## 15 **Abstract**

16 Understanding uncertainties and sensitivities of projected ecosystem dynamics under environmental change is of immense  
17 value for research and climate change policy. Here, we analyze sensitivities (change in model outputs per unit change in  
18 inputs) and uncertainties (changes in model outputs scaled to uncertainty in inputs) of vegetation dynamics under climate  
19 change, projected by a state-of-the-art dynamic vegetation model (LPJ-GUESS v4.0) across European forests (the species  
20 *Picea abies*, *Fagus sylvatica* and *Pinus sylvestris*), considering uncertainties of both model parameters and environmental  
21 drivers. We find that projected forest carbon fluxes are most sensitive to photosynthesis-, water- and mortality-related  
22 parameters, while predictive uncertainties are dominantly induced by environmental drivers and parameters related to water  
23 and mortality. The importance of environmental drivers for predictive uncertainty increases with increasing temperature.  
24 Moreover, most of the interactions of model inputs (environmental drivers and parameters) are between environmental  
25 drivers themselves or between parameters and environmental drivers. In conclusion, our study highlights the importance of  
26 environmental drivers not only as contributors to predictive uncertainty in their own right, but also as modifiers of  
27 sensitivities and thus uncertainties in other ecosystem processes. Reducing uncertainty in mortality related processes and  
28 accounting for environmental influence on processes should therefore be a focus in further model development.

## 29 **1. Introduction**

30 Terrestrial ecosystem models have emerged in the last three decades as a central tool for decision making and basic research  
31 on vegetation ecosystems (Cramer et al., 2001; Fisher et al., 2018; IPCC, 2014; Smith et al., 2001; Snell et al., 2014).  
32 Projections from different vegetation models, however, often disagree on important details, for example regarding the  
33 observable past (Bastos et al., 2020) or the future carbon uptake of forest ecosystems (Huntzinger et al., 2017; Krause et al.,  
34 2019). Among the possible reasons for such differences is the uncertainty in climate scenarios (Saraiva et al., 2019), model  
35 structural uncertainty (Bugmann et al., 2019; Oberpriller et al., 2021; Prestele et al., 2016), initial condition uncertainty  
36 (Dietze, 2017b) as well as uncertainty about the model parametrization (Grimm, 2005), which in turn make models'  
37 projections themselves uncertain (Dietze, 2017a). It is widely appreciated that understanding which exact factors drive these  
38 uncertainties is of immense value for directing research (Tomlin, 2013), but also to interpret and understand projections  
39 (Dietze et al., 2018). For example, the IPCC started in its Fifth Assessment Report to systematically analyze uncertainties  
40 and attribute them to model inputs (IPCC, 2014) similar to other predictive sciences (e.g. nuclear reactor safety (Chauliac et  
41 al., 2011), energy assessment for buildings (Tian et al., 2018) or policy analysis (Maxim and van der Sluijs, 2011)).

42

43 The two main tools to understand how uncertainties in model inputs (drivers, parameters, and model structure) affect model  
44 outputs are sensitivity analysis (SA) and uncertainty analysis (UA) (Cariboni et al., 2007; Caswell, 2019; Saltelli, 2002;  
45 Saltelli et al., 2008). The key difference between these two methods is that in an UA, the central starting point is the  
46 quantification of uncertainty in the model inputs (e.g. parameters, typically determined via expert elicitations and previous  
47 studies (Matott et al., 2009)). This uncertainty is then propagated to the model outputs, and back-attributed to the different  
48 inputs. An SA, on the other hand, calculates how the model output changes per unit or percentual change of the respective  
49 input (Jørgensen and Bendoricchio, 2001). This calculation is primarily independent of the inputs' uncertainties, although  
50 local SAs can be affected by the reference point and global SAs by the range over which the sensitivity is calculated.  
51 Overall, however, both methods share the goal of identifying inputs with a high influence on model outputs, with the  
52 underlying idea that better constraining these will increase robustness and reliability of model projections (Balaman, 2019).

53

54

55 Although the benefits for understanding model behavior and predictive uncertainties are obvious, relatively few SAs and  
56 UAs have been applied to complex ecosystem models and especially the widely used dynamic global vegetation models  
57 (DGVMs) that project terrestrial ecosystem responses to climate change or land management (see, e.g., Courbaud et al.,  
58 2015; Cui et al., 2019; Huber et al., 2018; Reyer et al., 2016; S. Tian et al., 2014; Wang et al., 2013). A reason for this is  
59 arguably the complex structure of most DGVMs (Fer et al., 2018), which makes SAs and UAs computationally demanding  
60 and difficult to interpret, especially when performing state-of-the-art global SAs and UAs that compute sensitivities and  
61 uncertainties across the entire parameter space (Saltelli et al., 2008) rather than just locally around a reference parameter set

62 (see e.g., Hamby, 1994). Moreover, several studies highlight that sensitivities and uncertainties of DGVMs also exist with  
63 respect to environmental drivers (Barman et al., 2014; Wu et al., 2017, 2018), especially solar radiation (Barman et al., 2014;  
64 Wu et al., 2018), temperature (Barman et al., 2014) and precipitation (Wu et al., 2017), and it is reasonable to expect that  
65 there can be interactions between parameter and environmental sensitivities, meaning that certain parameters are more  
66 sensitive in some environments than in others. It therefore seems important to investigate parametric sensitivities in  
67 conjunction with their environmental sensitivities in one combined analysis.

68

69 In this study, we concentrate on a well-established and widely applied DGVM, the Lund-Potsdam-Jena General Ecosystem  
70 Simulator (LPJ-GUESS) (Gerten et al., 2004; Sitch et al., 2003; B. Smith et al., 2001). Three previous SAs or UAs for the  
71 LPJ family identified the intrinsic quantum efficiency of CO<sub>2</sub> uptake (*alpha\_C3*) and the photosynthesis scaling parameter  
72 (from leaf to canopy) (*alpha\_a*) as the main contributors of sensitivity for net primary production (NPP) (about 50-60% of  
73 the overall sensitivity, Zaehle et al., 2005; Pappas et al., 2013) or foliage projective cover (Jiang et al., 2012). Additionally,  
74 these previous studies show that LPJ-GUESS projections of NPP and vegetation carbon pools showed high sensitivity to tree  
75 structure-related (sapwood to heartwood turnover rate, longevity of trees, Pappas et al., 2013; Wramneby et al., 2008; Zaehle  
76 et al., 2005), establishment-related (maximum sapling establishment rate, minimum forest floor photosynthetically active  
77 radiation for tree establishment, Jiang et al., 2012; Wramneby et al., 2008; Zaehle et al., 2005), mortality-related (threshold  
78 for growth suppression mortality, Pappas et al., 2013) and water-related parameters (minimum canopy conductance not  
79 associated with photosynthesis, maximum daily transpiration, Pappas et al., 2013; Zaehle et al., 2005). Regarding  
80 uncertainties, strong impacts on LPJ-GUESS projections of NPP and vegetation carbon pools (FPC for Jiang et al., 2012)  
81 were found for photosynthesis related parameters (Jiang et al., 2012; Zaehle et al., 2005), but also for water-related  
82 (minimum canopy conductance not associated with photosynthesis, Zaehle et al., 2005) as well as structure-related  
83 parameters (tree leaf to sapwood area ratio, crown area to height function Jiang et al., 2012), whereas soil hydrology  
84 parameters were not identified as very sensitive in earlier studies (Pappas et al., 2013).

85

86 Since the publication of these studies, however, the structure of the LPJ-GUESS model changed substantially. The most  
87 important changes are the inclusion of the nitrogen cycle (Smith et al., 2014) and new management modules (Lindeskog et  
88 al., 2021). Since these changes, no study has systematically examined how model sensitivities and uncertainties were  
89 affected by the new model structure. Moreover, previous SAs and UAs ignored management parameters, which, however,  
90 are expected to have large impacts on carbon pools and fluxes (Lindeskog et al., 2021).

91

92 A further limitation of most previous studies for LPJ-GUESS and other models (e.g. Mäkelä et al., 2020) is that they either  
93 analyzed sensitivities and uncertainties to parameter changes, or to changes in the environmental drivers, but not both. As  
94 discussed earlier, however, there are good reasons to expect that the sensitivity of parameters will change if environmental  
95 drivers change. Given that previous sensitivity analyses used different choices for these boundary conditions (different

96 sensitivities for the climate scenarios and sites in Jiang et al., 2012; for different elevations in Pappas et al., 2013; different  
97 sites in Wramneby et al., 2008), this not only limits the comparability between studies, but also questions the generality of  
98 the results for all climatic conditions. Only Jiang et al. (2012) combined parameter and driver sensitivities, but used for the  
99 latter only a number of fixed climate scenarios instead of a range of possible values, which prohibits a systematic joint  
100 analysis. Moreover, it would be interesting to compare the relative importance of drivers and parameters for the predictive  
101 uncertainty of model simulations and how these change between environmental zones (here we use the classification of  
102 Metzger et al., 2005) and thus on an environmental gradient. When sensitivities or uncertainties of parameters belonging to a  
103 specific process increase on an environmental gradient, this indicates that the process itself becomes more important on the  
104 gradient (Saltelli, 2002). By comparing such changes to existing ecological hypotheses, we can test if model sensitivities and  
105 thus process descriptions are in line with ecological expectations.

