Abstract. Nitrous acid (HONO) plays an important role in the formation of ozone and fine aerosols in the urban atmosphere. In this study, a new simulation approach is presented to calculate the HONO mixing ratios using a deep neural technique based on measured variables. The "Reactive Nitrogen species simulation using deep neural network (RND)" is implemented in Python. The first version of RND (RNDv1.0) is trained, validated, and tested with HONO measurement data obtained in Seoul from 2016 to 2021. RNDv1.0 is constructed using k-fold cross validation and evaluated with index of agreement, correlation coefficient, root mean squared error, and mean absolute error. The results show that RNDv1.0 adequately represents the main characteristics of the measured HONO, and it is thus proposed as a supplementary model for calculating the HONO mixing ratio in a polluted urban environment.

1. Introduction

Surface ozone (O_3) pollution has worsened over continental areas (Arnell et al., 2019;Monks et al., 2015;Varotsos et al., 2013;IPCC, 2014). Particularly, a warmer climate is expected to increase the surface O_3 concentrations and peak levels in polluted regions depending on its precursor levels (IPCC, 2021). As a short-lived climate pollutant (SLCP), O_3 interacts with the global temperature via positive feedback (Shindell et al., 2013;Myhre et al., 2017;Stevenson et al., 2013). Therefore, accurate predictions of the mixing ratios and variations of the surface O_3 are essential. While operational models such as the community multiscale air

quality (CMAQ) have been widely used for this purpose, uncertainties still arise from poorly understood chemical mechanisms involving reactive nitrogen oxides (NO_y) and volatile organic compounds (VOCs), and the lack of their measurements (Mallet and Sportisse, 2006;Canty et al., 2015;Akimoto et al., 2019;Shareef et al., 2019;Cheng et al., 2022).

In the urban atmosphere, NO_y typically includes NO_x (NO + NO_2), HONO, HNO_3, organic nitrates (e.g., PAN), NO_3, N_2O_3, and particulate NO_3^-. These species are produced and recycled through photochemical reactions until they are removed through wet or dry deposition (Liebmann et al., 2018;Brown et al., 2017;Wang et al., 2020;Li et al., 2020). NO_y plays an important role in critical environmental issues concerning the Earth's atmosphere from local air pollution to global climate change (Sun et al., 2011;Ge et al., 2019). The oxidation of NO to NO_2 and finally to HNO_3 is the backbone of the chemical mechanism producing ozone (O_3) and $PM_{2.5}$ (particulate matter with size $\leqslant$ 2.5 μm), and determines the oxidization capacity of the atmosphere. Recently, as O_3 has still increased even with decreasing NO_x emissions over many regions, including East Asia, interest in the heterogeneous reaction of NO_y, which is yet to be understood, has increased (Brown et al., 2017;Stadtler et al., 2018). Currently, the lack of measurement of individual NO_y species is hindering a comprehensive understanding of the heterogeneous reactions (Anderson et al., 2014;Wang et al., 2017b;Chen et al., 2018b;Akimoto and Tanimoto, 2021;Stadtler et al., 2018).

In particular, the evidence for the heterogeneous formation of HONO in relation to high $PM_{2.5}$ and O_3 occurrences in urban areas is increasing (e.g., (Li et al., 2021b)). As an OH reservoir, HONO expedites the photochemical reactions involving VOCs and NO_x in the early morning, leading to O_3 and fine aerosol formation. Nonetheless, its formation mechanism has not been elucidated sufficiently enough to be constrained in conventional photochemical models. In addition to the reaction of NO with OH (Bloss et al., 2021), various pathways of HONO formation have been suggested via laboratory experiments, field measurements, and model simulations: direct emissions from vehicles (Li et al., 2021a) and soil (Bao et al., 2022), photolysis of particulate nitrate (Gen et al., 2022), and heterogeneous conversion of NO_2 on various aerosol surfaces (Jia et al., 2020), ground surface (Meng et al., 2022), and microlayers of the sea surface (Gu et al., 2022). Among these, the heterogeneous reaction mechanism on the surface is of major interest.

HONO has been mostly measured during intensive campaigns in urban areas using various techniques, such as a long path absorption photometer (Kleffmann et al., 2006;Xue et al., 2019), chemical ionization mass spectrometry (Levy et al., 2014;Roberts et al., 2010), ion chromatography (VandenBoer et al., 2014;Gil et al., 2020;Ye et al., 2016;Xu et al., 2019), monitor for aerosols and gases in ambient air (MARGA) (Xu et al., 2019), and quantum cascade - tunable infrared laser differential absorption spectrometry (QC-TILDAS) (Lee et al., 2011;Gil et al., 2021). Among these methods, QC-TILDAS has served as a reference for the intercomparison of measurement data obtained using different techniques due to its high time resolution and stability (Pinto et al., 2014). Previous studies have reported that the maximum HONO of several ppb levels has been observed at nighttime. In comparison, the WRF-Chem and RACM2 model captured approximately 67 %–90 % of the observed HONO in megacities such as Beijing (Tie et al., 2013;Liu et al., 2019).

