Abstract. The Energy Exascale Earth System Model (E3SM) Project is an ongoing, state-of-the-science Earth system modeling, simulation, and prediction project developed by the U.S. Department of Energy (DOE). With an emphasis on supporting DOE’s energy mission, understanding and quantifying how well the model simulates water cycle processes is of particular importance. Here, we evaluate E3SM version v1.0 for its ability to represent atmospheric rivers (ARs), which play significant roles in water vapor transport and precipitation. The characteristics and precipitation associated with global ARs in E3SM at standard resolution (1° x 1°) are compared to the Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA2). Global pattern of AR frequencies in E3SM show high degrees of correlation (>=0.97) with MERRA2 and low mean absolute errors (<1 %) annually, seasonally, and across different ensemble members. However, some large-scale condition biases exist leading to AR biases - most significant of which are: the double-ITCZ, a stronger and/or equatorward shifted subtropical jet during boreal and austral winter, and enhanced northern hemisphere westerlies during summer. By comparing atmosphere-only and fully coupled simulations, we attribute the sources of the biases to the atmospheric component or to a coupling response. Using relationships revealed in Dong et al. (2021), we provide evidence showing the stronger north Pacific jet in winter and enhanced northern hemisphere westerlies during summer associated with E3SM’s double-ITCZ and related weaker AMOC, respectively, are the sources of much of the AR biases found in the coupled simulations.

1 Introduction

Atmospheric rivers (ARs) are central actors in the global water cycle and have significant human impacts. These features are narrow, filamentary structures of concentrated water vapor transport in the lower atmosphere responsible for transporting the majority of water vapor across the mid-latitudes towards the poles (Zhu and Newell (1998)). Recently, ARs have received a categorization similar to hurricanes which describes the wide range of possible AR impacts - both beneficial and destructive (Ralph et al. (2019)). Weaker ARs, with integrated vapor transport (IVT) values of around 250 kg m^{-1} s^{-1}, can provide regions such as the west coast of the U.S. with critical sources of precipitation, while exceptional ARs, with IVT values well over 1250 kg m^{-1} s^{-1}, can be associated with widespread flooding and hazards to both human life and infrastructure. A recent study examining the last 40 years of floods in the western U.S. found ARs pose a $1 billion-a-year flood risk (Corringham et al. 2019).
Many studies indicate that ARs will increase in frequency and/or intensity and will deliver more precipitation under global warming (e.g. Payne et al. (2020); Espinoza et al. (2018); Payne and Magnusdottir (2015)). On the west coast of the U.S. for example, ARs are expected to increase the occurrence of extreme precipitation and associated flood risk, including via their contribution to snow/ice melt Chen et al. (2019). With such important socioeconomic impacts, increasing our understanding of ARs in past, present, and future climates is critical to mitigate damage and protect life and property.

Although ARs have been directly observed since the late 1990s with aircraft and dropsondes (e.g. the California Land-falling Jets Experiment (CALJET) (Ralph et al. (2005)) and via satellites with passive microwave radiometers (Ralph et al. (2004); Ralph et al. (2006))), there still exists gaps and challenges to direct observations of ARs due to both the scale and the extreme environments associated with ARs. While efforts to directly observe ARs continues to be improved, much of these efforts to date have been regionally specific to the western U.S., where ARs play a critical role. Thus, many researchers have instead relied on the use of gridded reanalysis products - which incorporate a variety of observations - to study ARs in historical, regional, and global perspectives (Ralph (2019)). Given the socioeconomic impacts of ARs, there is also wide and increasing interest on the behavior of ARs in future climates which typically require the use of global climate models (GCMs) (e.g. Dettinger et al. (2011); Payne and Magnusdottir (2015); Warner et al. (2015); Shields and Kiehl (2016)). A critical step in using these GCMs, which are used to simulate ARs in a variety of climates, is to first establish confidence in the model’s ability to simulate ARs in the current climate.

Many efforts have already evaluated a large array of different models. For example, Guan and Waliser (2017) evaluated 22 GCMs that participated in the Global Energy and Water Cycle Experiment (GEWEX) Atmospheric System Study (GASS)-Year of Tropical Convection (YoTC) Multimodel Experiment which included both atmosphere-only and ocean-atmosphere-coupled models for the period of 1991-2010. They used reanalysis products to quantify model errors in the context of reanalysis uncertainty and found large errors across all models. Another study by Espinoza et al. (2018) evaluated 21 GCMs in the Coupled Model Intercomparison Project Phase 5 (CMIP5) for their representation of ARs in historical and two future climates (Representative Concentration Pathway, or RCP, 4.5 and 8.5). The multimodel mean (MMM) was a good representation of their reference dataset, ERA-Interim, but tended to have a general low bias for AR frequencies in the midlatitudes. Intermodel differences showed significant disagreement for AR frequencies in the subtropics. Payne and Magnusdottir (2015) performed a similar analysis on landfalling ARs to understand responses to warming in RCP8.5 and compared CMIP5 historical runs to both ERA-Interim and the Modern-Era Retrospective Analysis for Research and Applications (MERRA) as an initial step. Most models were able to resolve the general shape of wintertime landfalling AR frequencies but only few could resolve other characteristics such as interannual variability in amplitude of moisture flux and median landfalling latitude. A strong relationship between model biases in the North Pacific subtropical jet and landfalling AR frequency in the west coast of North America has been identified based on analysis of large ensemble simulations Hagos et al. (2016).