106

107 To answer these questions, we analyzed sensitivities and uncertainties in LPJ-GUESS for 200 randomly distributed sites  
108 across Europe (see Appendix A1.1). We address the issue of interactions between environmental and parametric sensitivities  
109 by simultaneously investigating uncertainty in environmental drivers (precipitation, temperature, solar radiation, CO<sub>2</sub>,  
110 nitrogen deposition) with parametric uncertainty in the most important processes (photosynthesis, establishment, nitrogen,  
111 water cycle, mortality, disturbance/management, and growth) for dynamic climate change from 2001-2100 and steady  
112 climate from 2100-2200. We simulated the most abundant tree species in Europe (*Fagus sylvatica*, *Pinus sylvestris* and  
113 *Picea abies*) individually and in mixed stands, as these species are suffering from climate change (e.g. Buras et al., 2018;  
114 Walentowski et al., 2017) and could benefit from mixed stands (e.g. Pretzsch et al., 2015). To test climate change impacts,  
115 we randomly sampled climate projections within the boundaries of RCP2.6 and RCP8.5. Thereby, our key objectives were to  
116 understand the sensitivities and uncertainties of LPJ-GUESS due to environmental drivers and parameters. We were  
117 especially interested in 1) overall sensitivities and uncertainties across European forests, 2) uncertainties per environmental  
118 zone and 3) uncertainties on a temperature gradient. Moreover, we investigated, 4) if and how environmental conditions  
119 change the uncertainties of environmental processes.

## 120 **2. Methods and Material**

### 121 **2.1. The LPJ-GUESS vegetation model**

122 LPJ-GUESS is a process-based ecosystem model that simulates vegetation growth, vegetation dynamics and biogeography  
123 as well as biogeochemical (e.g. nitrogen and carbon) and water cycles (Lindeskog et al., 2013; Olin et al., 2015; Smith et al.,  
124 2014). Ecosystem dynamic processes in the model include establishment, growth, mortality, and competition for light, space  
125 and soil resources. To simulate these processes, the model combines time steps on different scales from daily (e.g.  
126 phenological and photosynthesis processes) to yearly (e.g. allocation of net primary production to tree carbon components)

127 basis. LPJ-GUESS includes forest gap dynamics succession of cohorts (each represented by an average individual) of  
128 different plant functional types (PFTs) or species. Each PFT/species has a unique parameter set.  
129

130 In this study, we use a model version that was slightly modified from Lindeskog et al. (2021), which is based on the LPJ-  
131 GUESS 4.0 version, with a re-parameterization for spruce (*Picea abies*), pine (*Pinus sylvestris*) and beech (*Fagus sylvatica*)  
132 (see Appendix A1.2 for *Pin. syl.* and *Pic. abi.*). To account for the stochastic components of establishment, mortality and  
133 patch destroying disturbances, LPJ-GUESS simulates several replicate patches (25 for the simulation with the reference  
134 parametrization and 1 for each simulation in the SA and UA) representing “snapshots” of the grid-cell. In this model version,  
135 fire is based on the BLAZE model (Rabin et al., 2017). Thereby annually burned area is generated based on fire weather and  
136 fuel continuity and distributed to monthly intervals based on climatology (Giglio et al., 2010). Tree mortality is then  
137 estimated by computing firelines based on weather and converted into height-dependent survival probabilities (see Haverd et  
138 al., 2014) depending on empirical biome specific parameters.  
139

140 A first set of key parameters from our expert elicitation (see below) for **establishment** are the bioclimatic limits (i.e.  
141 minimum growing degree days (*gdd5min\_est*), minimum 20-year coldest month (*tcmin\_est*), maximum 20-year coldest  
142 month (*tcmax\_est*) and minimum forest photoactive radiation at forest floor (*parff\_min*)), which build the environmental  
143 envelope for establishment. Given the bioclimatic limits are fulfilled, at regular intervals new PFTs are established (here: 1  
144 year) given enough space, light, soil water and photoactive radiation at forest floor is available for establishment (B. Smith et  
145 al., 2001). Moreover, each of our three investigated species has a maximum establishment rate (*est\_max*) (B. Smith et al.,  
146 2001).  
147

148 **Structure of trees** in the model is mainly linked to the simulated growth of trees, which is triggered by allocating all net  
149 primary production (NPP) besides a reproduction debt of 10% (*reprfrac*) to tree components thereby satisfying mechanical  
150 balance (e.g. allometric eq. for the relationship between height and diameter with allometric parameters (*k\_allom2*,  
151 *k\_allom3*) (e.g. Huang et al., 1992), the relationship between tree leaf to sapwood area (*k\_latosa*) (e.g. Robichaud &  
152 Methven, 1992), the relationship between crown area and height (*k\_rp*) (packing constraint, Zeide, 1993), the maximum  
153 crown area (*crownarea\_max*) and leaf longevity (*leaflong*)) and functional balance as well as demographic constraints (Sitch  
154 et al., 2003). Each living tissue is assigned a turnover rate transferring sapwood into heartwood (*turnover\_sap*) and leaves  
155 (*turnover\_leaf*) and fine roots (turnover\_root) to litter. Investment into above and belowground growth is influenced by the  
156 resource stress as individuals are competing for light, space, nitrogen and water. Competition for light is determined by the  
157 photosynthetic response and light extinction in the canopy. Competition for space (*self-thinning*) is represented in the model  
158 via allometric equations between crown area and stem diameter (Sitch et al., 2003). Competition for nitrogen and water is  
159 determined by tree individual demand for nitrogen and water and soil availability of nitrogen and water and the PFT-specific  
160 root profile. Competition between species will favor certain life-history strategies in particular situations, for example shade-

161 tolerant (e.g. *Fagus sylvatica* and *Picea abies*) or intermediate-shade tolerant (e.g. *Pinus sylvestris*) growth responses, and  
162 dynamically changing root-to-shoot ratios.

163

164 **Tree mortality (natural or via harvest)** in the model responds to growth efficiency (ratio of annual NPP to leaf area) being  
165 too low over a 5-year period, e.g. due to light competition, maximum longevity of a PFT or changes in environmental  
166 conditions (e.g. tolerance to drought (*drought\_tolerance*) changes water uptake) exceeding the species suitable range. Light  
167 competition is modeled using the foliage projective cover (FPC), defined as the area of ground by foliage directly above it,  
168 using Beer's Law (B. Smith et al., 2011). The resulting shading mortality is distributed proportional to species' FPC growth  
169 in the respective year due to their biomass increase. Mortality is modeled inversely proportional to the growth efficiency  
170 (with a given species-specific threshold (*greff\_min*), e.g. Waring (1983)). Moreover, negative NPP of a species kills all  
171 individuals of the respective cohort. Background mortality probability increases with tree age, reaching one at the maximum  
172 longevity (*longevity*). Mortality has also a stochastic component. Natural disturbances are implemented in the model as  
173 process-based wildfires (with a given fire resistance for each species (*fireresist*)) and as patch-destroying disturbances (e.g.  
174 windthrow and landslides) with the same yearly occurrence probability for all patches (inverse of *distinterval*). Additional  
175 mortality arises from forest management activities, determined by thinning intensity (percentage of all trees cut,  
176 *thinning\_intensity*) and cutting intervals (*cut\_interval*), which can be set for each species individually. For a more detailed  
177 description of the management module and the additional management parameters see Lindeskog et al. (2021).

178

179 **Nitrogen** input is implemented in the model through nitrogen deposition (prescribed) and biological nitrogen fixation. The  
180 latter is simulated empirically as a linear function with intercept (*nfix\_a*) and slope (*nfix\_b*) of the five-year averaged actual  
181 evapotranspiration (Cleveland et al., 1999). The resulting amount of nitrogen accumulates in the ecosystem equally over the  
182 year and directly adds to the available mineral soil nitrogen pool. When nitrogen is in living tissue, a fraction (*nrelocfrac*) is  
183 re-translocated before leaf- and root shedding.

184

185 **Photosynthesis** is modeled as a function of absorbed photosynthetically active radiation, temperature (optimum temperature  
186 range for photosynthesis determined by *pstemp\_low* and *pstemp\_high*, Larcher, 1983), intercellular CO<sub>2</sub> (i.e. non-water  
187 stressed ratio of intercellular to ambient CO<sub>2</sub> (*lambda\_max*)), and canopy conductance thereby considering a species-specific  
188 respiration coefficient (*respcoeff*) (B. Smith et al., 2001) and nitrogen availability. The photosynthesis scheme is a modified  
189 version of the Farquhar photosynthesis model, but instead of prescribed values for the Rubisco capacity it is optimized for  
190 maximum net CO<sub>2</sub> assimilation at the canopy level (Smith et al., 2014).

191

192 **Water** availability for plants is based on precipitation and snowmelt in the two-layer soil hydrology submodule (for details  
193 see Hickler et al., 2004; Smith et al., 2001). Vegetation transpiration and evaporation (with a maximum evapotranspiration  
194 rate (*emax*)) from bare ground and leaves reduce water availability as well as runoff from saturated soil (Sitch et al., 2003).

195 Water vapor exchange by the vegetation canopy is calculated on a daily basis within the photosynthesis scheme (e.g.  
196 minimum canopy conductance not associated with photosynthesis (*g<sub>min</sub>*)). The water supply and transpirative demand are  
197 calculated on a daily basis and converted into a drought-stress coefficient. Given this coefficient, the investment in roots at  
198 the costs of leaves is calculated.