In recent years, machine learning (ML) methods have been employed in the atmospheric science field for pattern classification (e.g., new particle formation event) and forecasting and spatiotemporal modeling of O_3 and $PM_{2.5}$ (Arcomano et al., 2021;Shahriar et al., 2020;Krishnamurthy et al., 2021;Cui and Wang, 2021;Joutsensaari et al., 2018;Chen et al., 2018a;Kang et al., 2021). Among the ML methods, the neural network (NN) architecture is widely used owing to its powerful ability to process large volumes of data. In particular, a multilayer artificial NN (ANN), referred to as a deep NN (DNN), employs statistical methods to learn nonlinear relationships within the data and yield optimal solutions for a target species without prior knowledge of the underlying physicochemical processes (Reichstein et al., 2019;Schultz et al., 2021). DNN is more beneficial than other NN architecture, such as convolution NN or long-short term memory, because it works well for discrete spatiotemporal data. Generally, the performance of DNN is similar to or better than that of other ML methods for small as well as large datasets (Baek and Jung, 2021;Dang et al., 2021;Sumathi and Pugalendhi, 2021).

The DNN method requires lots of data to employ it as atmospheric chemical constituent estimation; therefore, the size of the measurement data is a limiting factor for trace species, such as HONO, that are not routinely measured. In this regard, previous studies had been attempted to estimate the daily average HONO mixing ratio by employing ensemble ML models with satellite measurements (Cui and Wang, 2021). Furthermore, a simple NN architecture

using ground measurement variables that is believed to be deeply involved in HONO formation, was used to calculate the hourly HONO mixing ratio (Gil et al., 2021). The accuracy of the hourly HONO estimated from input variables, such as aerosol surface areas and mixed layer height, is rated better than the daily HONO estimate.

This study aims to develop a user-friendly "reactive nitrogen species simulation using DNN' model (RNDv1.0) that estimates the HONO mixing ratios from the real-time measurements of criteria pollutants and meteorological variables. This study is the first to calculate the HONO mixing ratios using RNDv1.0. The entire construction process is comprehensively described, and the performance is evaluated via comparison with the results of simulations using a commonly used model and observations over several years.

2. Model description

The RNDv1.0 development follows systematic steps that are similar to a general ML model construction workflow, including data collection, preprocessing data, building the DNN, training, and validating the model, and testing the model performance (Figure 1). RNDv1.0 is written in Python, and the libraries necessary to build and operate RNDv1.0 are listed in Table 1. The dataset used to train, test, and validate can be downloaded from Gil (2021).

2.1. Collection of measurement data for model construction

To construct RNDv1.0, measurement data were obtained, including HONO, reactive gases, and meteorological variables. Note that the HONO measurement data were used for model construction but not required to run the RND model. The HONO mixing ratio was measured in Seoul using a QC-TILDAS system during May–June 2016, June 2018, and April–June 2019 (Lee et al., 2011;Gil et al., 2021), and a MARGA system during May–June 2021 and October–November 2021 (Gil, 2022). When testing and evaluating the atmospheric HONO measurement methods, QC-TILDAS was chosen as the reference method to compare the ambient HONO mixing ratios measured using several different techniques owing to its

124   advantages of low detection limits (~0.1 ppbv) and high temporal resolution (Pinto et al., 2014).

125   More details on measurements can be found elsewhere (Gil et al., 2021;Gil, 2022).

126   HONO was measured at the Olympic Park (37.52° N, 127.12° E) during the Korea–

127   United States Air Quality (KORUS-AQ) study in 2016 (Kim et al., 2020;Gil et al., 2021), at the

128   campus of Korea University (37.59° N, 127.03° E) in 2018 and 2021, and at the site near the

129   Korea University campus (37.59° N, 127.08° E) in 2019 (NIER, 2020) (Figure S1). In addition

130   to HONO, trace gases including O_3, NO_2, CO, and SO_2 as well as meteorological variables

131   including temperature (T), relative humidity (RH), wind speed (WS), and wind direction (WD)

132   were measured. Note that HONO was not significantly correlated with any of these variables

133   (Figure S2). The measurement statistics for the entire experimental periods are presented in

134   Table 2 and Table S1. In brief, the 10th and 90th percentile mixing ratios of hourly HONO, NO_2,

135   and O_3, were 0.3 and 2.0 ppbv, 10.0 and 47.0 ppbv, and 8.0 and 75.0 ppbv, respectively.