The United States Department of Energy (DOE) recently released the Exascale Energy Earth System Model version 1 (E3SMv1) which is a state-of-the-science Earth system model. The model was developed to support DOE’s energy mission, with an emphasis on modeling the long-term changes in air and water temperatures, water availability, storms and heavy precipitation, coastal flooding and sea-level rise on high performance computers (Leung et al. (2020)). The standard resolution
model has been shown to perform well when evaluated by means of a standard set of Coupled Model Intercomparison Project Phase 6 (CMIP6) Diagnosis, Evaluation, and Characterization of Klima simulations Golaz et al. (2019). E3SMv1 generally has a root-mean-square error (RMSE) against observations in the lowest (best) quantile for a variety of fields (e.g. net top-of-the-atmosphere radiation, surface air temperature, precipitation) when compared with an ensemble of 45 CMIP5 models. There are however, known biases in E3SMv1 which are common to other GCMs, such as a reduction in cloudiness over the subtropical stratocumulus regions and the well-known double Intertropical Convergence Zone (double-ITCZ) issue where there is excessive southern central Pacific precipitation (Golaz et al. (2019); Zhang et al. (2007)).

Evaluating E3SMv1 for ARs, which has not yet been done, is necessary given our need to understand issues surrounding the water cycle and its interactions with humans and other Earth systems. This paper aims to provide an overview of ARs simulated in E3SMv1 by: i) comparing against historical ARs detected in MERRA-2 (Modern Era Retrospective analysis for Research and Applications, version 2) to identify AR biases, ii) evaluating internal model AR variability using individual ensemble members, and iii) determining the large-scale and model sources of AR biases. ARs in this study are detected using the AR algorithm developed by Guan and Waliser (2019) which is a widely used algorithm and has been demonstrated to closely match key AR characteristics from direct airborne observations (Guan et al., 2018). The structure of this paper is as follows. In Section 2, E3SMv1, the reanalysis data set, and the AR detection algorithm are described. AR frequency, characteristics, precipitation, and large-scale conditions in E3SM are compared to MERRA2 in Section 3. Discussion and conclusions are presented in Section 4. Finally, the Appendix material is contained in Section 4.

2 Data and Methods

2.1 Exascale Energy Earth System Model

E3SMv1 was developed from the Community Earth System Model (CESM1) Leung et al. (2020). This study uses global, daily data from the standard (also referred to as the ‘low’) resolution, fully-coupled E3SMv1 model (Golaz et al., 2019). We use 35 years (1980-2014) from the historical simulation (which incorporates several historical, observed forcings including atmospheric composition changes). Five ensemble members of historical simulations are available from E3SMv1 in the CMIP6 archive. The E3SM Atmosphere Model (EAM) (Rasch et al., 2019), which was developed from the Community Atmosphere Model version 5 (CAM5), uses a spectral element dynamical core and is applied at a horizontal resolution of approximately 110 km (or 1° x 1°; 180 latitude grids x 360 longitude grids) and has 72 vertical levels. The historical runs follow the CMIP6 protocols outlined in Eyring et al. (2016). To understand the sources of model biases in simulating ARs, we also analyze atmosphere-only simulations for comparison with the fully coupled historical simulations as has been done in previous studies to identify sources of errors (e.g. Li and Xie (2012) and Li and Xie (2014)). The atmosphere-only simulations follow the AMIP protocol and are part of the CMIP6 DECK simulations. A full overview of E3SMv1 and EAM can be found in Golaz et al. (2019) and Rasch et al. (2019) respectively. We will henceforth refer to E3SMv1 as E3SM.
2.2 Reanalysis Data Set

In this study, daily reanalysis data from MERRA2 (Gelaro et al. (2017)) is analyzed for the same 35 year period as E3SMv1 (1980-2014). The native spatial resolution is \( \sim 50 \) km (or \( 0.5^\circ \times 0.625^\circ \); 361 latitude grids \( \times \) 576 longitude grids) but was re-gridded to match E3SMv1 to facilitate comparison. MERRA2 is an updated version of MERRA (version 1) which was developed to improve representations of the global water cycle. Good agreement between MERRA2 against airborne and satellite observations has been previously demonstrated for ARs (Guan et al. (2018); Ralph et al. (2012)).

2.3 Atmospheric River Detection Algorithm

ARs are detected using tARget v3 - the latest version of a widely used algorithm developed for global studies. Details of the detection algorithm can be found in Guan and Waliser (2019) and Guan and Waliser (2015). As a brief summary, this algorithm is part of the Atmospheric River Tracking Method Intercomparison Project (ARTMIP) (Shields et al., 2018a) and is among the relatively 'permissive' algorithms compared to other algorithms to facilitate global analysis including inland-penetrating ARs as well as polar ARs. This algorithm has been refined with various improvements since it was first introduced in Guan and Waliser (2015) to its current version. The algorithm, when applied to contemporary reanalysis products, detected ARs that were found to closely match airborne observations in terms of key characteristics such as AR width and total IVT across AR width (Guan et al., 2018). The algorithm uses a location- and season-specific IVT threshold set at the 85th percentile of the dataset analyzed but cannot go below 100 kg/m/s. This means the threshold is calculated separately for MERRA2 and the E3SM simulations.

3 Results

3.1 AR Frequency

We begin with the global distribution of AR frequencies shown in Fig. 1. These frequencies represent the ensemble mean from 5 historical simulations for E3SM compared to MERRA2. For each grid cell, the frequency shown represents the number of timesteps that grid cell was part of an AR divided by the total number of timesteps in the time period. This is done for the annual, extended boreal winter (NDJFM), and extended boreal summer (MJJAS). All % differences mentioned below, unless otherwise noted, are absolute differences, not relative differences. The annual frequency of ARs in E3SM closely matches MERRA2 as seen in Fig. 1a and 1b. In E3SM, as in MERRA2, frequency maxima are found in the extratropics over the Pacific and Atlantic ocean basins while minima can be seen near the equator, at high polar latitudes, and over the Tibetan Plateau. The difference of E3SM minus MERRA2 annual frequencies is shown in Fig. 1c. Overall, there is a slight positive bias (1-3 %) in E3SM frequency near the edge between the tropics and subtropics in both northern and southern hemispheres. E3SM also has positive biases in polar areas, specifically over Alaska, Siberia, and just offshore of Antarctica. Slight negative biases (1-2 %) are seen in the southern hemisphere subtropics (southwestern region of Australia and the over the south Atlantic east of
Brazil). Between E3SM (ensemble mean) and MERRA2, the annual frequency mean absolute error (MAE) is 0.60 % and the correlation is 0.98.