## 199 **2.2. Simulation setup**

200 We selected 200 study sites (see Appendix A1.1) spatially and environmentally stratified over Europe by applying random  
201 stratified sampling (using the R package *splitstackshape* Mahto, 2019) with longitudinal and latitudinal coordinates as well  
202 as mean precipitation, solar radiation and temperature as categories based on IPSL-CM5 Earth System Model CMIP5  
203 (Dufresne et al., 2013) climate data. We chose 200 sites as a compromise between the high computational demand of  
204 running LPJ-GUESS multiple times for all sites and a good spatial as well as environmental coverage of Europe. For these  
205 sites, we performed simulations for each of the three most common species in Europe (*Fagus sylvatica*, *Pinus sylvestris* and  
206 *Picea abies*) as monospecific stands and additionally all three species together as mixed stands.

207  
208 The simulation period was from 1861 to 2199. To start the simulations with equilibrium C pools and fluxes, we spun up LPJ-  
209 GUESS vegetation and soil carbon and nitrogen pools to pre-industrial equilibrium by recycling the 1861 to 1900 climate,  
210 the 1861 CO<sub>2</sub> concentration (Meinshausen et al., 2011) and nitrogen deposition. For the transient and future simulation runs,  
211 we used the bias-corrected monthly IPSL-CM5 Earth System Model CMIP5 (Dufresne et al., 2013). From this data set, we  
212 extracted temperature, precipitation, number of wet days per month, and incoming solar radiation from 1861 to 2099 for  
213 RCP4.5 as base scenario and RCP2.6/RCP8.5 as lower/upper boundaries for the climate ranges (see below). In addition to  
214 these data, monthly nitrogen deposition was extracted from Lamarque et al. (2013) and soil texture data from Batjes (2005).  
215 All these driving data had a spatial resolution of 0.5°x 0.5°. We recycled detrended data from 2090-2099 for all  
216 environmental drivers except CO<sub>2</sub> and nitrogen deposition and used these as potential stable climates for the 2100-2199  
217 period.

218

## 219 **2.3. Selection of parameters and drivers and their ranges**

220 The a priori selection of the most influential parameters that can be specified in the parameter file and their ranges was based  
221 on our expert knowledge (following the SHELF expert elicitation protocol, see Gosling, 2018) and a literature review. The  
222 resulting eleven (= 33%) parameters common for all species and 22 (= 20%) species-specific parameters (see Table 1) were  
223 grouped to the specific processes they contribute most to (Table 1, Grouping).

224

225 From the environmental drivers of the model, we selected incoming solar radiation, temperature, precipitation, atmospheric  
226 CO<sub>2</sub> and nitrogen deposition for our analysis. To obtain uncertainties for temperature, precipitation and solar radiation, we

227 calculated the mean deviations of RCP8.5/RCP2.6 to our base scenario RCP4.5 plus/minus one standard deviation as  
228 maximal/minimal per site. As the CO<sub>2</sub> data is global and not site-specific, we calculated ranges from the global data set  
229 (RCP2.6 as minimum, RCP8.5 as maximum) averaged over time and plus/minus a standard deviation. For nitrogen  
230 deposition, we used RCP6.0 as maximum and RCP2.6 as minimum with the same procedure as for the other drivers.  
231

## 232 **2.5. Sensitivity analysis and uncertainty analysis**

233 LPJ-GUESS predicts a substantial number of output variables, which could all be examined regarding their sensitivities and  
234 uncertainties. Here, we concentrate on carbon outputs (**gross primary production GPP**, **total standing biomass TSB** and  
235 **net biome productivity NBP**), because of forests' role for carbon cycling (Bonan, 2008), their large contribution to the land  
236 carbon sink (Pugh et al., 2019) and the economic importance of tree growth for forest owners (Pearce, 2001).  
237

238 Sensitivities and uncertainties were calculated by Monte-Carlo sampling from the assumed multivariate parameter and  
239 climate uncertainty. For the monospecific / mixed simulations, we drew respectively 10.000 / 50.000 parameter and climate  
240 combinations randomly from the prespecified uncertainty ranges, and ran the model based on these combinations for each of  
241 the 200 sites. Note, that for mixed simulations, for each simulation we individually drew parameter combinations for each  
242 species, i.e. the same parameter could be different for different species. In total, this means that  $200 \times (50.000 + 3 \times 10.000)$   
243 = 16 million LPJ-GUESS simulations were run.  
244

245 We quantified sensitivity and uncertainty indices by running multiple linear regressions with the model output averaged over  
246 time as response, and parameters and drivers as well as their second order interactions as predictors. With 200 sites, each  
247 having three monospecific and one mixed stands setup, we overall ran  $200 \times (3 + 1) = 800$  linear regressions. This analysis  
248 corresponds to a global SA/UA in the context of regression analysis and has been applied to other system models (e.g. Sobie,  
249 2009). The estimated effects from the regression can be interpreted as sensitivities, as the effect of a unit change of the driver  
250 on the response (model output) is estimated. By scaling the predictors to the range [-0.5, 0.5], we obtained the corresponding  
251 uncertainties. To check whether we missed non-linear effects, we additionally applied a random forest and extracted the  
252 variable importance (following Augustynczyk et al., 2017, see Appendix A1.3.). To calculate mean sensitivities/uncertainties  
253 for each species, we averaged site-specific sensitivities over all sites with an average annual biomass production greater than  
254 2 tC/ha. We have chosen this threshold because smaller values indicate that the environment is not suitable for the species,  
255 however, for each site at least one species was able to establish. For the mixed stands, we first averaged the three species-  
256 specific sensitivities/uncertainties per site and then averaged over all sites. Mean percentual sensitivities were calculated by  
257 dividing by the mean model output, while mean uncertainty contributions were calculated by dividing by the entire

258 uncertainty budget. Thereby, positive values mean that the respective output increases with increasing parameter values,  
259 while negative values mean that it decreases.

260

261 It is important to note that uncertainties and sensitivities have different interpretations, and which of these two is more  
262 relevant strongly depends on the purpose. The calculated percental sensitivities can be interpreted as percentage change in  
263 the corresponding output, when changing a parameter value 1% in the prespecified range. The calculated uncertainties per  
264 parameter/driver can be interpreted as relative proportion of the overall uncertainty budget coming from environmental  
265 drivers and parameters. For scenario-analysis, e.g. comparing different cut intervals of forests, sensitivities provide a direct  
266 estimate of the model response, e.g. how much biomass changes when the cut interval is changed. For a comparison of  
267 different model forecasts, uncertainties are usually more relevant. If a reduction of uncertainty via a model-data comparison  
268 is the purpose, both measures are important, as parameters with high sensitivities can contribute more or less predictive  
269 uncertainty, depending on their input uncertainty.

## 270 **3. Results**

### 271 **3.1. Mean sensitivities over Europe**

272 Regardless of the output variable, LPJ-GUESS was most sensitive to photosynthesis-related parameters (*respcoeff*,  
273 *lambda\_max*), parameters controlling the wood turnover (*turnover\_sap*) and tree allometry (*k\_rp*), water-related parameters  
274 (*emax*), mortality-related parameters (*greffmin*) and environmental drivers (temperature, CO<sub>2</sub> and solar radiation) (Fig. 1).  
275 When looking at differences in the strength of sensitivities for different outputs, TSB was most sensitive to the respiration  
276 coefficient (*respcoeff*), the growth suppression mortality threshold (*greff\_min*) and solar radiation while NBP projections  
277 showed negative sensitivity to wood turnover rates (*turnover\_sap*) and *longevity* and positive sensitivity to temperature, CO<sub>2</sub>  
278 and the ratio of intercellular to ambient CO<sub>2</sub> (*lambda\_max*). GPP was negatively sensitive to the respiration coefficient  
279 (*respcoeff*), growth suppression mortality threshold (*greffmin*), tree allometry (*k\_rp*) and temperature and positive to CO<sub>2</sub>,  
280 solar radiation and the maximum transpiration rate (*emax*). Establishment and nitrogen showed the smallest sensitivities for  
281 all three carbon-related projections (Fig.1). Note also that NBP had higher percental sensitivities than GPP and TSB.

282

283 Mixed stands were less sensitive to changes in parameters than mono-specific stands (Fig. 1). For monospecific simulations,  
284 species sometimes showed different magnitudes and even directions of sensitivities, especially *Fag. syl.* was more strongly  
285 affected by bioclimatic limits and *Pin. syl.* showed higher sensitivity to environmental drivers (temperature and solar  
286 radiation) than the other species. Moreover, TSB and GPP are negatively sensitive to temperature except for *Fag. syl.* For  
287 NBP, the direction of sensitivities changes between species for the non-water-stressed ratio of intercellular to ambient CO<sub>2</sub>  
288 (*lambdamax*), the respiration coefficient (*respcoeff*), the root turnover (*turnoverroot*), an allometric constant (*krp*) and the  
289 maximum evapotranspiration rate (*emax*).