136

137   **2.2. Data preprocessing**

138

139   The observation dataset was prepared for RNDv1.0 model construction. As input

140   variables, hourly measurements of chemical and meteorological variables were used, including

141   the mixing ratios of O_3, NO_2, CO, and SO_2, along with T, RH, WS, WD, and solar zenith angle

142   (SZA) to estimate the target species, HONO, as the output. The WD in degrees was converted

143   to a cosine value for continuity. In the last step of data processing, hourly measurement sets

144   were removed from the input data set if any of the nine variables were missing. Finally, 54.2 %

145   of all the available measurement data (2847 data points) were used to construct and evaluate

146   RNDv1.0.

147   Since the measurements of the considered nine variables varied over a wide range in

148   different units, they were normalized to avoid bias during the calculations. Among the widely

149   used normalization methods, *min–max scaling* method was adopted, and the input variables

150   were normalized against the minimum and maximum values herein (Eq. 1):

151

152      $$x_{sca} = \frac{x_{raw} - F_2(X)}{F_1(X)},$$ (Eq. 1)

153

154   where x_{raw} is the raw data, x_{sca} is the scaled value, and the scale factors of F_1 and F_2 correspond

155   to the maximum-minimum and minimum values of the input variable (X), respectively, which

156   are listed in Table 2.

157

158   **2.3. Neural network architecture and hyperparameters**

159

160   The network was built using the above input variables to calculate HONO. RNDv1.0

161   comprises five hidden layers (Figure 2), which employ an exponential linear unit (ELU) as an

162   activation function (Eq. 2).

163

164    $$ELU : \phi(x) = \begin{cases} e^x - 1 \ (x < 0) \\ \quad x \ (x \geq 0) \end{cases}.$$ (Eq. 2)

165

166   In a DNN, an activation function creates a nonlinear relationship between an input

167   variable and an output variable. When constructing a DNN model, ELU affords the advantage

168   of a fast training process and exhibits better performance in handling negative values than other

169   activation functions (Wang et al., 2017a;Ding et al., 2018). Moreover, the mean squared error

170   and Adam optimizer were applied as the loss function and optimization function, respectively.

171   The learning rate, epoch, and batch were set as 0.01, 100, and 32, respectively.

172

173   **2.4. Model training and k-fold cross validation**

174

175   RNDv1.0 was trained, validated, and tested with the HONO measurements obtained

176   during May–June 2016 and June 2018, April–June 2019, and May–June 2021 and October–

177   November 2021, respectively (Figure 3). The number of data used for the training and

178   validation was 1122 and that for testing was 1725.

Using the hyperparameters specified in the previous section, the model performance was first validated using the k-fold cross validation (KFCV) method, which is especially useful for small datasets (Bengio and Grandvalet, 2003). In the KFCV method (Figure 3), the entire data are randomly divided into k subsets, of which $k - 1$ sets are used for training and the remaining one is used for validation. In this study, k was set to 5. The accuracy was determined via index of agreement (IOA), which is expressed as follows (Eq. 3):

$$IOA = 1 - \frac{\sum_{i=1}^{n}(O_i - P_i)^2}{\sum_{i=1}^{n}(|P_i - \bar{O}| + |O_i - \bar{O}|)^2},$$ (Eq. 3)

where O_i, P_i, $\bar{O}$, and n are the observed value, predicted value, average of the observed values, and number of nodes, respectively.

As IOA varies according to the number of nodes, it was calculated for the measured (HONO_obs) and calculated (HONO_mod) mixing ratios by varying the number of nodes from 0 to 100 in each hidden layer. The best performance was obtained with 41 nodes, for which the average IOA was 0.89 ± 0.01 (Figure 4). The high IOA value signifies that the performance of RNDv1.0 is adequate, and it is capable of simulating the ambient HONO mixing ratio using the routinely measured criteria pollutants and meteorological variables.

The performance of RNDv1.0 was compared with that of other models, including CMAQv5.3.1 (Appel et al., 2021), random forest (RF), and single-layer ANN (Gil et al., 2021), using the 2016 measurement data. The RF model was constructed using the KFCV method and the same input variables as RNDv1.0 (Figure S4). Its performance was evaluated based on mean absolute error (MAE), root mean square deviation (RMSE), and Pearson correlation coefficient (r):

$$MAE = \frac{\sum_{i=1}^{n}|O_i - P_i|}{n},$$ (Eq. 4)

$$RMSE = \sqrt[2]{\frac{\sum_{i=1}^{n}(O_i - P_i)^2}{n}},$$ (Eq. 5)

$$r = \frac{cov(O,P)}{\sigma_O \sigma_P},$$ (Eq. 6)

where σ and *cov* denote the standard deviation and covariance, respectively.