For the NDJFM frequencies, E3SM (Fig. 1d) exhibits a close match with MERRA2 (Fig. 1e) but reveals seasonal biases (Fig. 1f). ARs are most frequent over the subtropics and midlatitudes over the north and south Pacific and Atlantic where the storm tracks are located. The biggest source of positive biases comes from north Pacific ARs affecting the entire west coast of North America with frequencies around 3-4 % higher than in MERRA2. These positive biases stretch from Mexico to Alaska nearly uninterrupted as well as nearly all the way across the subtropical north Pacific basin. Other positive biases exist over...
South America (originating from the Amazon Rainforest) and over India along with the Himalayas. Weak negative anomalies of ~1-2% are seen spreading throughout the southern hemisphere ocean basins as well as over northern Africa and east of Japan. The NDJFM frequency MAE is 0.72% and the correlation is 0.98.

The MJJAS frequencies in E3SM (Fig. 1g) are also in agreement with MERRA2 (Fig. 1h) but, as with NDJFM, with some biases (Fig. 1i). Frequency maxima can be seen in both E3SM and MERRA2 over the western areas of the north Pacific and north Atlantic basins and over the south Pacific and south Atlantic in the subtropics and midlatitudes. Positive biases are seen for E3SM in the following areas: the southern edge of the tropics near 20°S (with the exception of the negative frequency bias over South America), the Middle East, western boundary of the north Pacific, windward side of the Andes, and the polar latitudes offshore of the Antarctic. Negative biases are overall weaker and are found over South America on the leeward side of the Andes (between ~10-20°S), the Caribbean Sea, south Indian Ocean, and at mid and polar latitudes over Eurasia. The MJJAS frequency MAE is 0.82% and the correlation is 0.97.

Overall, E3SM and MERRA2 AR frequencies show very strong correlation (>=0.97) and low mean absolute errors (<1%) annually and seasonally. The magnitude and distribution of annual and seasonal AR frequencies are consistent with previous studies examining ARs in reanalysis (e.g. Guan and Waliser (2015)). However, in E3SM, the hemisphere experiencing winter (especially the northern hemisphere) tends to produce positive frequency biases throughout the border of the tropics and subtropics (~25°N and ~15°S). The hemispheric bias in summer is greater in the northern hemisphere and features notable positive anomalies throughout the tropics/subtropics over the Middle East and along the western boundary of the north Pacific. Additionally, AR frequencies are higher near some elevated topography (such as the Himalayas, the Alaska range, and Antarctica).

While the previous results are based on the 5-member ensemble mean, we next determine how well the individual historical E3SM ensemble members are able to match MERRA2’s AR frequencies using Taylor diagrams (Fig. 2). Taylor diagrams provide a graphical summary of similarity between two patterns using pattern correlation, centered root-mean-square difference (RMSD), and standard deviation (SD). The Taylor diagrams confirm E3SM’s ability to accurately simulate present day AR frequencies globally, across ensemble members, in the annual and seasonal with a high degree of similarity to MERRA2. Correlations are above 0.95 for all ensemble members and for the three periods analyzed (NDJFM, MJJAS, and annual) with the annual having the highest correlation. SDs are consistent with MERRA2. RMSDs in the annual are under 1.0% while in the seasonal periods, are under 1.5%. The diagrams also suggest that the internal variability of E3SM historical simulations is small - particularly in the annual - as the 5 ensemble members are tightly clustered.

As a measure of ensemble spread, the 5-member ensemble SD (different than the Taylor Diagram SD) of AR frequency - i.e. how much variance there is between the individual simulations and the ensemble mean - is shown in Fig. 3. For the annual (Fig. 3c), much of the global SDs are below 0.5%. A few regions, such as over east and southeast Asia, the Arabian Sea, and the Hudson Bay, have SDs that fall between 0.5% and 1.0%. Analysis of the coefficient of variation (not shown), calculated at each grid as the ratio between ensemble AR frequency SD and mean ensemble frequency, shows that the annual SDs are under 10% of the ensemble mean AR frequencies for virtually all grid points barring a few grid points over the equator and Antarctica (where AR frequencies are well <1%).
The seasonal SDs reveal sources of the higher annual SDs. During NDJFM (Fig. 3a), SDs are generally higher in the northern hemisphere and have notable peaks of ~1.5% over east Asia (which is a jet entrance region) and the north Pacific storm track region. These regional peaks suggest that differences in subtropical jet behavior during NDJFM between the 5 historical simulations may be responsible for the internal AR frequency variability. MJJAS SDs (Fig. 3b) peak for ~1.5% over various regions of the Asia summer monsoon - the Arabian Sea, over the Philippines, and east Asia - which suggests that during MJJAS, differences in monsoon, MJO, or subtropical jet behavior may drive AR frequency variability between E3SM ensemble members. In general, the northern hemisphere shows more internal variability.

3.2 AR Characteristics

Next, we examine several AR characteristics in E3SM (using a single historical simulation) and MERRA2. These characteristics are provided by the AR detection algorithm’s output for each individual AR. The distribution of all the ARs detected are
Figure 3. The historical E3SM 5-member ensemble standard deviation of AR frequencies for (a) winter, (b) summer, and (c) annual.

shown in Fig. 4. All characteristics show strong similarities in shape and peak at the same values, barring magnitude of mean IVT (4e).