290

291

### 292 **3.2. Mean uncertainties over Europe**

293 Looking at uncertainties, we found that environmental drivers contributed most of all processes/drivers to the predictive  
294 uncertainty (Fig 2), regardless of the considered model output. For TSB projections, CO<sub>2</sub>, solar radiation and temperature  
295 contributed substantial uncertainty (Fig. 2a). Additionally, large uncertainty contributions arose from growth suppression  
296 mortality thresholds (*greffmin*) and the respiration coefficient (*lambda\_max*). Uncertainty in NBP projections was  
297 substantially affected by model parameters (*longevity* (Mortality process), *tcmx\_est* (Establishment process), *turnover\_sap*  
298 (Tree structure process), *greffmin* (Mortality process) and *emax* (Water process)), additionally to the high contributions of  
299 temperature and CO<sub>2</sub> (Fig. 2b). For GPP projections, solar radiation and CO<sub>2</sub> contributed most to climate induced  
300 uncertainty, while the threshold for growth suppression mortality (*greffmin*) and maximum evaporation rate (*emax*)  
301 contributed most to parameter induced uncertainty (Fig. 2c). Notably, also nitrogen-fixation induced uncertainty was  
302 substantial (7-9%) for TSB and GPP. Most tree structure related parameters except the sapwood to heartwood turnover rate  
303 (*turnoversap*) and the fraction of NPP allocated to reproduction (*repfrac*) contributed only small uncertainties (Fig. 2).  
304 Uncertainty contributions analyzed by a random forest are similar to linear regression results (see Appendix 1.3.).

305

306 By analyzing uncertainty contributions on a species level, a more diverse picture emerged. *Fag. syl.* was more affected by  
307 temperature and less by solar radiation than the other species. Additionally, we found that uncertainty contributions of  
308 environmental drivers were substantially higher for mixed than for mono-specific stands.

309

### 310 **3.3. Geographic variation in uncertainties of TSB across Europe**

311 To project the uncertainties of TSB (for GPP and NBP see Appendix 1.4.) into the European environmental space, we  
312 filtered stands according to environmental zones, then calculated mean uncertainties per environmental zone and aggregated  
313 these per process.

314

315 The broad pattern of TSB uncertainty contributions for all three monospecific and mixed stands remains similar in all  
316 environmental zones. On average across all environmental zones, stands and species about 45% of the uncertainty was due to  
317 environmental drivers, 15% due to mortality-, 14% due to photosynthesis-, 12% due to structure-, 7% due to water- and 7%  
318 due to nitrogen-related parameters (Fig. 3).

319

320 For the individual environmental zones, however, there were subtle differences. In the Mediterranean mountain (MDN) and  
321 Pannonian (PAN) zone, environmental driver induced uncertainty was higher than on average especially for monospecific

322 stands (Fig. 3). In the Boreal (BOR), Atlantic central (ATC), and Atlantic north (ATN) zone, tree structure- related  
323 uncertainty increased compared to the average pattern (Fig. 3). In the Atlantic central (ATC) and Atlantic north (ATN) zones  
324 nitrogen related uncertainty increased for all species and stands (Fig. 3).

325

326 To examine this spatial pattern further, we investigated the change of uncertainties across a temperature gradient. To this  
327 end, we aggregated the uncertainties per site and process/driver and then fitted a linear regression with the process/driver as  
328 predictor and the aggregated uncertainties as dependent variables.

329

330 For TSB, we found that increasing mean annual temperature increased the uncertainty contributions of environmental  
331 drivers, water- and establishment-parameters, while the uncertainty due to nitrogen- and tree structure- related parameters  
332 decreased (Fig. 4a). Thereby, the uncertainty contributions of environmental drivers ( $\approx 0.4\%/^{\circ}\text{C}$ ) increased the most  
333 (measured in percentage points per  $^{\circ}\text{C}$ ) and uncertainty contributions of nitrogen fixation decreased most ( $\approx -0.5\%/^{\circ}\text{C}$ ).  
334 Mortality and photosynthesis stayed approximately constant on the gradient (Fig. 4b).

335

336 Looking in more detail at the environmental drivers, temperature ( $\approx +0.75\%/^{\circ}\text{C}$ ) as well as  $\text{CO}_2$  ( $\approx +0.2\%/^{\circ}\text{C}$ ) and  
337 precipitation ( $\approx +0.25\%/^{\circ}\text{C}$ ) induced uncertainty increased with mean annual temperature, while the uncertainty contribution  
338 of solar radiation ( $\approx -0.75\%/^{\circ}\text{C}$ ) decreased with mean annual temperature (Fig. 4c). Nitrogen deposition induced uncertainty  
339 contributions stayed approximately constant on a mean annual temperature gradient.

340

341 The above geographical and correlative observations of changing uncertainties across Europe receive further support when  
342 looking at the interactions between uncertainties of different drivers/parameters (Fig. 5). Interaction indices were calculated  
343 by averaging the interactions found in the linear regression over all sites and species (Fig. 5b). Moreover, to investigate the  
344 overall influence on other parameters or drivers we summed the absolute individual interaction indices of each parameter  
345 with each other (Fig. 5a).

346

347 We found that environmental drivers (temperature, solar radiation,  $\text{CO}_2$  and precipitation) had the highest sum of interactions  
348 for TSB (Fig. 5a). Moreover, the respiration coefficient (*respcoeff*), the growth suppression mortality threshold (*greffmin*),  
349 longevity, the sapwood to heartwood turnover rate (*turnover\_sap*) and maximum evaporation rate (*emax*) had a lower, but  
350 still high sum of interactions (Fig. 5a). Establishment and nitrogen related parameters had only a few weak interactions (Fig.  
351 5). Strong interaction effects occurred mostly with environmental drivers (Fig. 5b). A main part of these interactions was  
352 between the different environmental drivers themselves (solar radiation -  $\text{CO}_2$  and solar radiation - temperature).  
353 Additionally, we found interactions of parameters and environmental drivers (temperature-sapwood to hardwood turnover  
354 (*turnover\_sap*), temperature – threshold for growth suppression mortality (*greffmin*) and temperature-respiration coefficient  
355 (*respcoeff*) (Fig. 5b)) and moderate parameter-parameter interactions (*longevity* (Mortality process) - *greffmin* (Mortality

356 process), *respcoeff* (Water process) – *longevity* (Mortality process) (Fig. 5b)). Similar patterns were present for the other two  
357 carbon outputs (see Appendix A1.4.).

#### 358 4. Discussion

359 In this study, we analyzed sensitivities and uncertainties of the LPJ-GUESS vegetation model due to environmental driver  
360 and parameter variations across European forests. We found that the model is most sensitive to relative (percentage) changes  
361 in photosynthesis-related parameters, structure-related parameters controlling the wood turnover and tree allometry, water-  
362 related parameters, mortality-related parameters, and environmental drivers (Fig.1), irrespective of the considered output  
363 variable. When considering the different uncertainties (i.e. the entire plausible range) in these parameters and the  
364 environmental inputs, we found that environmental drivers and parameters controlling evapotranspiration, background  
365 mortality and nitrogen cycling contribute most to predictive uncertainty (Fig. 2). When correlated against a temperature  
366 gradient and thus geographically from north to south, uncertainty contributions to TSB increased for environmental drivers  
367 and decreased for tree structure and nitrogen-related parameters (Fig. 3, 4). Interactions between the uncertainty  
368 contributions were mainly between different drivers or between model parameters and drivers, whereas only a few  
369 parameter-parameter interactions were present (Fig. 5).

370

371 Our finding that average sensitivities of carbon-related projections across European forests were highest for photosynthesis-  
372 related parameters amplifies the evidence from earlier studies (Pappas et al., 2013; Zaehle et al., 2005), although we have  
373 used different parameter ranges. In addition, the finding about high sensitivity of LPJ-GUESS to parameters controlling tree  
374 structure and especially carbon turnover (*turnover\_sap*) (Fig. 1) is in line with results reported for a previous version of LPJ-  
375 GUESS (Pappas et al., 2013) and its important role for carbon allocation in trees found in empirical studies (e.g. Herrero de  
376 Aza et al., 2011). The finding that carbon-related projections are very sensitive to mortality-related parameters (*greffmin*) is  
377 also supported by previous studies on the sensitivity of vegetation models and underlines the importance of improving  
378 mortality submodules for generating precise projections of vegetation dynamics (Bugmann et al., 2019; Hardiman et al.,  
379 2011). Moreover, sensitivities in mixed stands were lower than in mono-specific stands for NBP and GPP (Fig. 1) (in line  
380 Wramneby et al., 2008). The reason for that imbalance may be that other species can dampen and even benefit from non-  
381 optimal life-history strategies of an individual species (Loehle, 2000). Another reason might be, that for mixed simulations  
382 we sampled parameters for each species individually, which reduces the influence of each parameter on stand-level carbon  
383 projections.