All models except CMAQ simulated the measured HONO mixing ratio fairly well (Figure 5). CMAQ not only underestimated the measured HONO but also failed to represent its diurnal variation (Figure 6). The statistical information about the performance of the four models is presented in Table 3. The mean HONO mixing ratio measured and calculated using CMAQ, RF, ANN, and RNDv1.0 was 0.94, 0.09, 0.95, 0.88, and 0.89 ppbv, respectively. Of the four models, RF exhibited the best performance followed by RND. ANN advantageously calculates HONO more accurately than RND as it uses more input variables, but it has a lower data capture rate (41.5 %) compared to RND (97.7 %) or RF (85.3 %).

2.5. Model test

RNDv1.0 and the RF model were tested using data obtained in June 2018, April 2019, and May–June 2021 and October–November in 2021, which were not used for RNDv1.0 training (Figure 3). Note that the RF model outperformed the other three models in the training and validation process (Figure 5). Although the performance of RNDv1.0 was slightly lower than that of the RF model, simulated and measured HONO mixing ratios were in good agreement. Interestingly, the performance of the RF model was much worse than RNDv1.0 in the testing process (Figure 7). The IOA and correlation coefficient of the RF model were extremely low (0.29 and −0.02, respectively).

The performance of RNDv1.0 was slightly lower than that of the RF model, but it well traced the HONO mixing ratio. Among the test dataset, the early winter (October–November) data are particularly valuable for demonstrating the applicability of RNDv1.0 because they stem from different weather conditions than the training dataset. For example, HONO mixing ratios reached over 4 ppbv when the daily average $PM_{2.5}$ concentration increased to $120\ \mu g\ m^{-3}$ during severe haze pollution events. Therefore, in the next step, the performance of RNDv1.0 was compared for the two cases by dividing the testing dataset into a group in which all input variables fall within the range of the training dataset and a group which does not meet this

criterion. In RNDv1.0, there was no significant difference in performance between the two groups (Figure S5 and Table S2). When the data in which at least one input variable does not fall within the range of the training dataset were excluded from the test dataset, no significant difference was observed in the performance of RNDv1.0 between the two that meet same atmospheric conditions or do not meet the criteria (Figure S5 and Table S2). These extreme atmospheric conditions can make the model performance be worsened. Except for these extremes, RNDv1.0 well traced the variation of the HONO mixing ratio. These results demonstrate the applicability of RNDv1.0, which is not strictly constrained by atmospheric conditions. The influence of input variable are further analyzed in the next section.

2.6. Bootstrap test and feature importance

A simple bootstrapping test was conducted for both RNDv1.0 and the RF model to evaluate the relative importance of the input variable to the HONO estimates. In this analysis, each variable was set to zero and MAE was calculated as an evaluation metrics (Kleinert et al., 2021). Among the nine input variables of RNDv1.0, NO_2 was found to have the greatest influence on HONO concentration, followed by RH and T (Table 5). The highest MAE of 0.59 ppbv could be considered as the maximum uncertainty of RNDv1.0 due to the input variable. The bootstrap test result well agreed with that of our previous study (Gil et al., 2021), where more variables such as aerosol surface area and mixing layer height were incorporated into the model, it highlights the crucial role of precursor gases and heterogeneous conversion in HONO formation.

In contrast, in the RF model, O_3 was the most important variable. This is likely due to the distinct inverse relationship between O_3 and HONO in the diurnal patterns, and the O_3 variations over a wide range. In conjunction with the evaluation of the test dataset presented in the previous section, the results of the feature importance for the two models demonstrate the ability of RNDv1.0 to simulate the HONO mixing ratio more adequately in urban areas compared to the RF model. Thus, it is reasonable to state that RNDv1.0 constructed using routinely measured criteria pollutants and meteorological variables can sufficiently capture the HONO variability in the urban atmosphere.

