surface energy fluxes (d).

810 does not change. There is a minute shift , and is higher for the conventional roof due to its lower albedo. There are small variations in incoming longwave radiation (L_{in}) due to the temperature change of surrounding facets. However, only a tiny fraction of the field of view of a roof facet on “Eastside ” Eastside is occupied by other facets; the sky constitutes the largest part. Under the given circumstances the remaining terms act to cool the surface. The magnitude of the emitted longwave (L_{out}) follows the Stefan-Boltzmann law and decreases along with the facet increases along with surface temperature.

815 The remaining three fluxes are the surface conductive heat flux ($\lambda \frac{\partial T_s}{\partial z}$), the sensible and the latent heat flux . These three fluxes vary more substantially on short timescales. The surface energy balance was calculated every ten seconds and thus the turbulent fluctuations of the sensible and sensible heat flux (H) and latent heat flux can still be distinguished. For the green roof the sensible heat flux is relatively small, since the temperature difference to the air is minor. The net energy loss that leads to the cooling is thus caused by evapotranspiration from the vegetation. The latent heat flux is also a function of the

820 temperature difference to the air and we can see a decline over time. For the conventional roof the radiative fluxes are close to balance as well, but no evapotranspiration is possible and $E = 0$. The strong temperature difference initially leads to very large sensible heat fluxes. The large temperature gradient within the roof further causes substantial heat conduction into the roof. As the surface cools down these fluxes also taper off. (E) vary more substantially on short timescales due to the turbulent transport. The green roof is able to evapotranspire, resulting in a non-zero latent heat flux and comparatively less heating of the

825 surface than the conventional roof and thus a smaller sensible heat flux. The soil moisture was kept at field capacity during the simulation, enabling the high latent heat flux. The fact that the surface is warmer than the interior results in a conductive heat flux ($-\lambda \frac{\partial T}{\partial \xi} |_0$) into the facet. Finally, the sum of these terms can be seen to be zero, which confirms that the surface energy balance is satisfied.

(a) temperature evolution of a green roof facet and the corresponding surface energy fluxes. (b) Temperature evolution of a conventional roof facet and the corresponding surface energy fluxes. The markers are for the sake of clarity, the data was plotted every 10 s and the markers do not correspond to particular data points.

5 Concluding remarks

The A new urban LES model uDALES 1.0 was presented in this article. The inclusion of explicit representation of buildings as well as energy, vegetation and chemistry processes into a high-resolution atmospheric LES opens a multitude of

835 new possibilities in terms of simulating urban air quality and the urban climate. The model parts have been verified or validated and results are shown here or referenced accordingly: in section 2.5.1 the implementation of the wall function is verified against simulations by Cai (2012a), where we find good agreement in temperature values and distribution for flow over a canyon-like geometry; the scalar transport, building representation, turbulence and advection models are validated against wind tunnel experiments in section 4.1. Modelled wind velocities and Reynolds stresses soundly agree with the experiments and the scalar

840 concentrations match very well; the general performance of the implemented surface energy balance is verified in section 4.2 by comparing with an urban energy balance model.

The All model parts of uDALES were verified or validated: the wall functions (section 2.5.1), scalar transport, building representation, turbulence and advection models (section 4.1) and the surface energy balance (section 4.2). Good agreement between uDALES and the comparison data was observed in all cases. The inclusion of explicit representation of buildings as well as energy, vegetation and chemistry processes into a high-resolution atmospheric LES model permits the study of a multitude of applications, ranging from the attribution of the urban heat island effect to various processes such as radiation trapping or heat storage in the built environment, air quality studies at very high resolutions to investigate hotspots and real-time pedestrian exposure, to the effect of urban vegetation on the outdoor climate and the energy budget of buildings. The validation and verification cases already hint at demonstrated a number of possible these applications of uDALES and in section 4.3 a showcase of the full model capabilities is demonstrated. uDALES has been used to Improved simulations of the urban microclimate can be performed with uDALES, in particular to study: the effect of urban vegetation on the outdoor climate and the energy budget of buildings; the attribution of the urban heat island effect to various processes such as radiation trapping or heat storage in the built environment; pollutant transport and reaction with very high resolutions to investigate hotspots and real-time pedestrian exposure section 4.3 demonstrated an urban climate application of uDALES in a single case.