384

385 We found that uncertainty contributions of environmental drivers were comparable to the uncertainty contributions of all  
386 parameters together (Figs. 2-5, see also Snell et al., 2018 for the FLMs model, but see Petter et al., 2020, who found that  
387 most uncertainty is induced by the choice of the forest model). Especially high uncertainty contributions arose from

388 temperature (negative effect for TSB, GPP positive for NBP), CO<sub>2</sub> (positive effect for all variables) and solar radiation  
389 (positive effect for all variables). These results are supported by the earlier studies on the effect of environmental drivers in  
390 DGVMs (Barman et al., 2014; Wu et al., 2017, 2018). The positive effect of CO<sub>2</sub> could be explained by increased water-use  
391 efficiency and the CO<sub>2</sub> fertilization effect (also found for other DGVMs Keenan et al., 2011; Galbraith et al., 2010), which in  
392 LPJ-GUESS is an emerging property of the formulation of photosynthesis and respiration (see Hickler et al., 2008).  
393 However, empirical studies do not find such an effect (Körner, 2006), which could be linked to the fact that LPJ-GUESS  
394 does not model phosphorus cycling which could be the limiting nutrient (for a DGVM study see Fleischer et al., 2019). We  
395 speculate that the negative effect of temperature (also found for multiple DGVMs, see Galbraith et al., 2010) arises from  
396 decreased photosynthetic efficiency and increased respiration rates with higher temperatures (see the empirical study of  
397 Gustafson et al., 2018, here confirmed by the negative relationship between temperature and the respiration coefficient). This  
398 effect, however, differed in magnitude and direction between tree species (Fig. 2) - while there was a strong effect for *Pic.*  
399 *abi.* and *Pin. syl.*, *Fag. syl.* was less affected, which could be a sign of its higher resistance to increasing drought (Buras and  
400 Menzel, 2019; Tegel et al., 2014; but see Charru et al., 2010). From the parameters, especially water-, nitrogen- and  
401 mortality-related parameters contributed a substantial amount of uncertainty. The uncertainty contributions from mortality  
402 parameters (Bugmann et al., 2019, for a variety of DGVMs) and water (Pappas et al., 2013, with different parameter ranges  
403 for LPJ-GUESS) were already highlighted by earlier studies.

#### 404 405 **4.1. Geographical and environmental patterns in sensitivities and uncertainties**

406  
407 Several of our results suggest that environmental context influences the sensitivity of LPJ-GUESS model parameters. First,  
408 we found changing uncertainties across different vegetation zones (Fig. 3) and on an environmental gradient (Fig. 4) and that  
409 most interactions occurred with environmental drivers (Fig. 5). Moreover, uncertainty contributions analyzed by a random  
410 forest were similar to the linear regression results, but assign higher importance to environmental drivers (see Appendix  
411 A1.3). All these findings indicate that environmental context can change the importance of different processes in the model,  
412 which is in line with the biological expectation that the environment affects the physiology of organisms directly and thus  
413 indirectly the fitness and biotic interactions (e.g. Seebacher & Franklin, 2012; Tylianakis et al., 2008), and that  
414 environmental responses can be particularly nonlinear (e.g. Burkett et al., 2005) or show higher order interactions.

415  
416 Interestingly, our results of decreased uncertainty contributions of structure-related parameters and increased contributions  
417 of environmental drivers on the temperature gradient (Fig. 4) also seem in line with the stress-gradient hypothesis (Maestre  
418 et al., 2009), an empirically-observed pattern which states that in stressful environments, positive interactions should occur  
419 more often than in benign environments (e.g. Callaway, 2007). For the ecosystem that we consider, we interpret increasing  
420 temperature as increasing stress (e.g. Ruiz-Pérez and Vico, 2020), and structure as the best indicator for competitive  
421 interactions as the structure dictates resource allocation (e.g. bigger crown, but identical stem diameter leads to more

422 photosynthesis; more sapwood to heartwood turnover requires less NPP). With this interpretation, one would conclude that  
423 under increasing stress, the importance of competition-related parameters decreases in the model, as expected from the  
424 stress-gradient hypothesis. We acknowledge that a fair amount of interpretation is needed to arrive at this conclusion, and we  
425 do not claim that this result lends evidence to the empirical discussion about the generality of the stress-gradient hypothesis,  
426 but we find it noteworthy that such a large-scale pattern emerges in the model from lower-level processes, without having  
427 been imposed (see also Levin, 1992).

428

#### 429 **4.2. Associated uncertainties of previous changes in model structure and implications for future model development**

430

431 The management and the nitrogen cycling module are the most recent improvements of the LPJ-GUESS model (Smith et al.,  
432 2014; Lindeskog et al., 2021). Compared to previous sensitivity and uncertainty analysis, the high contributions of the  
433 nitrogen fixation to the predictive uncertainty of TSB and GPP (Fig. 2 a,c) are novel, though not surprising, as nitrogen is an  
434 important factor for the productivity of most temperate and boreal ecosystems (Vitousek and Howarth, 1991). The main  
435 reason why few earlier studies report those uncertainties is that vegetation models have only recently begun to integrate  
436 nitrogen cycling and limitation (e.g. B. Smith et al., 2014). The management module showed only small uncertainties, which  
437 could be due to the narrow parameter ranges for the cut interval and thinning intensity reflecting typical forest owners'  
438 choices. As forest owners usually try to maximize their profits (Johansson, 1986; but see Brazee and Amacher, 2000) and  
439 thus biomass production, low sensitivities of the management module are not surprising. A more suitable and important test  
440 case and application of the management module would be a historical reconstruction of foliage projective cover data or  
441 similar outputs of the LPJ-GUESS model.

442

443 Our study helps to guide the model application, discussion of uncertainties and model development of LPJ-GUESS and other  
444 DGVMs. First, future model applications and model comparisons should focus on mortality as this process contributes high  
445 uncertainties for carbon-related projections (see Fig. 1-3, see also Fisher et al., 2018). Thereby, it should be investigated if  
446 these uncertainties stem from the intra-specific variability of the parameters itself (Bolnick et al., 2011), parameters are just  
447 not identifiable (see Marsili-Libelli et al., 2014), or if a model data comparison could reduce uncertainties in the parameters  
448 (e.g. Hartig et al., 2011; Dietze, 2017b). Using time series inventory data might help as it is informative for constraining  
449 mortality modules (Cailleret et al., 2020). Second, small sensitivities of establishment related parameters are surprising as we  
450 know that not all three investigated species can effortlessly establish across all of Europe, e.g. *Fag. syl.* can only establish on  
451 locations with no extreme drought and heat and no extreme winter frosts (Bolte et al., 2007). Thus, either we missed  
452 important parameters of this module, or the parametrization of the model needs to be updated. Third, when introducing new  
453 processes or coupling with other models (e.g. Forrest et al., 2020) calculating interactions helps to get a first impression  
454 where these new processes influence other model processes and potentially detect missing links. Moreover, future model

455 applications can interpret their results with regard to the sensitivities in different factors (Saltelli et al., 2019) and discuss  
456 uncertainties and the causing factors, when used in policy advice (Laberge, 2013).

457

### 458 **4.3. Limitations**

459

460 We caution that our results regarding the importance of different factors for predictive uncertainties (but not sensitivities)  
461 depend on the a priori defined uncertainty range of the contributing factors (see Wallach & Genard, 1998), as well as on  
462 several other technical choices in our study. For determining uncertainty ranges of the drivers, we used RCP scenarios;  
463 however, these were not created as probabilistic min / max ranges. For the model parameters, we relied on expert guesses,  
464 reducing subjectivity as far as possible by following the SHELF expert elicitation protocol (Gosling, 2018). Future studies  
465 could include more experts and their opinion on parameter distributions to reduce variability in this protocol. As the model is  
466 sensitive to parameters and environmental drivers, and because these influence each other, we treated them in a combined  
467 sensitivity and uncertainty analysis (Saltelli et al., 2019), however, when interpreting it should be kept in mind that the one  
468 group relates to uncertainties in the model, while the other is external, so the two are conceptually very different (see also  
469 Dietze, 2017b). A certain ambiguity also arises from the definition of the indicators: here, we calculated sensitivities and  
470 uncertainties by capturing only linear components and second-order interactions, and we may therefore miss highly non-  
471 linear (and in particular hump-shaped) responses in LPJ-GUESS (Roux et al., 2021). However, our comparison to  
472 uncertainties calculated with random forest variable importance, a method that would also capture nonlinearities, did not  
473 reveal any qualitative differences in the ranking of parameter importance (Appendix A1.3). Overall, while we acknowledge  
474 that a certain amount of subjectivity exists in the choice of input uncertainty and calculation of indices, we believe that our  
475 results are quantitatively robust to those choices.

476

477 Moreover, we acknowledge that LPJ-GUESS is known to be sensitive to the scaling parameters *alpha\_a* and *alpha\_C3*  
478 (Pappas et al., 2013; Zaehle et al., 2005), which we have omitted from our analysis. These parameters, however, are not  
479 accessible in the parameter input file. Instead, they are hard coded in the model's source code and therefore a normal user  
480 would not change them. We argue that these parameters should thus be counted towards the more general and here neglected  
481 contribution of structural uncertainty (i.e. the uncertainty regarding the functional form of processes or even to entire  
482 modules) to the joint model uncertainty. Several previous studies suggest that the sensitivity of vegetation models to  
483 structural changes can be large, often larger than to parameters (e.g. Bugmann et al., 2019), and it would certainly be useful  
484 (although very complicated) to explore these uncertainties together with the here considered factors in a joint analysis. In the  
485 present study, however, we considered only the parameters that would be accessible to normal LPJ-GUESS users, and  
486 neglect structural uncertainty that could be explored by changing the source code.

487

## 488 **5. Conclusions**

489 Our findings highlight the relative importance of parametric uncertainties in different processes and their interactions with  
490 uncertainties in environmental drivers for carbon projections with LPJ-GUESS. Our results demonstrate that environmental  
491 context changes uncertainty contributions of other processes across the European environmental gradient. The pattern of  
492 decreasing importance of competition towards the warmer areas is in line with the stress-gradient hypothesis, which posits  
493 that the importance of competition decreases with increasing environmental stress. Our findings improve our understanding  
494 of forest ecosystem models, enable pathways for future ecosystem model development and thus builds a basis for more  
495 realistic projections. In the future, parametric uncertainties could be reduced by model-data fusion (e.g. Trotsiuk et al., 2020)  
496 of LPJ-GUESS, concentrating on the parameters contributing most uncertainty in each geographic region (Fig. 3). Reducing  
497 uncertainties in the drivers is more difficult. To some extent, environmental drivers are themselves influenced by the  
498 vegetation (Strengers et al., 2010), so model-data fusion on a fully coupled model including feedback loops between  
499 vegetation and climate, as well as a general improvement of climate models, could reduce driver uncertainty to some degree.  
500 Effectively, however, much of the uncertainty in this section arises from potential greenhouse gas emission trajectories, for  
501 which a probabilistic assignment is difficult due to their dependency on human decision-making.