Length and width of ARs (Fig. 4a and 4b) in E3SM are generally consistent with MERRA2 and with previous characterizations of AR geometry (e.g. Guan and Waliser (2015)). The median length and width for E3SM differs only slightly with MERRA2 with E3SM ARs being $\sim$3% longer and wider. The AR length/width ratio are, however, in good agreement with MERRA2 (Fig. 4c).

The hemispheric median centroid latitude of ARs is consistent, but the distributions reveal that E3SM produces more ARs with centroid latitudes in the tropics, subtropics, and southern polar latitudes while producing less ARs in the midlatitudes compared to MERRA2 (Fig. 4d). These results are supported by the frequency differences in Fig.1.

The median magnitude of mean IVT of ARs in E3SM is 10.6 % larger than MERRA2 (Fig. 4e). The distribution of ARs peaks at 500 kg m$^{-1}$ s$^{-1}$ for E3SM but peaks at weaker magnitudes around 350 kg m$^{-1}$ s$^{-1}$ for MERRA2. E3SM has higher AR frequencies equatorward of the subtropics and lower frequencies throughout the midlatitudes (Fig. 1c and 4d) which is likely the main source of the higher mean IVT values. ARs that are closer to tropical moisture sources are able to generate higher moisture transports.
The direction of mean IVT (0° for IVT directed to the north) in the northern hemisphere is directed towards the northeast (median angle of 65° and 62° for E3SM and MERRA2 respectively) and in the southern hemisphere, is directed towards the southeast (median angle of 120° and 123° for E3SM and MERRA2 respectively) (Fig. 4f). These median values, along with the distributions, indicate that E3SM ARs tend to have mean IVT directed slightly more zonally compared to MERRA2. E3SM ARs have higher probabilities around 90° (indicating a mean IVT direction directed to the east) and around 270° (indicated a mean IVT direction directed to the west).
Coherence of IVT directions within an AR is calculated as the fraction of AR grid cells with IVT directed within 45° of the mean AR IVT (Guan and Waliser (2015)). Model and reanalysis show similarly high coherences of 0.99 (E3SM) and 0.98 (MERRA2) (Fig. 4g).

3.3 AR Precipitation

We now compare a variety of metrics related to AR precipitation. For reference, annual precipitation - not just from ARs - is included (Fig. 5a-c) for both models and reanalysis along with the differences. AR precipitation is defined in this study as the precipitation that falls within an AR boundary.

For annual AR precipitation, E3SM reproduces the distribution and magnitude of precipitation characterized in previous studies (e.g. Guan and Waliser (2015); Ralph (2019)) as well as with MERRA2 but with some differences. E3SM has higher AR precipitation estimates on the edge of the tropics and subtropics but lower estimates along the equator where AR frequency is very low (Fig. 1). The western coasts of North and South America also produce higher rates of AR precipitation in E3SM. The seasonal differences in AR precipitation for the NDJFM and MJJAS tend to stay quite consistent to the annual differences.

Next, we examine the percentage of precipitation attributed to ARs in both datasets annually (Fig. 6). ARs can be responsible for over 30 % of the annual precipitation in the expected extratropical areas such as the west coast of North and South America. Some other areas of note with high AR precipitation fractions include Korea/Japan, the Middle East, southeastern U.S., Greenland, and Australia. These areas of high AR precipitation fractions are not unique to E3SM and have been characterized in previous studies (Guan and Waliser (2015); Ralph (2019)). The precipitation fraction differences, shown in Fig. 6c, reveal that E3SM, however, does attribute a higher fraction of precipitation to ARs off the coast of southwestern U.S. and Chile. There is also a strong band of higher AR fractions (reaching above 20 % higher than MERRA2) extending from the Sahel/Sahara region of Africa to the Middle East to India. The polar regions exhibit higher AR fractions. The midlatitude regions attribute less precipitation to ARs in E3SM, particularly over the southern hemisphere oceans. Areas of higher AR precipitation fraction tend to be co-located with areas of positive AR frequency biases with the exception of northeast Africa, the Arctic, and over the Amazon (Fig. 6c).

Globally and annually, ARs are responsible for 17.84 % and 17.95 % of precipitation in E3SM and MERRA2 respectively. Interestingly, while the overall precipitation percentage is very consistent, the fraction of AR precipitation that falls over ocean and land vary between the two datasets. In E3SM, 17.38 % (82.62 %) of the AR precipitation falls over land (oceans) while in MERRA2, only 14.81 % (85.19 %) falls over land (oceans). Topographic features seem to be able to extract precipitation from AR events more effectively in E3SM compared to MERRA2.

3.4 Large-scale AR Conditions

In this section, we look into the sources of the E3SM AR frequency and precipitation biases by examining the large-scale conditions relevant to ARs. We begin with the AR precipitation biases in the fully-coupled E3SM simulations. The E3SM AR precipitation biases (Fig. 5f) are generally well co-located and of similar magnitude with the general precipitation biases present in E3SM (Fig. 5c). While this reflects the important contributions of AR precipitation to the total precipitation in
Figure 5. Top row shows annual precipitation in E3SM, MERRA2, and the difference. The next three rows are organized as in Fig. 1 but for AR precipitation instead of AR frequency. The colorbar on the top (bottom) corresponds to the absolute (difference in) precipitation or AR precipitation.
some regions, it also suggests that the AR precipitation and total precipitation biases share similar sources of large-scale circulation biases. For example, model biases in the subtropical jet would affect precipitation produced by AR and non-AR storms, as both are influenced by the jet and storm tracks. A large source of general E3SM precipitation biases come from a known and common bias in fully-coupled simulations - the double-ITCZ bias and excessive precipitation over the maritime continent (Golaz et al. (2019)). Two notable exceptions where there are positive AR precipitation biases but no equivalent general precipitation biases are i) off the coast of the U.S. southwest and ii) the region around Pakistan and India. However, these regions in E3SM compared to MERRA2, attribute a higher fraction of the annual precipitation to ARs (Fig. 6) and also have positive AR frequency biases, suggesting certain large-scale circulation biases may have larger influence on AR frequency than the frequency of non-AR storms.