265

3. Operation and application of RNDv1.0

267

268   The RNDv1.0 package is provided as an operational model, and the .h5 files that can

269   be opened in Python. To run RNDv1.0, the measurement data for nine input variables are

270   required and needed to be properly prepared, as described in Section 2.2. Once the input data

271   are ready, open RNDv1.0 with the input data files using the code provided in the example

272   (Figure S3). Then, RNDv1.0 calculates and presents the HONO results as scaled values (x_{sca}),

273   which then can be converted to the HONO mixing ratio (ppbv) via the two scale factors shown

274   in Table 2 (Eq. 5):

275

276    $$HONO\ (ppbv) = HONO_{sca} \times F_1(HONO) + F_2(HONO). \hspace{2cm} (5)$$

277

278   The HONO calculated using Eq. 5 can be applied to an urban photochemical cycle

279   simulation. As is already known, the photolysis of HONO is a major source of OH radicals in

280   the early morning when the OH level is low, and this OH affects daytime O_3 formation through

281   photochemical reactions with VOCs and NO_x, which are primarily emitted during the morning

282   rush hour in urban areas. Furthermore, the OH produced from HONO promotes the

283   photochemical oxidation of SO_2 and VOCs, leading to aerosol formation. However, the HONO

284   formation mechanism is still poorly understood, which hinders the accurate simulation of O_3

285   and fine aerosols as well as HONO in conventional photochemical models.

286   The framework for 0-dimension atmospheric modeling (F0AM), which utilizes the

287   MCM v3.3.1 chemical reaction mechanisms (Wolfe et al., 2016), can be used to simulate the

288   diurnal variation of O_3 with the measurements of several reactive gases (NO, NO_2, CO, HCHO,

289   VOCs, and HONO). Detailed information about F0AM can be found in

290   (https://sites.google.com/site/wolfegm/models) and in previous studies (Wolfe et al., 2016; Gil

291   et al., 2020). When the F0AM model is run without HONO, it is unable to reproduce the

292   concentration and diurnal cycle of the observed O_3 (Figure 8). In comparison, the model well

293   simulates the O_3 within 2 ppbv when HONO is considered, which is the result of RND v1.0.

This is mainly due to the missing OH produced by HONO photolysis in the early morning. Its production rate is estimated to be 0.57 pptv s^{-1}, contributing approximately 2.28 pptv to the OH budget during 06:00–11:00 (Local Sun Time) (Gil et al., 2021). Given that OH is mainly produced from the photolysis of O$_3$ under high sun, the early morning supply of OH from HONO photolysis will expedite the photochemical cycle involving NO$_x$ and VOCs, promoting O$_3$ and secondary aerosol formation. The presence of HONO in the photochemical model allows for the accurate estimation of OH radicals; thus, the incorporation of RNDv1.0 into conventional models will improve their overall performance.

4. Summary and implications

In this study, we developed the RND model to calculate the mixing ratio of NO$_y$ in urban atmosphere using a DNN along with measurement data. The target species of RNDv1.0 is HONO, and its mixing ratio is calculated using criteria pollutants, including O$_3$, NO$_2$, CO, and SO$_2$, as well as meteorological variables, including T, RH, WS, WD, and SZA. These variables are routinely measured through monitoring networks. RNDv1.0 was trained and validated using the HONO measurements data obtained in Seoul by adopting a KFCV method and tested with other HONO datasets. The test results demonstrate that RNDv1.0 adequately captures the characteristic variation of HONO.

RNDv1.0 was constructed using the measurements made in a high NO$_x$ environment where the maximum NO$_2$ reached about 80 ppbv. During the measurement period, the HONO mixing ratio was increased up to about 7 ppb under the influence of air masses originating from China. When applying RNDv1.0 to regions or times heavily affected by transport, the model could possibly underestimate the HONO level without more detailed information, such as nanoparticles. Indeed, a previous study showed that HONO formation is closely related to the surface area of particles with diameters in the range of hundreds of nanometers (Gil et al., 2021). Nevertheless, RNDv1.0 is advantageously a relatively inexpensive test for measurement quality control and location selection, and it supports the data used for traditional chemistry models based on the current knowledge of the urban photochemical cycle. Therefore, RNDv1.0 can serve as a supplementary tool for conventional forecasting models. Attempts are currently being

made to estimate ground HONO from satellite observations (Clarisse et al., 2011;Theys et al., 2020;Armante et al., 2021), and RNDv1.0 will be useful for validating the satellite-derived HONO.

5. Acknowledgements

This study was supported by the National Research Foundation of Republic of Korea (2020R1A2C3014592) and Korea Institute of Science and Technology (KIST2E31650-22-P019).

6. Code availability

The RND model codes (.h5 files) with preprocessed sample data can be downloaded from (Gil, 2021).

7. Author contributions

JG and ML designed the manuscript and developed the model code. JK, GL, and JA provided the HONO measurements and CK provided the CMAQ model data. All the authors contributed to the manuscript.

8. Competing interests

The authors declare that they have no conflict of interest.