502

## 503 **Appendix A**

504

### 505 **A1.1 Site selection**

506 We sampled 200 sites geographically and environmentally stratified over Europe and thereby avoided sites near the sea. The  
507 corresponding sites with the average temperature (Fig. A1) covers most of European climates and vegetation zones.

### 508 **A1.2. Re-parametrization for better fit to observed data**

509 There are several technical and methodological reasons requiring a re-parametrization of LPJ-GUESS for our study. First,  
510 most of European forests are managed and species are planted far outside of their natural distribution. Second, the  
511 introduction of the nitrogen cycle (Smith et al., 2014) changed the model structure and thus parameters require an  
512 adjustment. Third, the productivity of trees in managed forests did not fit to the reported inventory data (Fig. A2). To  
513 account for all these issues, we adjusted the parametrization of (Hickler et al., 2012) to allow species growing according to  
514 their actual (i.e., caused by forest management) distribution instead of their natural distribution.

515

516

517 Especially *Picea abies* and *Pinus sylvestris* are planted far outside their natural distribution (Figure S2). In particular we  
518 adjusted bioclimatic limits, drought tolerances, longevity, leaf turnover, disturbance intervals and allometry for these species.

### 519 **A1.3. Random forest results**

520 To check the consistency of the results obtained via linear regressions, we compare them to variable importance of random  
521 forest. The variable importance measures additionally non-linear effects and thus, should be able to deal with non-linear  
522 models like DGVMs. We calculated the variable importance the same way as we did for the linear regression by fitting a  
523 random forest with all parameters against the sum of differences between model outputs with default values and model  
524 outputs with sampled parameters. As our parameters were sampled from a uniform distribution with no correlation between  
525 the individual parameters, random forest variable importance can be compared to linear regression results.

526

527 The ranking is very similar to the ranking of the parameters and environmental drivers obtained via linear regression (Fig.  
528 A3). There is, however, a difference in the magnitude of the uncertainty induced by drivers, which is higher compared to  
529 linear regression (Fig A3). The higher uncertainty due to drivers is thus a nonlinear effect and stresses our conclusion that  
530 environmental conditions change the uncertainty contributions of other parameters.

531

### 532 **A1.4. Interactions of GPP and NBP**

533 Interactions of gross primary production (Fig. A4 a,b) and net biome production (Fig. A4c,d) are similar to the interactions  
534 of total standing biomass. These interactions are mostly between environmental drivers and environmental drivers or  
535 between environmental drivers and parameters (Fig. A4). Some strong interactions are between parameters and parameters,  
536 however, in such interactions there are always parameters included having strong interactions with environmental drivers  
537 (Fig. A4).

538

539 High sums of strong interactions arise from temperature, precipitation, solar radiation, greffmin, emax and respcoeff (Fig.  
540 A4a,b).

### 541 **Code and Data Availability**

542 LPJ-GUESS development is managed and the code maintained in a permanent repository at Lund University, Sweden.  
543 Source code is made available on request. The model version presented in this paper is identified by the permanent revision  
544 number r10207 in the code repository. There is no DOI associated with the code. Code to perform the sensitivity and

545 uncertainty analysis can be found on zenodo under <https://zenodo.org/record/5873672#.YebgTmAxnYU>. Results from the  
546 LPJ-GUESS runs are available under <https://zenodo.org/record/4670295#.YKIkI-tCRqs>.

#### 547 **Author contribution**

548 JO and FH conceived and designed the study and wrote a first draft. JO implemented the case studies, ran the experiments,  
549 and analyzed the results. CH, AK and PA advised regarding running the LPJ-GUESS model. CH, AR and AK determined  
550 the prior ranges for the parameters. All authors contributed to discussing and interpreting the results, and to the preparation  
551 of the manuscript.

552

#### 553 **Competing interests**

554 The authors declare that they have no conflict of interest.

555

#### 556 **Acknowledgements**

557 We acknowledge funding from the Bavarian Ministry of Science and the Arts in the context of Bavarian Climate Research  
558 Network (bayklif). We thank the LPJ-GUESS developers for developing and maintaining the LPJ-GUESS model. We also  
559 thank two anonymous reviewers for their valuable comments and feedback on an earlier version of the manuscript.

## 888 **Tables**

889 **Table 1: The model inputs investigated in the sensitivity analysis can be grouped in a) common parameters b) species-specific**  
890 **parameters and c) drivers. The ranges for the parameters have been determined from experts and literature, default parameter**  
891 **values that changed from Hickler et al. (2012) due to the reparameterization are explained in Appendix A1.2 .\* denotes an**  
892 **averaging over sites.**

a) Common Parameters

Grouping	Parameter	Explanation	Unit	Default Value	Min. Value	Max. Value	Default Value	Min. Value	Max. Value	Default Value	Min. Value	Max. Value	Literature sources
Mortality / Management	differential	average ratio for genetic each destroying distances	year	920	200	1000	-	-	-	-	-	-	-
Nitrogen	nfx_a	Frst limit in N factor exp	-	0.102	0.102	0.367	-	-	-	-	-	-	-
Nitrogen	nfx_b	Second limit in N factor exp	-	0.624	0.754	0.624	-	-	-	-	-	-	Chouvenet et al. 1999
Nitrogen	metabolic	Fraction of N mineralized prior to leaf and root shedding	-	0.5	0.1	0.8	-	-	-	-	-	-	-
Phytosynthesis/Light	limbda_max	Non-water-stressed ratio of litterfall to biomass (C02 pp)	-	0.8	0.8	0.8	-	-	-	-	-	-	Pappas et al. 2013
StructuralPhenology	rsprfac	Fraction of NPP allocated to reproduction	-	0.1	0.05	0.3	-	-	-	-	-	-	-
StructuralPhenology	turnover_foli	Rate of fine root turnover	1/year	0.7	0.65	0.75	-	-	-	-	-	-	-
StructuralPhenology	crowtree_max	maximum crown area	mm <sup>2</sup>	40	20	60	-	-	-	-	-	-	-
StructuralPhenology	k_allomz	height - allomz <sup>2</sup> - diameter (Nakajima)	-	60	30	80	-	-	-	-	-	-	-
StructuralPhenology	k_p	crown area = k crown <sup>2</sup> - height <sup>2</sup> * r <sup>2</sup>	-	1.6	1.3	1.6	-	-	-	-	-	-	-
Water	etmax	Maximum evapotranspiration rate	mm/day	5	2	6	-	-	-	-	-	-	Kahner 2009

b) Species-specific Parameters

Group	Parameter	Explanation	Unit	Default Value	Min. Value	Max. Value	Default Value	Min. Value	Max. Value	Default Value	Min. Value	Max. Value	Literature sources	
Establishment	parf_min	Min frost hour PAR for grass germination data	Jun/2day	2500000	1500000	3500000	1000000	750000	1600000	1000000	750000	1600000	-	
	gdd5min_est	Min GDD on 5 deg C base for establishment	°C day	500	250	700	350	300	700	1300	1050	1450	-	
	trmin_est	Min 20-year coldest month mean temp for establishment	°C	-29	-100	-15	-29	-100	-15	-5	-8	-5	-	
	trmax_est	Max 20-year coldest month mean temp for establishment	°C	5.5	-1.0	6	3	-2	6	7	5	8	Schibani et al. 2017	
	est_max	Max seeding establishment rate	1/m <sup>2</sup> /year	0.2	0.1	0.25	0.1	0.05	0.2	0.2	0.05	0.25	-	
	slbiter	Shape parameter for recruitment (slr growth rate reduction) (logically 1/m <sup>2</sup> under no-stress conditions (N))	year	500	300	900	300	200	1000	400	250	650	-	
	lrsresist	Resistance to herbivores	-	0.4	0.05	0.7	0.1	0.05	0.8	0.1	0.05	0.8	-	
	longevity	Expected longevity under no-stress conditions (N)	year	90	40	140	90	60	120	105	80	140	-	
	gdd_min	Threshold for growth suppression monthly	kgC/m <sup>2</sup> /yr	0.21	0.07	0.28	0.135	0.03	0.19	0.02	0.02	0.001	0.13	Pappas et al. 2013
	drought_toleran	Impediment drought-tolerant establishment plus water uptake from 0 field to 1 root at all drought-tolerant	-	0.25	0.1	0.4	0.48	0.2	0.65	0.39	0.2	0.49	-	
	Mortality / Management	thinning_tolerant	percentage of treebed concentration that is kept after thinning	-	0.9	0.45	1	0.9	0.5	1	0.9	0.55	1	-
	Mortality / Management	responset	Reproduction coefficient	-	1	0.8	2.2	1	0.8	2.2	1	0.5	1.5	-
Phytosynthesis/Light	patemp_low	Approx lower range of temp optimum for photosynthesis	°C	10	6.75	15	10	6.75	14	15	8	20	Thomas et al. 2013; Peltola-Vermäen et al. 2015	
Phytosynthesis/Light	patemp_high	Approx higher range of temp optimum for photosynthesis (log C)	°C	25	16	30	25	16	30	25	20	30	Zhang et al. 2014	
StructuralPhenology	cdm_leaf_min	minimum leaf CN ratio	-	31.90	27.32	38.37	38.37	31.9	43.16	24.06	22.7	27.19	-