Figure 6. The fraction of annual precipitation attributed to ARs for each grid cell for E3SM (a) and MERRA2 (b). The difference (E3SM minus MERRA2) is shown in (c). The colorbar on the top (bottom) corresponds to the absolute (difference) percentages. Contour lines in (c) indicate the 1.5 % positive AR frequency biases from Fig. 1c.
Figure 7. Seasonal differences between E3SM and MERRA2 (from top row to bottom row): IVT, geopotential height at 500 hPa, zonal wind at 200 hPa, and zonal means over the Pacific and Atlantic basins (100-360° E) of zonal wind at 200 hPa.
Related to the double-ITCZ, Dong et al. (2021) investigated models with this bias and found that models which feature a present-day double-ITCZ bias tend to exhibit an excessively wet U.S. southwest and understate the drying over the Mediterranean basin in global warming projections. The former on the U.S. southwest wetting is due to these interconnected relationships: under global warming, models with double-ITCZ bias feature enhanced central Pacific rainfall as a wet-get-wetter response, which increases the upper-tropospheric heating in the Pacific subtropics and the meridional temperature gradients, resulting in an accelerated upper-level north Pacific subtropical jet and a deepened and southeastward shifted Aleutian low, both leading to increased precipitation in the U.S. southwest. The latter on the Mediterranean basin drying is a result of future changes stemming from a present day weaker Atlantic Meridional Overturning Circulation (AMOC) that is energetically related to the double-ITCZ and models with weaker AMOC in the historical simulations tend to simulate a weaker AMOC response to warming. Given the double-ITCZ bias in E3SM, an analogy may be drawn between the implications of the double-ITCZ bias on the precipitation response to warming (i.e., difference between future and historical simulations) discussed by Dong et al. (2021) and the implications of the double-ITCZ bias on the precipitation bias in the historical simulations (i.e., difference between E3SM simulations and MERRA2), which is our focus. More specifically, we focus on if and how the aforementioned processes related to a double-ITCZ bias (stronger subtropical jet and weaker AMOC) influence AR biases in E3SM while also noting other large-scale biases.

In our study, the U.S. southwest and neighboring areas in E3SM feature positive AR biases during the NDJFM period (Fig. 1f). Although Dong et al. (2021) looked at future projections of large-scale circulation and precipitation changes, we find similarities to the above features in the large-scale circulation and precipitation biases which can explain the sources of some of the AR biases. Over the central north Pacific, we find E3SM features a stronger, southward shifted north Pacific jet (Fig. 7e and 7g) and deepened geopotential heights during the winter compared to MERRA2 (Fig. 7c). These circulation biases are consistent with the double-ITCZ bias in E3SM through the aforementioned interconnected processes and contribute to enhanced moisture transport (Fig. 7a) and thus positive AR biases on the southern flank of the north Pacific storm track and landfalling regions (U.S. southwest). The coastal U.S. southwest also features an area of enhanced atmospheric moisture (not shown) which is likely a result of an underestimation of west coast, subtropical stratocumulus clouds (Golaz et al. (2019) Fig. 4c) leading to increased downward radiation and thus increased evaporation and moisture. While most of the stronger positive moisture transport anomalies are directed towards the U.S. west coast, the central Pacific low geopotential height anomalies also support weaker enhanced transport to Alaska/Siberia - an area of positive AR frequency bias. While the jet bias in the North Pacific may be partly explained by the double-ITCZ bias in E3SM, biases in the subtropical jet are also noticeable in other regions that may or may not be related to the double-ITCZ. For example, over India, another area with positive AR frequency biases during NDJFM, the subtropical jet is similarly stronger and southward shifted compared to MERRA2. With the subtropical jet aimed more south of the Himalayas and the Tibetan plateau, an enhanced trough develops over Central Asia (Fig. 7c) which weakens the offshore winter monsoon and generates positive moisture transport anomalies onshore during the winter (Fig. 7a).

During MJJAS, the austral winter, the southern hemisphere subtropical jet is slightly stronger and shifted equatorward (Fig. 7f and 7h). This strengthening and equatorward displacement is not as strong or coherent as the northern hemisphere jet shift.
The strengthening and/or shift is most apparent over areas corresponding to the positive AR frequencies around the 20° S latitude over Australia, the south Pacific, and south Africa (Fig. 1i). Moisture transport anomalies (Fig. 7b) at these locations are poleward and westerly; they are supported by low geopotential height anomalies to their south (Fig. 7d). For the northern hemisphere MJJAS, the westerlies in general are enhanced in E3SM equatorward of about 40° N until the tropics. In contrast to the NDJFM response, the MJJAS upper-level winds are strengthened over the north Atlantic stretching east all the way to east Asia. Over the northwestern Pacific, there are positive AR frequencies along the western boundary of the Pacific basin - a region associated with East Asian summer rainband. Enhanced summertime westerlies across the Tibetan plateau has been linked to an intensified pre-Meiyu rainband resulting from increased meridional stationary eddy circulation and moisture convergence downstream of the Tibetan Plateau in east Asia (Chiang et al. (2019)). The E3SM anomalies show strengthened westerlies over the Tibetan Plateau along with increased moisture convergence east of the Tibetan Plateau and increased transport poleward at the location of the east Asian rainband. The enhanced transports reach up to Alaska, supported by the low geopotential height anomalies over Siberia and Alaska. Another region with positive AR anomalies is the Arabian Peninsula. Moisture flux anomalies over this region seem to be due to redirected Indian monsoon moisture. The high geopotential height anomaly in the Arabian Sea directs moisture transports towards the Arabian Peninsula with less moisture reaching India.