The effect of urban trees is currently widely studied and initial steps have been undertaken to include tall vegetation into uDALES (Grylls and van Reeuwijk, 2021). Trees can have a significant influence on pedestrian-level air quality and temperature; their interaction with . However, they influence a variety of processes such as radiation, latent heat and turbulence generation demand a , which require very careful consideration, however. The huge parameter space of cities make general conclusions from simulations difficult. It is therefore of great interest to be able to simulate a variety of similar cases, where as few parameters change as possible. The modelling of buildings on a Cartesian grid with immersed boundaries allows an effortless set-up of idealised urban layouts. uDALES is currently being further developed to incorporate automatically generated urban landscapes, with which one can study the effects of various building configurations linked to parameters such as plan and frontal area density (Sützl et al., 2021b). A systematic study of building patterns addresses the complexity gap in current urban studies between idealised building geometries and case specific real urban geometry. . This functionality will be incorporated in the main branch of uDALES in a future release. The availability of an urban LES is ideal for the study of urban areas with reduced complexity. Indeed, the huge complexity of cities make it nearly impossible to draw general conclusions. uDALES can import idealised fractal-like urban landscapes from the Urban Landscape Generator (Sützl et al., 2021b). This tool generates urban landscapes keeping key morphological indicators such as plan- and frontal-area density constant. A systematic study of building patterns addresses the complexity gap in current urban studies between idealised building geometries and case specific real urban geometry. The combination of uDALES and Urban Landscape Generator was used to develop a distributed drag parameterisation (Sützl et al., 2021b) which was subsequently tested with the Met Office London Model (Sützl et al., 2021a). uDALES remains in active development; ongoing work includes an upgrade of the parallelisation to 2D by aligning uDALES with the open-source DNS code XCompact3D (Bartholomew et al., 2020) through the 2D domain decomposition library 2DECOMP&FFT (Li and Laizet, 2010).

Code availability. The code of uDALES has been published on <https://github.com/uDALES/u-dales>. The provided model input files are for uDALES v1.0.1 (commit id 6429fd3). We encourage contributions by other users.

Data availability. All the output data and scripts to produce the relevant figures are available on Zenodo: <https://doi.org/10.5281/zenodo.5480826>. The model input for the comparison with Cai (2012a, section 2.5.1), the model validation (section 4.1), test of the energy balance (section 4.2) and the show case (section 4.3) have also been included. A general guide on how to set up the model and examples are available on the code repository.

Author contributions. IS authored the article and prepared tables and figures. IS initially set-up and validated DALES on Imperial College infrastructure, adopted the model development by Tomas et al. (2015) and added and validated facets, wall-functions, wall energy and water balances. TG extended the model with emission and nitrogen oxide/ozone chemistry capabilities, as well as inflow boundary conditions. TG, BSS and SOO conducted the comparison with DAPPLE and authored the corresponding section. SOO and CEW conducted the Eastside demo simulations. MvR acquired funding and supervised the model development. All authors edited the paper text.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. The authors wish to acknowledge the support of the European Institute of Technology, Climate KIC Innovation project Blue Green Dream; EPSRC Centre for Doctoral Training in Sustainable Civil Engineering (grant reference EP/L016826/1); EPSRC Mathematics of Planet Earth Centre for Doctoral Training (Grant Reference EP/L016613/1); and the computational resources for this work were provided by the Imperial College high-performance-computing facilities and the national supercomputers ARCHER and ARCHER2. Resources for the latter were provided by the EPSRC-funded UK Turbulence Consortium (grant reference EP/R029326/1) .

We would like to extend our gratitude to Prof. Harm Jonker and Dr. Jasper Tomas who thoroughly introduced us to the DALES model, and to David Meyer and Sam Owens for their contribution to the code availability and maintenance. for his contribution to making the code open-source and professionalising the workflow. Furthermore, we would like to thank Prof. Alan Robins and Prof. Zheng-Tong Xie for providing the DAPPLE wind tunnel data and geometry. MvR is grateful to Prof. Cedo Maksimovic for enthusing him to work on urban fluid mechanics problems.