StructuralPhenology	k_chlib	Coefficient in equation for predicting chilling time requirement	-	100	80	800	100	80	800	600	250	800	-	
Water	gmm	minimum canopy conductance rate across photosynthesis	mm/s	0.3	0.22	0.38	0.3	0.22	0.38	0.5	0.42	0.58	Pappas et al. 2013	

c) Drivers

Environmental Drivers	Parameter	Explanation	Unit	Default Value	Min. Value	Max. Value	Default Value	Min. Value	Max. Value	Default Value	Min. Value	Max. Value	Literature sources
Environmental Drivers	hsol	Mean deviations solar radiation from standard scenario RCP 4.5 per day	W/m <sup>2</sup>	RCP 4.5	-83.9*	65.2*	-	-	-	-	-	-	-
Environmental Drivers	temp	Mean deviation temperature from standard scenario RCP 4.5 per day	°C	RCP 4.5	-5.40*	5.82*	-	-	-	-	-	-	-
Environmental Drivers	prec	Mean deviation precipitation from standard scenario RCP 4.5 per day	mm/month	RCP 4.5	-5.19*	6.27*	-	-	-	-	-	-	-
Environmental Drivers	CO2	Mean deviations CO2 from standard scenario RCP 4.5 per day	ppm	RCP 4.5	-95.4	237	-	-	-	-	-	-	-
Environmental Drivers	ndep	Mean deviations (mm) precipitation from standard scenario RCP 4.5 per day	gmm/2/year	RCP 4.5	5.39E-07*	-4.22E-07*	-	-	-	-	-	-	-

895

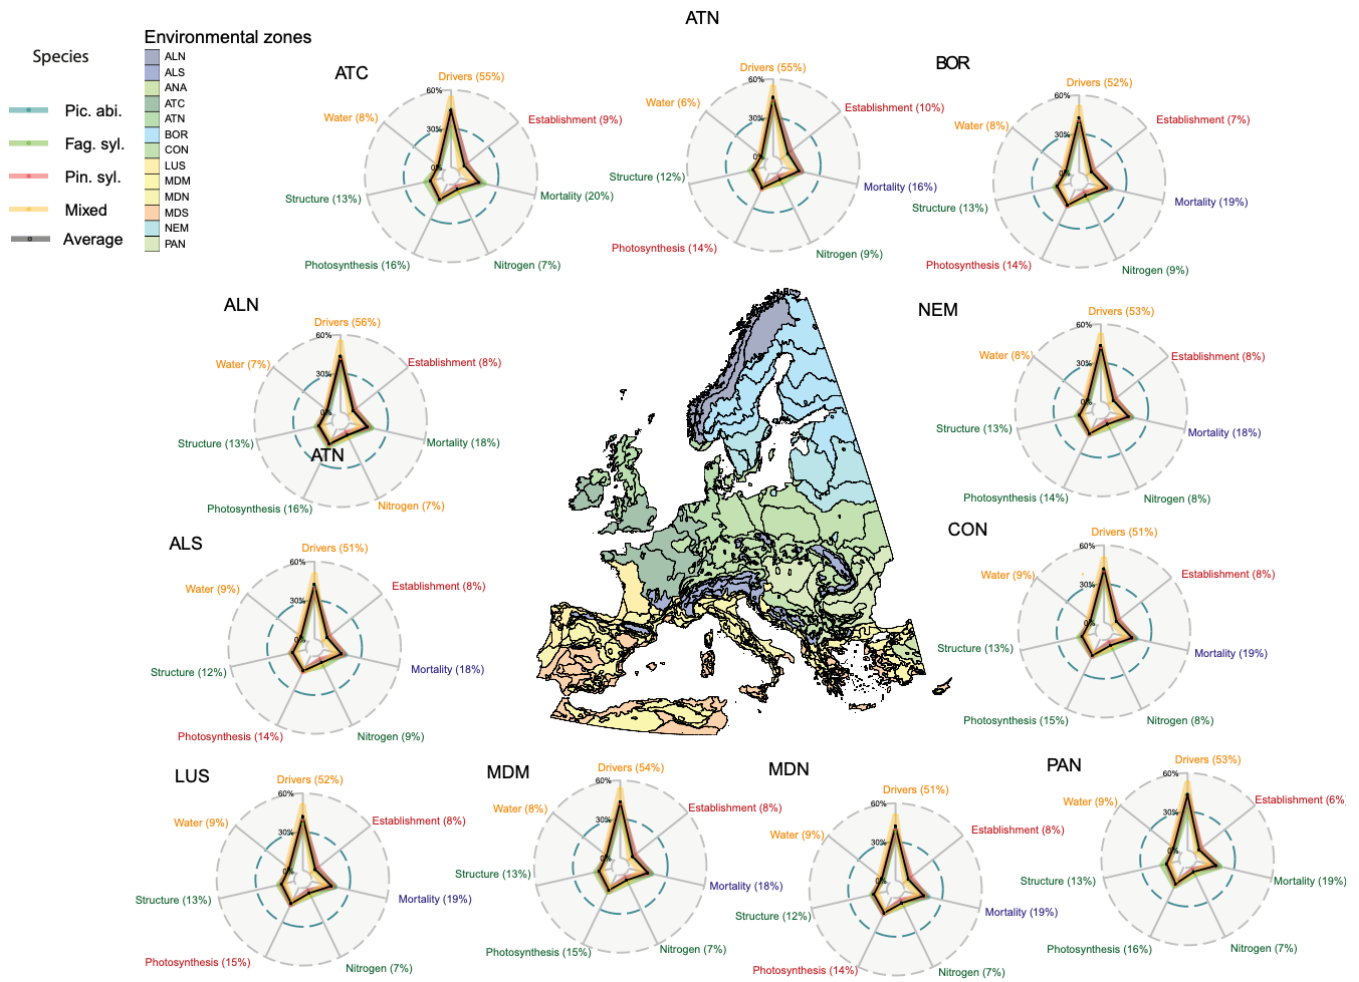

896 **Fig.1:** Relative sensitivities (percent output change per percent parameter change) of the individual parameters and environmental  
 897 drivers regarding a) total standing biomass, b) net biome productivity and c) gross primary production. Sensitivities were not  
 898 substantially different between *Fag. syl.* (green squares), *Pic. abi.* (blue circles) and *Pin. syl.* (red triangles), but parameter  
 899 sensitivities were stronger for mono-specific stands than mixed stands (purple asterisks). The height of the bar reflects the mean  
 900 over mono and mixed stands. Positive values for points and bars indicate a positive and negative values a negative relationship  
 901 with the corresponding output.

902

903

904 Fig. 2: Uncertainty contributions in percent of the individual parameters and environmental drivers regarding a) total standing  
 905 biomass, b) net biome productivity and c) gross primary production showed no strong differences between *Fag. syl.* (green  
 906 squares), *Pic. abi.* (blue circles) and *Pin. syl.* (red triangles) and were stronger for mono-specific stands than mixed stands (purple  
 907 asterisks). The height of the bars reflects the mean over mono and mixed stands. Positive values for points and bars indicate a  
 908 positive and negative values a negative relationship with the corresponding output.

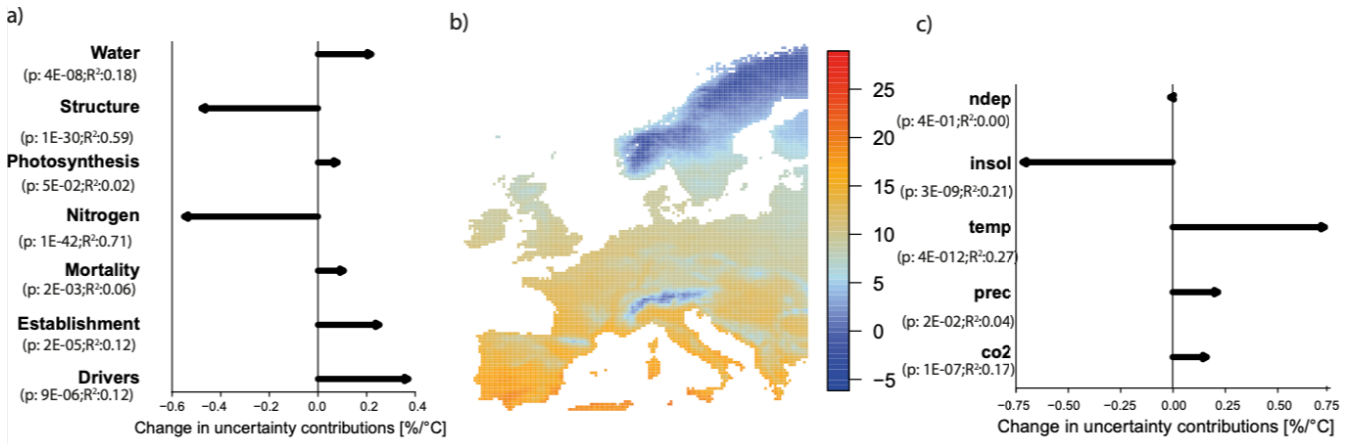

909

910 **Fig. 3: The aggregated relative uncertainties of total standing biomass per environmental zone (with more than five sites) show a**  
 911 **higher importance of drivers in the south than in the north. The environmental zones are from Metzger et al. (2005): ALN–Alpine**  
 912 **North; ALS – Alpine South; ANA - Anatolian; ATC – Atlantic Central; ATN– Atlantic North; BOR–Boreal; CON–Continental;**  
 913 **LUS – Lusitanian; MDM – Mediterranean Mountains; MDN – Mediterranean North; MDS – Mediterranean South; NEM –**  
 914 **Nemoral; PAN – Pannonian. In the radar plots of each environmental zone, the color and percentage value of the process label**  
 915 **indicates which simulation setup (monospecific with corresponding species or mixed) has contributed most uncertainty and how**  
 916 **much.**