Annually, regardless of the season (although stronger during MJJAS), Antarctica features positive biases just offshore. We find the southern hemisphere polar jet to exhibit more meridional movement than MERRA2 during MJJAS (Fig. 7f). This enhances the southwesterly moisture transports (Fig. 7b) towards Antarctica on the eastern side of the low anomalies. The same geopotential height anomalies that support the subtropical AR biases are also responsible for this variable jet movement. Additionally, Golaz et al. (2019) also reports fully-coupled historical simulation SSTs in the Southern Ocean to be ∼2 degrees C higher than observations. We find higher atmospheric moisture in the southern hemisphere (up to 2 kg m⁻²; not shown) from the subtropics to Antarctica given this warm SST bias during both seasons. Together, these biases may contribute to the higher AR frequencies near the Antarctic coast.

From examining the major AR biases and large-scale conditions in E3SM regionally and seasonally in the previous sections, we find these features to be most significant: i) the double-ITCZ bias, ii) a stronger and/or equatorward shifted subtropical jet during boreal and austral winter, and iii) stronger westerlies during the northern hemisphere summer. As previously mentioned, Dong et al. (2021) found that models with a double-ITCZ and associated wetting in the equatorial central Pacific under global warming to feature an enhanced subtropical jet and weaker mean-state AMOC. The large-scale anomalies we have uncovered suggest that the double-ITCZ bias in E3SM may play a large role in some large-scale circulation biases such as the subtropical jet bias in North Pacific that contribute to the E3SM AR biases. We look for further evidence by isolating biases in the atmospheric model using the AMIP (Atmospheric Model Intercomposion Project) simulations and comparing them to the fully-coupled model for ARs. The AMIP simulations have prescribed SSTs and sea ice concentrations from observations. While atmospheric models may exhibit weak double-ITCZ biases, such biases are severely exacerbated in fully-coupled models (Zhang et al. (2019)). This holds true for E3SM as can be seen in Golaz et al. (2019) Fig. 6b and 6c where the fully-coupled simulation has a far stronger double-ITCZ. Thus, by comparing AMIP and coupled simulations we can determine which biases
Figure 8. Historical ensemble (5 members) mean AR frequencies minus AMIP ensemble (3 members) mean AR frequencies.

are common to both simulations - implicating the EAM - or unique to the fully-coupled, historical simulation - implicating a coupling response (specifically the double-ITCZ response) or other components (e.g. the ocean component or sea ice).

We first compare the ensemble AR frequencies. The AMIP ensemble consists of 3 members (compared to the 5 members for the fully-coupled ensemble). For context, the AMIP frequencies have slightly better correlations and MAEs (as expected) than the fully-coupled ensemble when compared to MERRA2 (e.g. annual ensemble frequency correlation is improved from 0.98 to 0.99 and annual MAE is improved from 0.60 % to 0.54 %). In Fig. 8, we subtract the AMIP ensemble frequencies from the fully-coupled ensemble frequencies. Common to both ensemble simulations (determined by examining differences between Fig. 1c, 1f, and 1i and Fig. 8a-c) are the positive AR biases over elevated topography, India/Arabian Peninsula, central South America, and Alaska/Siberia. This suggests that these biases likely arise from the EAM. Golaz et al. (2019) reported that both AMIP and the fully-coupled historical simulations have excessive precipitation over elevated terrain as well as other precipitation biases (e.g. a wet bias over the Indian Ocean).

However, we also identify several biases that are unique to the fully-coupled simulations. Compared to AMIP, the fully-coupled simulations have positive AR frequency biases (∼3 %) over the Pacific basin and over Africa at subtropical latitudes during the winter season of each hemisphere suggesting that the wintertime subtropical jet is affected going from AMIP to fully-coupled simulations - particularly on the equatorward flank. During NDJFM, the southwest region of the U.S. and the...
central north Pacific are zones of enhanced AR frequencies. This is an aforementioned area where the double-ITCZ bias response in models deliver excessive moisture (Dong et al. (2021)). For the southern hemisphere, the double-ITCZ bias is also expressed as positive AR frequencies where typical double-ITCZ precipitation biases exist (see Fig. 5c). During MJJAS, the major biases are over the summer rainband region of east Asia, south Africa, and the eastern subtropical Pacific in the southern hemisphere. Given the AR biases over the subtropics in the fully-coupled simulation compared to the AMIP simulation, we now examine the changes in the behavior of the subtropical jet between these two simulations.

![Figure 9](https://doi.org/10.5194/gmd-2021-364)

**Figure 9.** Seasonal differences between E3SM fully-coupled and AMIP: zonal wind at 200 hPa (top row) and zonal means over the Pacific and Atlantic basins (100-360° E) of zonal wind at 200 hPa (bottom row).

In Fig. 9, we compare upper-level zonal winds (zonal wind at 200 hPa) globally for NDJFM and MJJAS. During NDJFM in the northern hemisphere, positive upper-level zonal wind anomalies in the fully-coupled simulation (Fig. 9a) generally match in location to the anomalies of E3SM compared to MERRA2 (Fig. 7e) while the negative anomalies, particularly over Asia, are weaker. This would suggest that coupling in E3SM is a major source of a stronger, slightly equatorward shifted, boreal winter subtropical jet. The Pacific and Atlantic basin zonal mean zonal winds show similar shifts when comparing the fully-coupled simulation to MERRA2 as well as AMIP (Fig. 7g and Fig. 9c). The southern hemisphere differences are generally consistent with MERRA2 differences from the equator to the subtropics but the midlatitudes to the polar latitudes lack the positive
anomalies. The enhanced westerlies over the southern ocean is a bias common to both fully-coupled and AMIP simulations implicating the EAM.