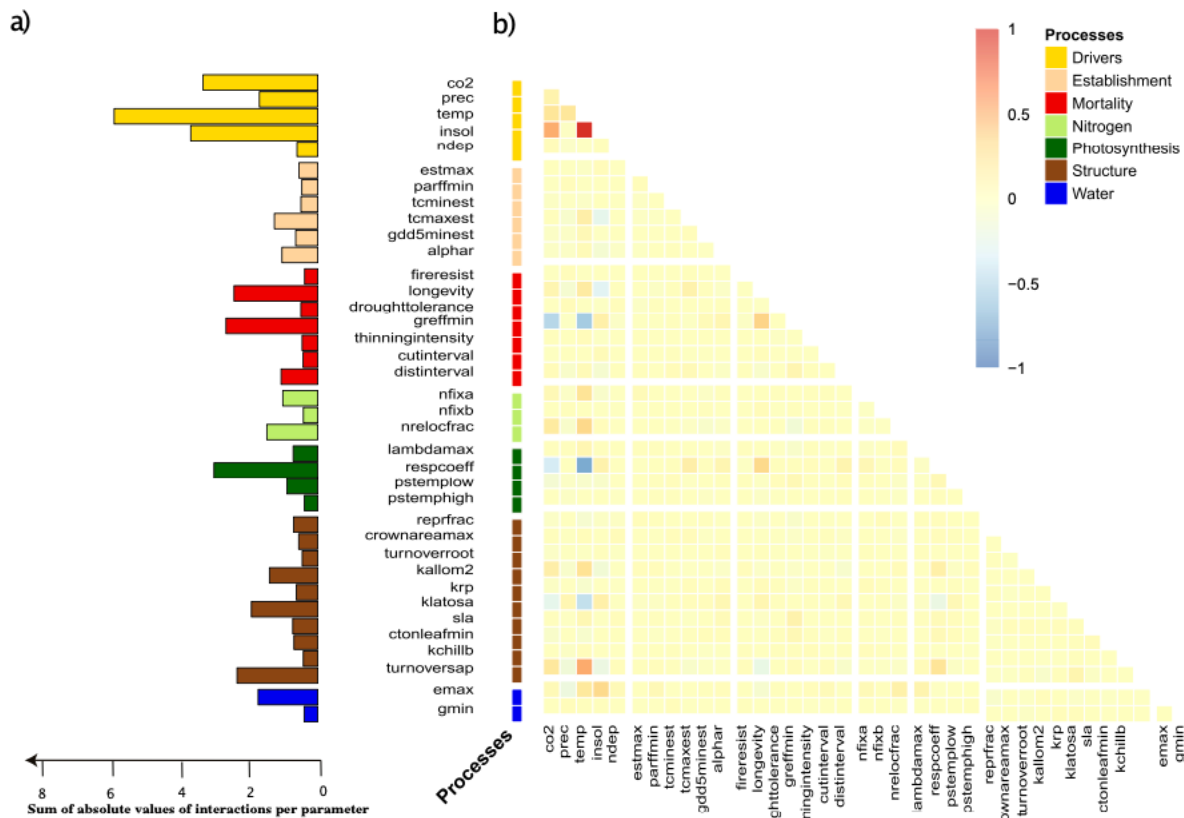

917

918

919 **Fig. 4: The uncertainty contributions to total standing biomass projections of parameters and environmental drivers change across**  
 920 **a mean annual temperature gradient across Europe from north to south (with p-values and R<sup>2</sup> for the processes/drivers). With**  
 921 **increasing temperature, the importance of drivers and establishment became higher for total standing biomass, while the**  
 922 **uncertainty contributions from nitrogen and structure declined (4a). The uncertainty contributions due to temperature increased**  
 923 **on the temperature gradient and the contributions from solar radiation decreased (4c).**

924

925 Fig. 5: The induced uncertainty of environmental drivers, mortality- and photosynthesis-related parameters changed the most  
 926 depending on other parameters (Fig. 5a). Strong individual interactions between parameters and environmental drivers in  
 927 monospecific projections of total standing biomass were rare (Fig. 5b). If strong interactions occurred, these were mainly between  
 928 two environmental drivers or environmental drivers and parameters and only rarely between two parameters (Fig. 5b).

929

930 **Tables Appendix A**

931 **Table A1: Differences in parametrization of Hickler et al. 2012 and our study for the investigated species (Fag. syl.,**  
 932 **Pic. Abi. and Pin. Syl)**

939

940 **Fig. A1: Our 200 sampled sites geographically and environmentally stratified over Europe cover the most important countries,**  
 941 **climate and temperature zones.**

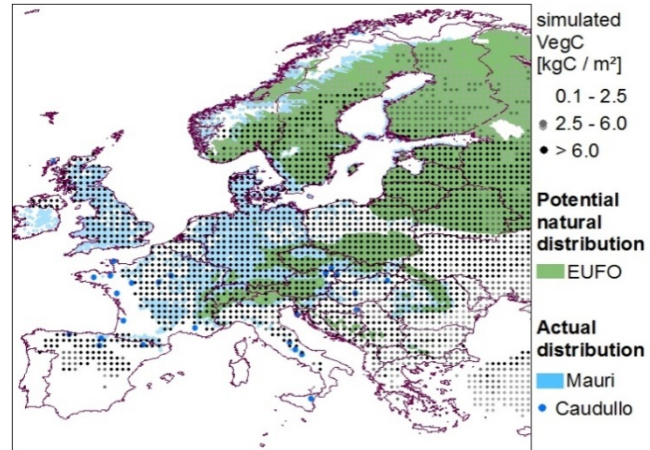

Parameterization as in Hickler et al. (2012)

a) *Picea abies*

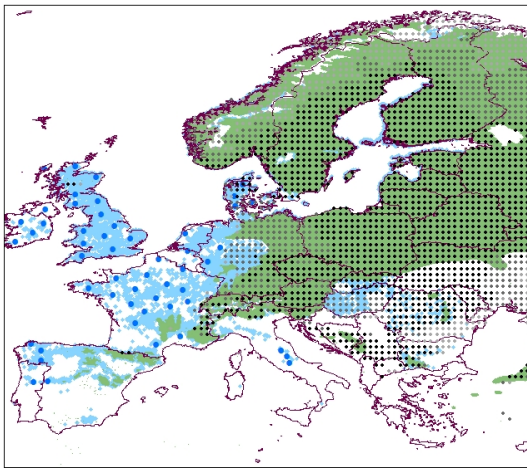

Re-parametrization to fit to actual distribution

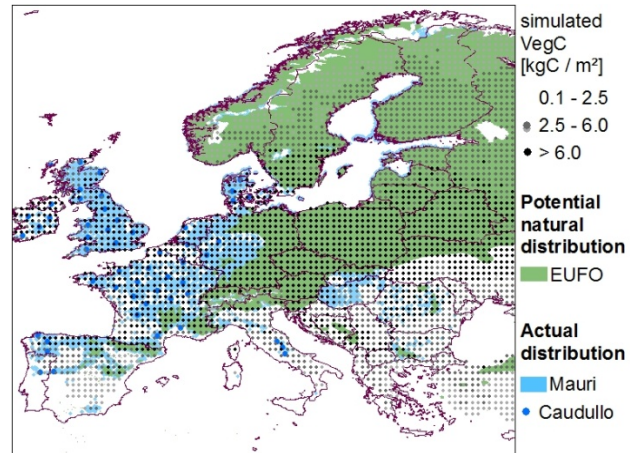

b) *Picea abies*

c) *Pinus sylvestris*

d) *Pinus sylvestris*

942 Fig. A2: Simulated (black points), observed (blue) and natural distributions (green) of the adjusted parametrization (b, d)  
943 compared to applying the parametrization from Hickler et al., 2012 (a, c) for *Picea abies* and *Pinus sylvestris*. EUFO =  
944 EUFROGEN, 2008 and 2013, Mauri =(Mauri et al., 2017), Caudullo =(Caudullo, 2017). The simulations were run from 1600 to  
945 2010 without management and without competition between species. The plotted biomasses were averages over the last 20 years.

946

947 **Fig. A3: Results of the random forest uncertainty contributions. The uncertainties due to environmental drivers are higher than**  
 948 **the uncertainties due parameters compared to linear regression, but the ranking of parameters is similar to linear regression**  
 949 **results.**

**Individual interactions**

**Individual interactions**

951 **Fig. A4: Interactions of uncertainty contributions of GPP and total standing biomass are similar to net biome productivity with**  
952 **most interactions arising from environmental drivers.**