The global MJJAS zonal wind (200 hPa) anomalies between the fully-coupled and AMIP simulations qualitatively matches the MJJAS anomalies when comparing to MERRA2 for most regions. A notable feature is the clear strengthening and southward shift of the subtropical jet seen over subtropical latitudes over much of the northern hemisphere - particularly from north Africa moving east to the Pacific Basin. The enhanced westerlies over the Tibetan Plateau again correspond with increased AR activity downstream over the east Asian summer rainband region. South Africa has a band of enhanced westerlies in the fully-coupled simulation when comparing to both MERRA2 (Fig. 7f and Fig. 9b). For both of these regions, the evidence points to the biases arising from coupling.

Lastly, we explore what physically causes the jet behavior shifts between fully-coupled and AMIP simulations. For NDJFM, the most significant change is a strengthening of the subtropical jet over the north Pacific and for MJJAS, the enhanced westerlies throughout much of the northern hemisphere. Building off the work of Dong et al. (2021), the two significant responses to a double-ITCZ bias that the authors uncovered in models are a strengthened subtropical Pacific jet in projections and a weaker mean-state AMOC in present day. We look for evidence that these responses occurs for E3SM going from the AMIP to the fully-coupled simulation using upper-troposphere (500-200 hPa) temperatures differences (Fig. 10). Dong et al. (2021) found that due to the double-ITCZ, enhanced precipitation over the southern Central Pacific generated subtropical changes induced by latent heat release. This leads to enhanced upper-tropospheric warming over the subtropics (Dong et al. (2021) Fig. 2b), which increases the meridional temperature gradient locally, accelerating the subtropical jet along with a southeastward shift of the Aleutian low in projections. We find a similar upper-tropospheric response in temperature in North Pacific (Fig. 10a); a striking patch of warming occurs in the same area of the subtropical north Pacific with a corresponding cool patch to the north. This enhances the subtropical Pacific jet as seen in Fig. 7g.

Dong et al. (2021) also find evidence of weaker present-day AMOC in models with a double-ITCZ bias. While the authors focus on the implications for winter precipitation projections over the Mediterranean basin, in this study we examine whether a weaker mean state AMOC can enhance MJJAS westerlies. The MJJAS response is clearly different than that of the NDJFM response. Fig. 10b reveals widespread cold anomalies throughout the northern hemisphere contrasted with some warm anomalies throughout the southern hemisphere. The strongest cold anomalies are concentrated in a subtropical/midlatitude band over north Africa stretching east to east Asia. The strong upper-troposphere cold anomalies at these latitudes increase the meridional temperature gradient supporting an accelerated summertime subtropical jet. In fact, the band of cold anomalies sits just north of the enhanced subtropical jet anomalies over Africa, Europe, and Asia (Fig. 9b). The hemispheric temperature contrast of a warm southern hemisphere and a cold northern hemisphere is suggestive of a weaker AMOC (Liu et al. (2020)); a weaker AMOC would deliver less cross-equatorial heat to the northern hemisphere causing the northern hemisphere to be cooler. The weaker AMOC and the double-ITCZ are related as a double-ITCZ attempts to counteract less northward heat transport with increased northward heat transport via a stronger southern hemisphere ITCZ (Zhang et al. (2019)).

We also examine the surface air temperature to verify a weaker AMOC in the fully-coupled simulation. Specifically, we look for the classic AMOC “fingerprint” which consists primarily of a strong cold temperature anomaly over the subpolar Atlantic
Ocean and to a lesser degree as a warm temperature anomaly over the Gulf Stream (Caesar et al. (2018)). In Fig. A1, we show surface temperature differences between the fully-coupled and AMIP simulations and find the AMOC "fingerprint" well defined along with a hemispheric contrast in temperature. Liu et al. (2020) isolated the global surface air temperature response to a weakened AMOC and find widespread northern hemisphere cooling and more modest southern hemisphere warming (Liu et al. (2020) Fig. 2E). This is consistent with Golaz et al. (2019) and Hu et al. (2020), both of which reported a weaker AMOC calculated directly from the ocean model output in the fully-coupled E3SM simulation when compared to observations.

## 4 Conclusions

In this study, we have evaluated E3SM v1.0 at standard resolution for its ability to simulate ARs globally. We compared the fully-coupled historical simulation to MERRA2 and began with an examination of global AR frequencies. We find that E3SM is able simulate ARs with very high degrees of correlation and low MAEs annually (annual correlation 0.98; MAE 0.60 %) and seasonally (NDJFM correlation 0.98; MAE 0.72 %; MJJAS correlation 0.97; MAE 0.82 %). Amongst historical ensemble members, we determined that the internal variability of AR frequencies is low with the 5-member SD under 0.5 % for nearly all grid points. There are however, some notable biases such as: i) positive biases occurring near the tropic/subtropic edge mainly during the boreal winter but also the austral winter, ii) enhanced AR activity in the Middle East and the western boundary of the north Pacific basin during boreal summer, and iii) on the windward side of elevated terrain (e.g. Tibetan Plateau).

AR characteristics are compared using probability distributions and we find the E3SM AR characteristics are generally consistent (shape and peak) with MERRA2. Some differences are that the median magnitude of mean AR IVT is higher and ARs tend to be slightly more zonal in E3SM. The positive subtropical AR biases in E3SM are likely the source of both characteristic differences.
E3SM distributions of AR precipitation show good agreement with MERRA2 although there is a clear bias resembling the double-ITCZ bias and excessive maritime continent precipitation. This manifests as reduced AR precipitation along the equatorial Pacific and excessive AR precipitation just off the equator in the double-ITCZ regions. AR precipitation fractions reveal a bias in E3SM to attribute excessive precipitation just off coast of the western U.S. and western Chile as well as over the region near northern Africa/the Middle East/India. An examination of the large-scale conditions relevant to ARs in E3SM reveals these features to be most significant in producing AR biases in E3SM: i) the double-ITCZ bias, ii) a stronger and/or equatorward shifted subtropical jet during boreal and austral winter, and iii) enhanced westerlies during the northern hemisphere summer. The work of Dong et al. (2021) showed there is a significant relationship in models with a double-ITCZ bias to have a stronger projected north Pacific subtropical jet as well as a weaker present day AMOC, with implications for projecting future precipitation changes in southwestern U.S. and the Mediterranean basin during winter. Given the clear double-ITCZ bias in the fully-coupled E3SM, we investigated whether the interconnected processes of the North Pacific jet, Aleutian low, and AMOC with a double-ITCZ were present in E3SM and if they could explain AR biases. Analysis of the E3SM large-scale circulation biases identified biases in the subtropical jet during both NDJFM and MJJAS that could contribute to the AR precipitation biases. The strengthened and slightly equatorward-shifted North Pacific jet and the impact on AR precipitation in the U.S. Southwest is consistent with the signature identified by Dong et al. (2021) as related to the double-ITCZ during winter.

Motivated by the analysis of large-scale circulation biases and their general correspondence with the AR precipitation bias, we further compared the fully-coupled (strong double-ITCZ bias) and AMIP simulations (no to weak double-ITCZ bias) to isolate the changes that occur when moving from an atmosphere-only model to a fully-coupled model while specifically looking for evidence of a stronger subtropical jet and weaker AMOC. The analysis suggests that the AR biases over elevated terrain, India/Arabian Peninsula, central South America, and Alaska/Siberia arise from the EAM, as similar biases are found in both AMIP and coupled simulations. Biases arising from coupling or other model components include the positive AR frequencies over the north Pacific subtropics and U.S. southwest region during NDJFM and over the east Asia summer rainband region and the southern hemisphere eastern subtropical Pacific during MJJAS. These coupling biases suggest that the model responses to a double-ITCZ revealed in Dong et al. (2021) could be the source. We show evidence that the physical processes leading to a stronger north Pacific subtropical jet and enhanced northern hemisphere westerlies during the summer are consistent with Dong et al. (2021). The north Pacific subtropical jet is enhanced via increased, upper-troposphere temperature gradients generated through teleconnections induced by enhanced diabatic heating in the equatorial Pacific Ocean related to the double-ITCZ. On the other hand, the enhanced northern hemisphere westerlies during summer are due to a band of strong cold anomalies in the upper-troposphere stretching east from north Africa to east Asia. The upper-troposphere temperature differences also reveal a hemispheric temperature contrast with the northern hemisphere containing widespread cold anomalies while the southern hemisphere contains warm anomalies - suggestive of a weaker AMOC. We find that the fully-coupled simulation does indeed have a weaker mean state AMOC evidenced by the AMOC “fingerprint” in surface temperature comparisons, which is consistent with the weak AMOC reported by Golaz et al. (2019) and Hu et al. (2020) based on analysis of the ocean circulation in the coupled simulations.
We note, however, that the cold bias in the northern hemisphere and the opposite bias in the southern hemisphere may also be contributed by the strong model response to aerosol forcings, as noted by Golaz et al. (2019). Aerosol forcing is strongest over the northern hemisphere midlatitudes (Friedman et al. (2013); Hansen et al. (1998); Ma et al. (2012)) during spring through summer and during MJJAS is indeed when we see the strongest signal in cold anomalies. Another contributing factor for the interhemispheric temperature contrast could be from the delayed warming - related to E3SM’s strong aerosol forcing - in the coupled historical simulation between 1960-1990 which keeps the global surface air temperature lower than observations until about 2010. The long period of delayed warming could reduce the interhemispheric temperature asymmetry signal from climate change which has amplified warming of the northern hemisphere (Friedman et al. (2013)). The cool northern and warm southern hemisphere bias in the coupled E3SM simulation may also explain why the northern hemisphere jet strengthening and shift is more significant than the southern hemisphere as the upper-level temperature gradients are increased and decreased over the subtropical latitudes for the respective hemispheres. More generally, biases in the subtropical jet in E3SM may be contributed by other sources of model biases besides the double-ITCZ and related weak AMOC. Future analysis including the high resolution E3SM simulation (Caldwell et al. (2019)) may offer additional insights on AR and large-scale circulation biases, as AMOC is noticeably stronger at high resolution compared to the low resolution simulations analyzed here.

This study not only provides a comprehensive, global overview of AR representation in the fully-coupled historical E3SM v1.0 simulation that should give users of E3SM confidence in its ability to realistically simulate ARs but also seeks to understand how and why some biases are present. While we have framed this analysis through the lens of ARs, the biases in large-scale conditions are relevant to other phenomena and also provide potential areas of improvement in the EAM and the fully-coupled simulations. Analysis of the high-resolution simulation and future projections by E3SM is useful to further understand model biases and their implications for projecting future changes in AR frequency and intensity and extreme precipitation.

Code and data availability. E3SM and MERRA2 datasets used in this study are available at https://esgf-node.llnl.gov/projects/e3sm/ and https://disc.gsfc.nasa.gov/datasets?project=MERRA-2 respectively. The tARget v3 algorithm can be requested from BG and outputs using tARget v3 are available via ARTMIP (Shields et al. (2018b)).
